Burra Burra mine, Ducktown, Tenn. Data from C. H. McNaughton (180) in 1929. Orebody is an irregular lenticular mass of iron sulphides, carrying 1.6% Cu in chalcopyrite. Walls are highly metamorphosed schists and graywackes, usually standing unsupported over 100-ft spans; walls are firmer than ore, which tends to break into coarse blocks, but does not readily break free from walls. Orebody, nearly 0.5 mile long, ranges from a few feet to max of 180 ft wide, and varies in dip from 75° at surface to 50° at 1 600 ft, with local dips as low as 35°. DEVELOPMENT. Entry is by an inclined shaft in footwall and a vert shaft in hanging. Crosscuts to orebody and haulage drifts are driven at 196-ft vert intervals. STOPING. Sub-level stoping, first adopted in 1925, has largely replaced former shrinkage and glory-hole mining. Fig 270 shows method for widths less than 40 ft. Haulage levels, *H*, are driven on footwall; raises, *R*, are put up in ore along footwall at some convenient distance apart, 340 ft in Fig 270. At vert intervals of 40 ft, sub-drifts, *S*, 4 by 6 ft, are driven between raises in ore near footwall. At 40-ft intervals along the haulage drift, 4 by 5-ft raises, *P* ("pull holes"), are put up on footwall to first sub-drift. These are widened at top to expose walls and are funneled. Grizzlies with 20-in spaces are placed at bottom of "pull holes," directly over haulage level. Stoping begins on second sub-drift at a raise, by cutting out the raise to full width of orebody between the first and second sub-drifts. Then, a crosscut ("notch"), 5 ft wide by 6 ft high, is driven to hanging wall from second sub-drift; the floor of the notch provides a "bench" from which down holes are drilled to form a second bench 6 ft below. These operations are repeated until the stope faces reach the shape shown in Fig 270. Benches below the first are 10 ft deep. Stoping is done as on the sub-drifts above; the work on a lower sub-drift is kept far enough ahead of that on the sub-drift above to assure that the men are always working under the protection of solid ground. Mounted hammer drills are used for horiz holes in cutting notches (slabbing), and jackhammers for vert holes on benches. Slabbing rounds are drilled with 3 flat holes in a vert row and 10 ft deep, with 2–2.5-ft burden; bench holes are 4–5 ft apart along stope face, with burden of 2.5 ft. Blasting is done at night with a bulky 35% powder and elec detonator. In 1929, an aver of 48 tons of ore per machine-shift was broken; powder consumption, 0.33 lb per ton; bulldozing on grizzlies required an added 0.167 lb powder per ton. In a block 320 ft long, stope development, comprising 2 raises between levels, 4 sub-drifts, and 8 "pull holes," amounts to 2 210 ft and develops 93 tons of ore per ft.

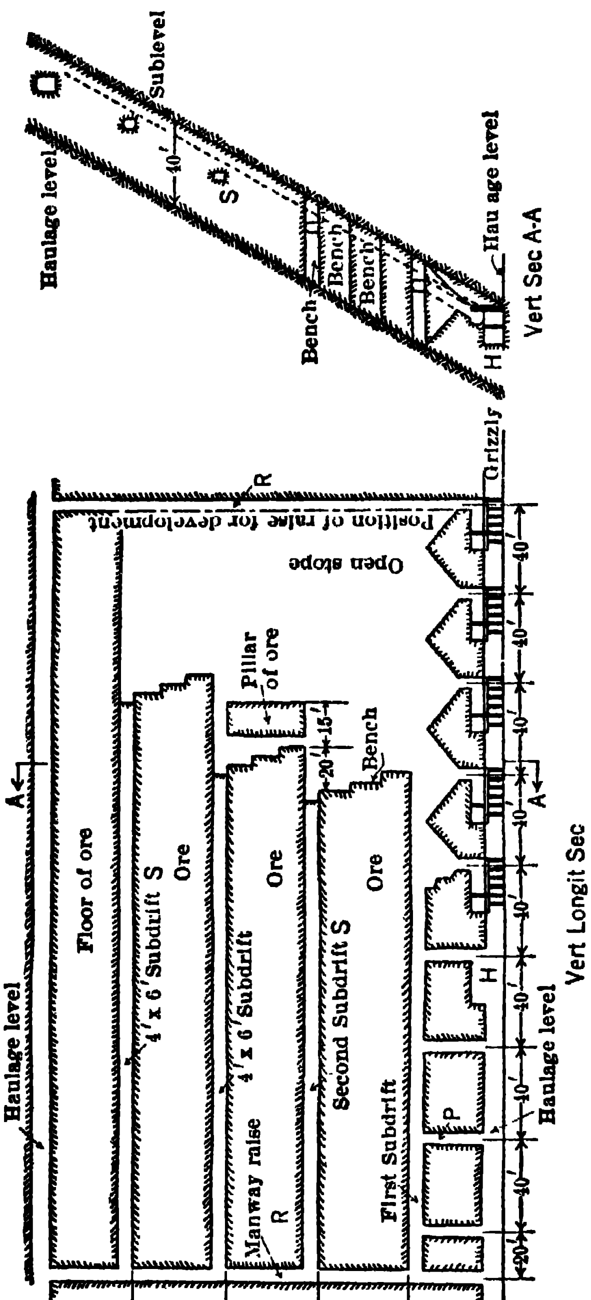

Fig 270. Sub-level Stoping in Narrower Orebodies, Ducktown, Tenn (180)

Working in wide ore. Where the orebody exceeds 40-ft width, sub-level stopes 40 ft wide are carried across the orebody, with 40-ft pillars between them, as in Fig 271. From a main-level drift *D* in footwall, 20–30 ft from the ore, crosscuts *C* are driven under center lines of stopes. Manway raises *R* are driven from footwall drift to main level above, paralleling the footwall and along center lines of alternate pillars. At 40-ft vert intervals, sub-level drifts *S* are driven from a manway raise to center lines of adjacent stopes, along which 4 by 6-ft sub-level crosscuts *L* are driven to hanging wall. At 40-ft intervals along main-level crosscuts, "pull hole" raises *P* are driven to first sub-level crosscut. From the last "pull hole" in a crosscut, an inclined raise *H* is driven to hanging wall and thence along the wall to the main level above. Stoping starts by breasting out the ore to the pillar lines on first sub-level and funneling the "pull-hole" raises, as in Fig 271, beginning at hanging wall and working toward the foot. Starting at second sub-level, hanging-wall raise *H* is widened to full width of stope between first and second sub-levels, benches are developed, and mining proceeds as described above for the longit stopes. In 1929, no pillars between sub-level stopes had been extracted, but pillar recovery by undercutting and breaking with long holes (up to 120 ft, with sectional steel) was anticipated. Advantages of sub-level stoping over previous shrinkage methods are reflected in the accompanying costs per ton for stope labor for year 1928.

Cost of Stoping Labor, Burra Burra Mine

	Drilling in stopes	Blockholing and loading	Total
Sub-level stopes. . .	$0.094	$0.079	$0.173
Shrinkage stopes. . .	0.128	0.144	0.272

Horne mine, Noranda, Quebec. Data from H. M. Butterfield and E. Henderson (120) in 1934, and from O. Hall in 1937 (121). Supplementary information was generously contributed by the management in 1938. Sub-level stoping is applied to principal, or "H," orebody, a large, irregular, generally vert body of massive sulphide carrying values chiefly in copper and gold, occurring as a replacement of brecciated rhyolite. From depth of 500 to 1 200 ft, and from 1 500–3 000-ft level, orebody averages about 1 000 000 tons per 100 ft of depth. It narrows like an hour-glass near the 1 250-level and widens again at 1 500-level. Portion above 1 250-level is called "Upper H"; that below, "Lower H." These main portions aver about 600 ft long, varying in width from 40–540 ft. Ore is unusually strong. General development. Mine is served by 3 vert shafts; one, near the center of "H" orebody, is used as a service shaft; other two, in country rock, are for ore-hoisting. Level interval is 125 ft below depth of 600 ft. Main-level drifts are 7.5 by 8 ft. Stoping. A modified form of sub-level stoping was used in mining "Upper H" orebody. Main difference from usual procedure is that raises, on 40° incline, take the place of sub-level drifts or crosscuts. Method was originally developed by E. Hibbert and employed at the Mother Lode mine, Greenwood, B C, Bib (207) and p 586 2nd edn of this book. Fig 272 shows general plan of work. Orebody was divided into vert stoping panels 46 ft wide, separated by 35-ft pillars. From a haulage drift, usually within the orebody, inclined chute raises were driven on center lines of both stopes and pillars, and grizzlies installed, as at *G*. From each grizzly, a raise *R* was driven at an inclination of 40° to a height set as a limit of the particular block for which it was to serve, about 190 ft in Fig 272. From the back of this raise, at 26-ft centers, 6.5 by 7-ft raises *S* were driven on 40° incline to intersect raise *T* from a level above, parallel to raise *R* and marking another limit of the stoping block; in Fig 272, raise *T* is about 150 ft from *R*. Purpose of raises *S* corresponds with that of sub-level drifts in the usual sub-level stoping. Other stoping blocks above, separated from each other by inclined pillars, were similarly developed, Fig 273. About 30 miles of raises were driven in developing "Upper H" orebody. Raises *R* and *S* in the stoping panels were later widened by slabbing rounds to full stope width of 46 ft. Assay sections, from sampling raises during driving, afforded an accurate outline of the orebody and full knowledge of the ore grades. These data, together with the great number of working faces, permitted close control of grade during the widening of raises and also in subsequent bench mining. The numerous working faces also afforded easy control of tonnage.

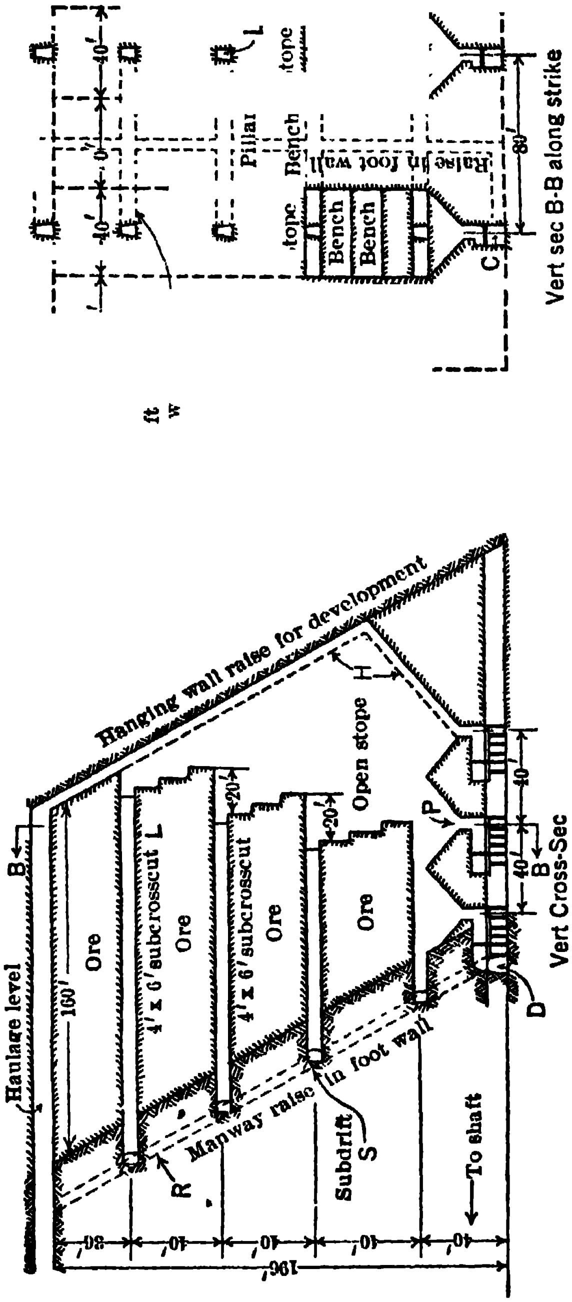

Fig 271. Sub-level Stoping in Thick Orebodies Tenn (180)

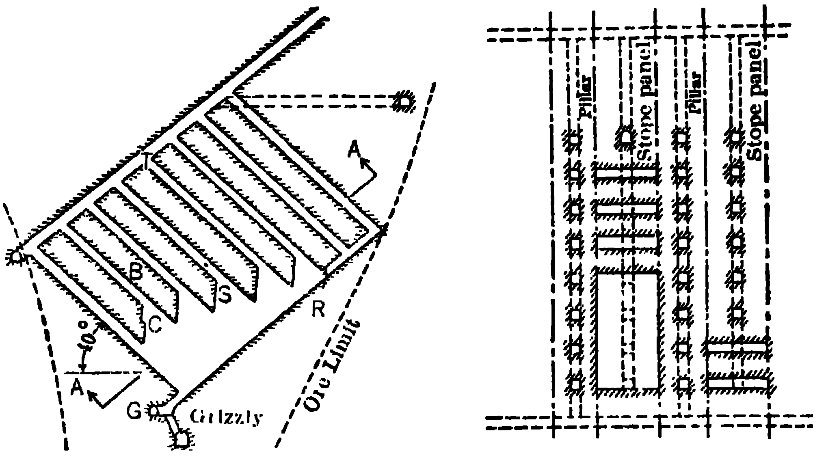
This mode of stope development was followed by underhand mining of the blocks of ore *B* (Fig 272) between the widened raises of the stope panels General stope face was carried in inverted steps, benching on the face of each block being done in advance of that on face of next block above. At first each face was mined in 2 cuts, as at *C*, by down holes with jackhammers, the miners having to wear safety belts. Later practice was to break the faces with a single cut, by drilling long holes from beneath, using jointed drill steel. (This method would seem to require carrying general stope face parallel with raise *R*, rather than as shown in Fig 272. Author.)

In general, mining of pillars follows filling of completed stopes, but, if permitted by wall conditions, pillars are blasted out before the adjacent stopes are filled. Where this is done, pillars are drilled from the central raises concurrently with stope drilling. Much experimenting has been carried on to find a filling material which will cement itself; best mixture is 50% granulated slag, 38% crushed slag, and 12% mill tailings (rich in pyrrhotite). After several months of oxidation and consolidation, drifting through this type of fill is



Vert Longit Sec

like drifting in rock. For mining strong, low-grade pillars next to well compacted fill, a method resembling sub-level caving (Art 75) has been devised: blocks are mined from top downward, removing about 30% of the interior of a block; upon simultaneous blasting of the rest, the fill caves in on top of the broken ore as it is drawn out. When removal of one block is completed, the next block below will be attacked. In higher-grade ore and under less ideal conditions, filling methods (Art 59), square-sets (Art 45), or top-slicing (Art 70) may be employed.

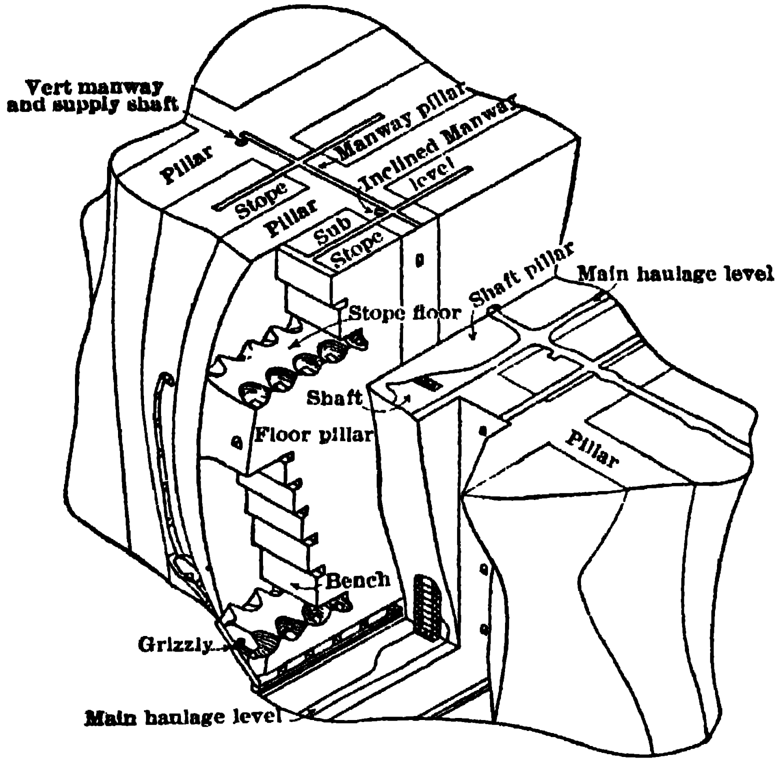

Fig 274. Sub-level Stoping, "Lower H" Orebody, Horne Mine, Noranda, Quebec

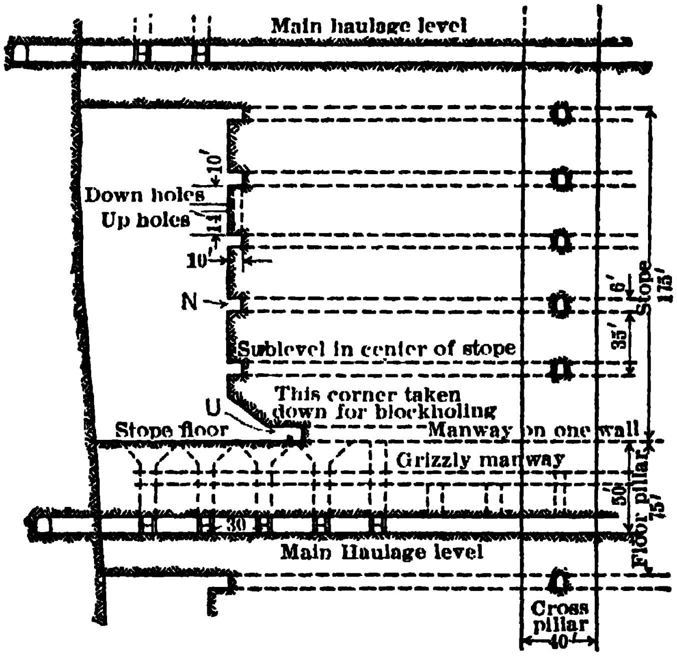

Fig 275. Side Elev, Horiz Sub-level Stope, "Lower H" Orebody, Horne Mine, Noranda, Quebec

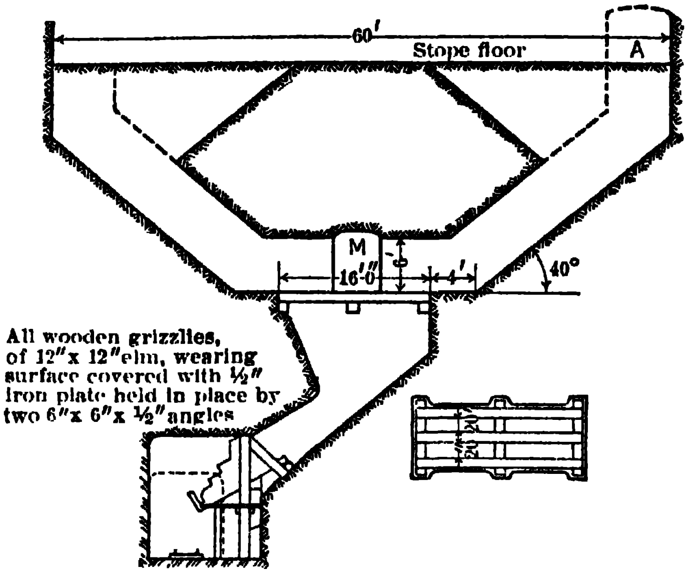
The more usual form of sub-level stoping is employed in "Lower H" orebody, with lifts of 250 ft. This orebody is divided by 1 longit pillar and 4 transverse pillars into 10 stoping segments, generally 60 ft wide (Fig 274). All pillars except 2 are 40 ft wide; shaft pillar and 1 other, 60 ft. Level pillars extend 50 ft above and 25 ft below levels, giving stope height of 175 ft (Fig 275). Main-level drifts are parallel with and near a pillar line of a stope section. Chute raises (Fig 276) are 30 ft apart. About 25 ft above the haulage level, grizzlies, 16 ft long with 20-in openings, are set crosswise of stope section; inclined raises are driven from each end of grizzly to reach the stope floor at the pillar lines. At stope-floor elevation, a drift *A* (Fig 276) is driven along a pillar line, breaking into the grizzly raises on this side. From this drift, beginning at the contact end of the stope, the stope floor is breasted out across to the other pillar; the grizzly raises are coned out as they are exposed. During mining, the stope-floor undercut *U* is maintained one drawhole in advance of stope face. A manway drift *M*, on center-line of the stope section, connects all grizzlies of a given stope. Stopes are opened by 5 sub-levels, 35 ft apart vertically, each connecting with the central main shaft.



All wooden grizzlies, of 12″x 12″elm, wearing surface covered with ½″ iron plate held in place by two 6″x 6″x ½″angles

Fig 276. Chute Raise and Grizzly, Horne Mine, Noranda, Quebec

Original practice was to drive one line of sub-level drifts along the center line of the stopes, *A* (Fig 277). A raise was then driven the full height of stope, along the contact of ore and wall-rock, and connected with each sub-level. Stoping started by widening this raise to full stope width of 60 ft. Benches, 10 ft wide, were next made by driving a crosscut or notch *N* (Fig 275) across the stope face at each sub-level. Benches between sub-levels were broken by 2 rows of uppers and 2 rows of down holes, *A* (Fig 277). All holes in stope face were fired simultaneously by elec on Saturday nights, making a break 175 ft high, 60 ft wide, and 10 ft thick: total, 8 000 tons. About 4 tons of ore were broken per lb of powder in primary blasting. Some secondary blasting was done on stope floor before the ore entered the raises to grizzlies; in blockholing, miners worked under protection of brow of lowest bench.

Recent practice of breaking benches is by "ring drilling." Each sub-level is opened by 2 drifts along the pillars, *B* (Fig 277), instead of 1 drift through center of stope. All stope drilling is done from within these drifts. Using jointed steel, miner drills a half circle of holes, 12–20 ft deep, moves the bar back 6 ft and repeats. In massive sulphide, about 50 ft of hole is drilled and about 190 tons are broken per machine-shift. Holes are blasted with 40% gelatin dynamite, about 0.2 lb per ton of ore. Advantages of "ring drilling" are that miner works in safe place, and drilling is a routine carried on as far in advance of blasting as desired.

Drilling blast holes with diamond drill. Sub-level stoping is also used in mining, for flux, a body of hard, slightly mineralized rhyolite. Stopes are 105 ft wide, with sub-level interval up to 60 ft; otherwise, the plan is same as at *B* (Fig 277). Drilling is by diamond drill, as ground is too hard for satisfactory drilling of deep holes (sometimes 60 ft) with usual drifter machine (see above). Light, "prospector" diamond-drill machine is used. About 30 ft of hole is drilled, breaking 150 tons, per drill-shift. Powder consumption per ton is about same as in sulphide stopes, namely 0.2 lb of 40% gelatin per ton. For additional details of diamond drilling, see Bib (121, 616).

Costs. Mr. O. Hall (121) states (1937) that cost of exploration and development is about 30¢ per ton. Cost of mining, exclusive of development, averages about 90¢ per ton, as follows: stoping, 30¢; grizzly blasting, 10¢; mucking and tramming, 14¢; hoisting, 8¢; steel and tools, 7¢; rock drills, 5¢; power and misc, 16¢; total, 90¢.

Flin Flon mine, Manitoba. Data from M. A. Roche (565) in 1931, from Roche and J. P. Caulfield (566) in 1935, and W. J. Marshall (567) in 1936. Main orebody, of massive sulphide, contains Au, Ag, Cu, and Zn. Hanging wall is hard, fine-grained greenstone, free from faults and schistose areas. Footwall varies from quartz porphyry to soft talc schist, and is somewhat flatter than hanging wall. General dip, about 70°. Width of ore, from 450 ft (including waste horses) at the surface to about 40 ft on 900-ft level. Ore is very heavy and hard. A sub-level mining method is employed, with heavy equipment for scraping ore to loading chutes, and cages in service raises. DEVELOPMENT. Main hoisting shaft is vert, sunk in hanging wall about 500 ft from outcrop and centrally located in respect to orebody. Vert interval between main haulage levels, formerly 260 ft, is now 520 ft. Fig 278 shows general layout. Haulage drifts, 10 by 10 ft, are driven in footwall, parallel to orebody. Crosscuts, 10 by 10 ft, are generally 250 ft apart and driven far enough into hanging wall to allow room for ore trains. Crosscuts are usually on center-lines of 40-ft pillars between stopes. Service raises, driven 20–30 ft in footwall, are on center-lines of pillars; they may be vert or inclined to conform with dip of orebody, and are equipped with cages. From each crosscut, a raise is driven at a point near center (crosswise) of orebody to 12 ft above the roof of crosscut. At about 6 ft above the roof, a 36-in manganese-steel grizzly is built across the raise. Drifts *S* (Fig 278) called "scram drifts," 10 by 10 ft, connect the raises; they are at a 5% up-grade to a point midway between raises. At intervals of 40 ft along the "scram drift," 7 by 7-ft draw raises are driven to bottom of the first sub-level which is about 46 ft above the back of the haulage level. Stoped ore drops through the draw raises to "scram drift," in which a scraper drags the ore to the grizzlies for loading into cars beneath. The draw raises start from backs of single-round crosscuts, thus providing a brow to limit the height to which the broken ore can pile up in the scram drift, so the scraper can always pass over the ore pile and get behind it to move the ore. A raise at the longit center of stope is driven from the first to the highest sub-level of the block to be mined in one "lift." Original lifts of 260 ft have been increased to 520 ft. Stopes are developed by sub-level drifts, 5 by 7 ft, near center of orebody and at 40-ft vert intervals. They are driven from the service raises in the pillars. STOPING. When the draw raises are completed to first sub-level, they are coned out to connect with each other (Fig 278). Actual stoping starts on second sub-level, at the center raise. The ground around the raise is drilled and blasted through to the cones below, and the raise is widened laterally until both walls are exposed. While this is being done at the second sub-level, a 10-ft bench, from foot to hanging wall, is made on each side of the raise. These benches are then drilled with 2 rows of 6–8-ft vert down holes, 5 ft apart along the bench and 18 in to 2 ft apart across it. Two successive cuts, each of 12-ft holes, complete the vert slice to the undercut stope below. Working at the open ends of the second sub-level drift, the miners then drill horizontally to establish another 10-ft bench from foot to hanging wall. When 2 benches have been completed on any sub-level, benching starts on the next sub-level above. This gives a sequence in which the benching from one sub-level is not more than 2 benches ahead of that from the sub-level above; hence, miners are protected from mining operations above them, and, at the same time, enough support is left for the overhanging ore, so that the men above can work in safety. Fig 279 shows a typical scram drift in plan and section. Double-drum scraper hoists with 150-hp motors are used. Scrapers are 84 in wide, arc type, made of manganese steel, and weigh 3 600 lb. Lead rope is 1.25-in, 6 by 7, plow-steel; tail rope, 1.25-in, 6 by 19, plow-steel. Rope speed, 300 ft per min; aver load, 2.4 tons, per trip, or a capac of 307 tons, per hr for continuous scraping. Crew consists of 1 operator and 1 bulldozer; latter blasts down hung-up raises and assists operator. Scraper loads into 10-ton cars, spotted beneath grizzly. LONG-HOLE DRILLING IN STOPES. W. J. Marshall (567) describes in 1936 an apparently successful experiment, in which the bench between 2 sub-levels is broken in a single cut by drilling holes about 24 ft deep, tapering from 3 in at collar to $1^5/_8$ in at bottom. Drilling is by drifter on a cross-arm between 2 vert columns. Holes usually dip about 70°; their spacing lengthwise of bench is 5–8 ft; rows about 4 ft apart. Holes are sometimes sprung before loading. Number of sticks of powder per hole is from 85 for an unsprung hole to 160 for one sprung 3 times. An aver of about 40 ft is drilled per machine-shift. In breaking 21 500 tons, an aver of 6.02 tons was broken per ft drilled. Cited advantages of long-hole drilling: (*a*) Elimination of mucking on benches. (*b*) Greater safety. In ordinary benching, second and third benches are sometimes dangerous for the men, due to narrowness of ledge. (*c*) No difference in break, compared with 3-bench method, has been noticed. (*d*) Lower mining cost per ton.

McIntyre mine, Schumacher, Ont (171). Waste rock is mined by sub-level stoping to provide fill for horiz cut-and-fill stopes described in Art 60. Block of rock opened for sub-level stoping is 270 ft long, 110 ft wide, and 175 ft high (Fig 280). A 9 by 9-ft drift is driven under center of block and a grizzly level driven 29 ft above rail. Sub-levels, 6.5 by 5 ft, are 25 ft apart vert. End of block is opened first by a 24-ft shrinkage stope,

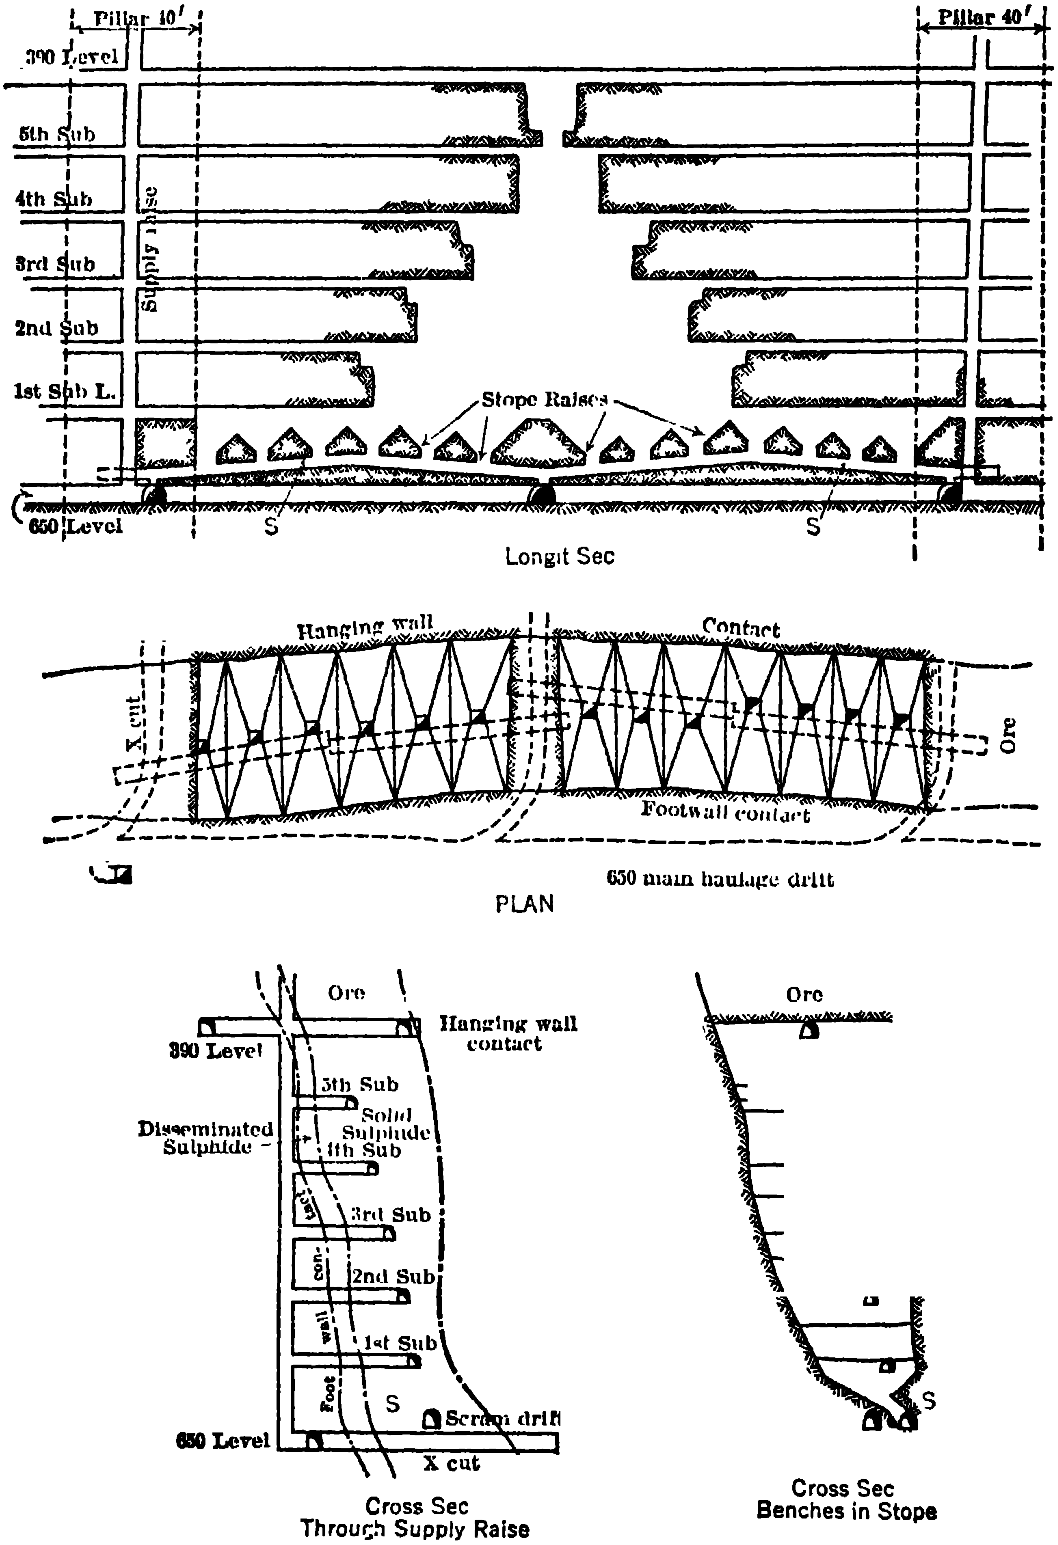

Fig 278. Typical Sub-level Stope, Flin Flon Mine, Manitoba

carried full width and height of block; thereafter rock is broken by vert holes drilled up and down from crosscuts or notches driven across the block from the sub-levels.

Mount Isa Mines, Ltd, Mount Isa, Queensland. Data from J. Kruttschnitt and V. I. Mann (500) in 1937. Ore deposits are replacements in zones of shearing and folding in a thick series of shales dipping 55–60°. Strike and dip of orebodies conform in general with those of shale beds. Below oxidized zone, ore comprises Ag-Pb-Zn sulphides, usually interbanded with pyrite and pyrrhotite. Aver metal content of ore is about 4.8 oz Ag per ton, 8.2% Pb, and 8.1% Zn. Principal orebody, as known, has max length of 2 000 ft and proved depth of 1 200 ft. Mineralization occurs over a stratigraphic thickness of 160 ft, permitting, in part, stoping across full width; usually, stoping is confined to a 32-ft band of ore along hanging wall and a 40–70-ft band along footwall. Upper part of orebody, largely oxidized, was mined by surface glory-hole (Art 99); sub-level method was used in sulphide ores below. GENERAL DEVELOPMENT. Mine is served by 2 main vert shafts and 2 auxiliary vert shafts. Main shafts are in footwall; one for service,

the other for hoisting ore. Level interval in original sub-level stoping was 200 ft vert. For new work, levels are 175 ft apart. Haulage drifts and crosscuts are 10 ft wide and 9 ft high. Main-level development depends on stope lay-out; where width of ore exceeds 75 ft, stopes run across the lode and are developed by crosscuts; for widths less than 75 ft, stopes are longit and served by drifts.

Longitudinal stopes. Haulage drift is located centrally respecting the orebody at the stope-undercut. Length of stope and general procedure are adjusted to width of ore and ground conditions; for widths of 6–14 ft, sub-level drifts are 30 ft apart and 7 by 5 ft in sec. Benches, 6–8 ft wide, are cut at each sub-level above the undercut and carried down with jackhammers until they break through to stope below. Usually, 3 such cuts are required, the last being 12 ft deep. Safety belts are worn by all men on the benches, the ropes being fastened in the sub-level drift above. Fig 281 shows plan of work in wider stopes, where ore is 75 ft wide. Stopes, 72 ft long, are limited on one end by a 25-ft pillar, through which a 5 by 7-ft service raise is driven on footwall between main levels, and on other end by a 20-ft pillar. Each stope is served by 2 sets of chute raises, each set comprising 2 inclined raises at right-angles to strike and driven from chutes opposite one another. A grizzly, running crosswise of orebody and having 12 by 24-in openings, is set over each chute raise at 23 ft above main level. From outer ends of grizzlies, inclined raises on footwall side and vert raises on the hanging-wall side are driven to floor of the "undercut" level, 24 ft above the grizzly. A horiz slice 8 ft high (under-cut stope) is breasted out here, and tops of raises are "belled," but these operations are delayed until No 1 sub-level is well advanced, to avoid premature breaking of bottom by heavy blasting in sub-level headings. In stopes approaching 75 ft wide, a narrow supporting rib is left along center-line of undercut as a temporary pillar for No 1 sub-level. Sub-level interval is 27 ft; 2 drifts, "center headings," are driven on each sub-level. At the elev of these, a short crosscut *A* (Fig 281) is driven from service raise into the stope pillar. A drift runs from this crosscut to the pillar edges, and along each side thereof crosscuts *B* are driven to the ore limits. "Center headings" are 12 ft wide by 10 ft high. Crosscuts *B* later serve as points of attack in mining out a vert slice, or "cut-off stope," at the end of sub-level stope. Broken ore from center headings is scraped to cut-off raise *C* until headings advance to "scraper raises" *D*, which then become the mucking transfer. "Cutting-off" operations at end of the stope at which mining will start are carried on concurrently with sub-level development, but timed to avoid interference with driving sub-level headings. between sub-levels is done by "ring drilling" (Fig 282), starting after No 1 and No 2 sub-level headings are completed. Work begins at the cut-off stope and retreats to the service-raise pillar. When a heading is ready for drilling, surveyors paint a center line along roof of heading, horiz elev lines along each side, and short vert lines on the sides at proper ring intervals, usually 4–5 ft. Machine mountings are 3.5-in columns, set midway between 2 rings to be drilled, so that the arm, when clamped, is directly under and parallel with center line. Elev of arm is such that center-line of machine will be level with the elev lines on each side of heading. Each hole is drilled on a definite plan, the drill being set accurately by a clinometer designed for this purpose. Holes in bottom half of ring and those inclined slightly above horiz are drilled with drifters; the others, with automatically rotated stopers. Skilful miners average 60–90 ft of hole per drill-shift. Blasting is done electrically by special crews. Ring in hanging-wall heading is blasted with instantaneous detonators, and the corresponding ring in the footwall heading with delay detonators, both connected to same circuit. Wooden spacer plugs, 1.25 in by 8 in, are inserted between sticks of powder for wider distribution. Blasting on sub-levels is kept in step, so that no heading is blasted more than 4 rings in advance of heading above. Explosives are 40 and 60% gelignite, consumption being 0.40 lb per ton in primary blasting and 0.027 lb in secondary blasting. In longit stopes, regularity of walls is essential for clean extraction by "ring-drilling."

Measurements for length of holes taken from center of heading

Total footage drilled per ring = 247'
Tons broken per 4' ring = 291
" " " 5' " = 358

Fig 284. Ring-drilling Diagram for Transverse Stope, Mt Isa Mines, Queensland

Transverse stopes. Fig 283 shows layout of transverse stope, where level interval is 200 ft. Stopes are 30 ft wide, with 15-ft pillars; they are opened in pairs, main-level cross-cut for serving both being driven on center-line of pillar between them. The manway drift connecting grizzlies is common to both stopes. In Fig 283, the sub-level interval is 27 ft, as in the longit-stopes, but the center headings are 10 by 10 ft, instead of 10 by 12. Procedure in sub-level development, and in breaking ground by ring drilling, is similar to that for longit stopes. Fig 284 shows a 24-hole ring-drilling diagram.

Operating data. For year ended June 30, 1936, man-hours per ton for developing and mining by sub-level stoping about 704 000 tons of ore were as in adjoining table. During same period, over tons per manshift underground were 1.66. Explosive consumption was 0.96 lb per ton, 0.15 lb for development, 0.81 lb for mining. Timber consumption, 1.43 bd ft per ton.

Total.	0.344	1.368	1.712

Summary. Following factors led to choice of sub-level stoping at Mount Isa: (*a*) need of a low-cost method, owing to relatively low-grade ore: (*b*) desirability of allowing

development, stope preparation, breaking, and drawing of ore to proceed concurrently; (*c*) tendency of ore to oxidize rapidly, adversely affecting mill recovery, favored method in which accumulations of broken ore could be minimized; (*d*) safety factor; (*e*) need of eliminating, as far as possible, features depending on judgment and skill of miners, due to the comparative inexperience of most miners available; (*f*) though laminated in structure, ore is hard and breaks in large blocks, thus making caving methods unsuitable.

Champion mine, Mich. For sub-level stoping, with filling, at this mine, see Art 63.

44. SUMMARY OF OPEN-STOPE METHODS

Applications. Open stoping methods, described in Art 29–43, are designed for widely different conditions of dip, width of deposit, character of ground, and grade of ore. Generalizations, applying to all types of open stoping, are difficult, but the following principles apply: (*a*) low-cost mining by open stoping is sometimes possible through sacrifice of part of the deposit in permanent pillars; then the method is applicable to low-grade orebodies not warranting higher-cost methods in any circumstances; (*b*) possibilities of selective mining vary; on steep dips they are usually limited to the leaving of low-grade areas as pillars; in thin deposits on flat dips a high degree of selectivity is possible; (*c*) underground sorting of ore is possible in flat deposits, but only to a limited extent on steep dips, especially where widths exceed economic length of stulls; (*d*) use of open stoping usually presupposes strong ore and strong walls, except in thin deposits of flat or moderate dip that can be worked by a retreating system, as at Calumet & Hecla (Art 39) and Pilgrim mines (Art 35); (*e*) methods are usually limited to tabular deposits with regular, well defined walls, but are sometimes used in large, massive deposits with irregular walls, as at Horne mine (Art 43). The following comparison of underhand and overhand methods applies in part to breaking ground in any stoping method, and in part to open stopes in veins; it also draws attention to factors to be considered in planning open-stope methods in other types of deposit.

Underhand methods. ADVANTAGES: (*a*) all drill holes are down holes; this is advantageous for hand-drilling and permits efficient use of hand-held jackhammers, with resultant simplicity in drilling; (*b*) miners stand on ore while working, which may be safer than overhand stoping in narrow veins of weak ore with strong walls; (*c*) underhand methods, where applicable, require less timber than overhand; (*d*) in general, loss of fines is less in underhand than in overhand work. DISADVANTAGES: (*a*) danger, because men work under inaccessible backs and walls, the height and area of which increase as stope is extended, and loose pieces may fall; (*b*) due to above conditions, the level interval must usually be smaller than for overhand methods; (*c*) facilities for storing waste in stopes are poor; (*d*) broken ore from face collects at a single point, which may interfere with economical handling.

Overhand methods. ADVANTAGES (not indicated above): (*a*) miners work near back of stope, where they can examine face carefully and take down loose ground, and are not exposed to danger from pieces falling from a height; (*b*) waste or ore is readily stored in stopes; (*c*) a greater variety of working plans is available than in underhand stopes and any type of machine drill may be used; (*d*) an open, overhand method may be changed to a square-setting, shrinkage, or filling method, far more readily than underhand stoping; (*e*) gravity aids in breaking ground; (*f*) broken ore slides down the dip under the impetus of blasting; this allows handling of ore to the level below without mechanical devices on flatter dips than is possible in underhand stopes. DISADVANTAGES are largely the converse of advantages of underhand; in addition, support for men is necessary in overhand stopes on dips over about 40°, whether required by walls or not (Art 93).

TIMBERED STOPES

The term "timbered stope" is used here to denote stopes in which timbering is the dominant feature of the method. Stulled stopes (Art 38, 39) are types of timbered stope.

45. SQUARE-SET METHOD

Square-sets were first used in the U S in 1860 by Philip Deidesheimer, at Ophir mine, Comstock Lode, Nev. In early days, the method was often called the Nevada square-set system.

Description. The stope faces are advanced by successive small excavations, each timbered before the next is begun. Timbers in adjoining sections are framed into and mutually support one another, forming a continuous structure of horiz FLOORS, composed of rectangular frames supported at their corners by POSTS (Fig 285). One pair of parallel horiz timbers are CAPS, those at right-angles to caps being GIRTS (ties, braces or collar braces). Posts, about 7 ft high, are 5–6 ft apart c to c, both capwise and girtwise. Caps are often stronger than girts, the principal function of girts being to hold the posts in position. In veins, caps usually have their long dimension at right-angles to the strike; in masses, in the direction of max lateral pressure. Square-sets support men and broken ore, as well as the stope walls. Lowest floor of a stope is called the SILL FLOOR; this may be level with bottom of haulageway (Fig 287), or at a higher elev (Fig 289, 293). Highest working floor is the MINING FLOOR and next below is the SHOVELING FLOOR, made by laying planks across caps or girts (Fig 285). Above the sill are the 1ST FLOOR, 2ND FLOOR, etc. The first set erected on any floor is a RAISE SET; it has 4 posts, 2 caps and 2 girts. First set in a new row on a floor is a LEAD SET, requiring 2 posts, 2 girts and 1 cap, or 2 posts, 1 girt and 2 caps. In working alongside of sets in place, SIDE SETS or CORNER SETS are used, consisting of post, cap and girt. When a stope is well opened, nearly all sets added are corner sets (Fig 286). OPEN SQUARE-SET STOPES are those in which the sets alone are relied upon to support the walls; in FILLED SQUARE-SET STOPES, waste filling is used for added support.

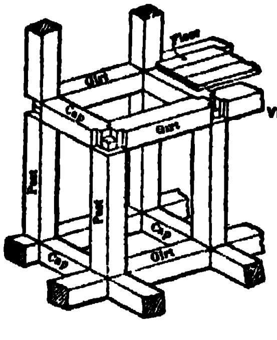

Fig 285. Square-set Timbering

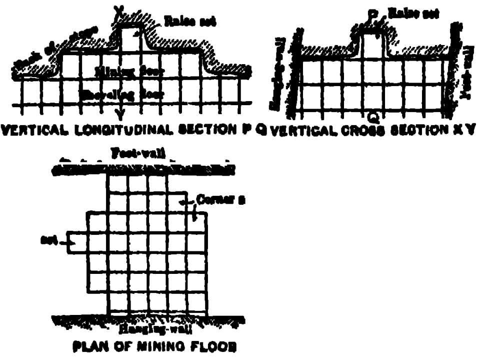

Fig 286. Diag of Square-set System

Breaking ground in square-set work follows general overhand practice (Art 26–28).

46. FORMS OF SQUARE-SET STOPES

General. Some stoping methods are based upon the use of square-sets, in others their use is incidental. When waste filling is used, the stope is the same as the corresponding form of untimbered filled stope (Art 60–65), except for the use of square-sets as temporary support before filling can begin. There is a similar correspondence between an unfilled square-set stope and an open stope of same form.

Occasionally square-sets are used in open overhand unfilled stopes, chiefly to provide working platforms; as at New Idria mine, Calif, where ore is over 10 ft wide, with steep dip. Nearly all square-set timber is reclaimed and reused until worn out (320).

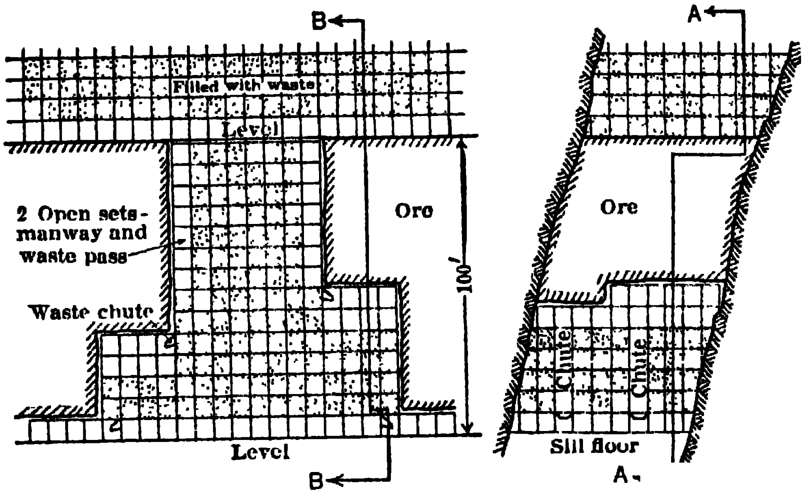
Mining large, weak deposits by square-setting usually requires a division of the orebody, between any two levels, into stoping blocks of limited horiz area. Such stope work is called a BLOCK SYSTEM. Size of blocks is adjusted to strength of ground, so that work in any block is rapid enough to avoid excessive press. This sectionalizing is sometimes done by dividing orebody into alternate stope and pillar panels (see Frood mine, below), mining of pillars following completion of stope panels on both sides. In other cases, small blocks are stoped and filled; then corresponding blocks are mined alongside (Fig 287). Individual blocks may be mined by any form of square-set stope described below. DEVELOPMENT REQUIREMENTS vary with type of stope. A drift, either in wall or in orebody, is a prerequisite to opening the sill floor. In wide orebodies, there may be a grillage of drifts and crosscuts. At least one raise to the level above is usually necessary in each stope, for ventilation and handling timbers and filling.

a. Flat-back or Stepped-face Overhand Stope

Anaconda Copper Mining Co, Butte, Mont. Data from W. B. Daly, Mgr of Mines, in 1939. Copper ores occur in complicated vein systems; stoping widths, 4–100 ft, usually 10–30 ft; dips generally steep; country rock, commonly granite. Principal gangue mineral is quartz, with pyrite and blende. Numerous faults cause sloughing and

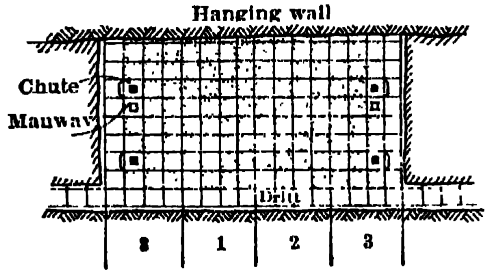
squeezing of walls. Closely filled flat-back square-set stopes are used where square-set rill stopes or horiz (flat-back) cut-and-fill stopes (Art 60), or ordinary filled-rill stopes (Art 65) are not applicable.

In narrow veins the level interval is 100 ft or 200 ft; levels usually driven in the vein. Drifts are timbered with square-sets; offsets into footwall are usually made at every 5th and 6th set, to be used later for chutes and manways. When drift is far enough advanced, 2-compt raises to the level above are started in every 3d or 4th offset. When 2 adjacent



Vert Longit Sec A-A

Cross Sec B-B



Plan on Sill Floor

Fig 287. Block System (diagrammatic); numbers show order of mining blocks

raises are up far enough, the first 2 stope floors between them are mined and timbered, ore being handled through stop boards into cars on level. Sheeting of small stulls laid on sheeting caps is then placed over the drift caps, and a temporary floor of 3-in lagging is laid over caps of second floor; then intermediate chutes and manways are built. Stope is now carried up with a stepped face, a new floor being started when floor below passes a chute. Waste, from sorting in levels above and sometimes from inclined raises in footwall, is kept within 1 or 2 sets of back. Fig 288, from Gardner and Vanderburg (189), is a longit sec of a square-set stope in a narrow orebody at Butte. The mode of advancing the stope face typifies general practice in square-set stopes, applicable to wide orebodies as well as to narrow veins. Fig 288 shows the introduction of waste filling, but otherwise depicts open stoping with aid of square-sets; it would also represent a section of a transverse stope carried perpendicular to the strike in a wide orebody.

Argonaut mine, Calif. Fig 289 shows a narrow, square-set stope for which filling is obtained by mining wall rock. In such cases, raises to the level above would be unnecessary, but are advisable for ventilation and safety.

McIntyre mine, Schumacher, Ont (171). For description of geol features and mining by horiz cut-and-fill, see Art 60. Flat-back square-set stopes are used for mining heavy ground, especially where ore is wide. Sets are of cap-butting type, to resist side press. Posts are 10–11-in squared rounds, 8 ft long; caps, same size timber, 5.5 ft long; girts, 7 by 9-in squared, 4 ft 11 in long. In mining wide areas, timber cribs placed on the fill and blocked to back as auxiliary support are largely used. When blasting, sets are reinforced by diagonal timbers and added temporary posts under caps. Breast holes 10–12 ft deep are drilled, and blasted with max of 2–3 sticks of powder. Chutes are 50 ft apart and lined with 3-in plank; fill-raises, 300 ft apart. Ore and fill are handled in 1-ton cars on 16-lb sectionalized track, with turntables instead of switches.

Frood mine, Sudbury, Ont (49, 93). Data from H. J. Mutz, Supt of Mines, and others of staff of International Nickel Co of Canada, in 1930, 1937. Mining method here illustrates square-setting in large-scale work; a "block" system is used; individual stopes are flat-back overhand stopes. **Orebody** is in a brecciated zone in altered sediments and intrusives. Metallic minerals, chiefly pyrrhotite, pentlandite, and chalcopyrite. Outcrop extends more than a mile, and is over 600 ft wide in places. Mineralization is relatively weak in upper part of orebody, but intensifies at depth to massive sulphides, 40–200 ft wide. There are occasional lenses of quartz-diorite within the massive sulphide. Dip of ore averages 65°; walls, irregular. At depth of 2 000 ft and below, ore is rich enough to require a method allowing selective mining and high extraction. **Development**. There are 2 vert shafts sunk from surface in footwall, and an inside vert shaft, to handle men and

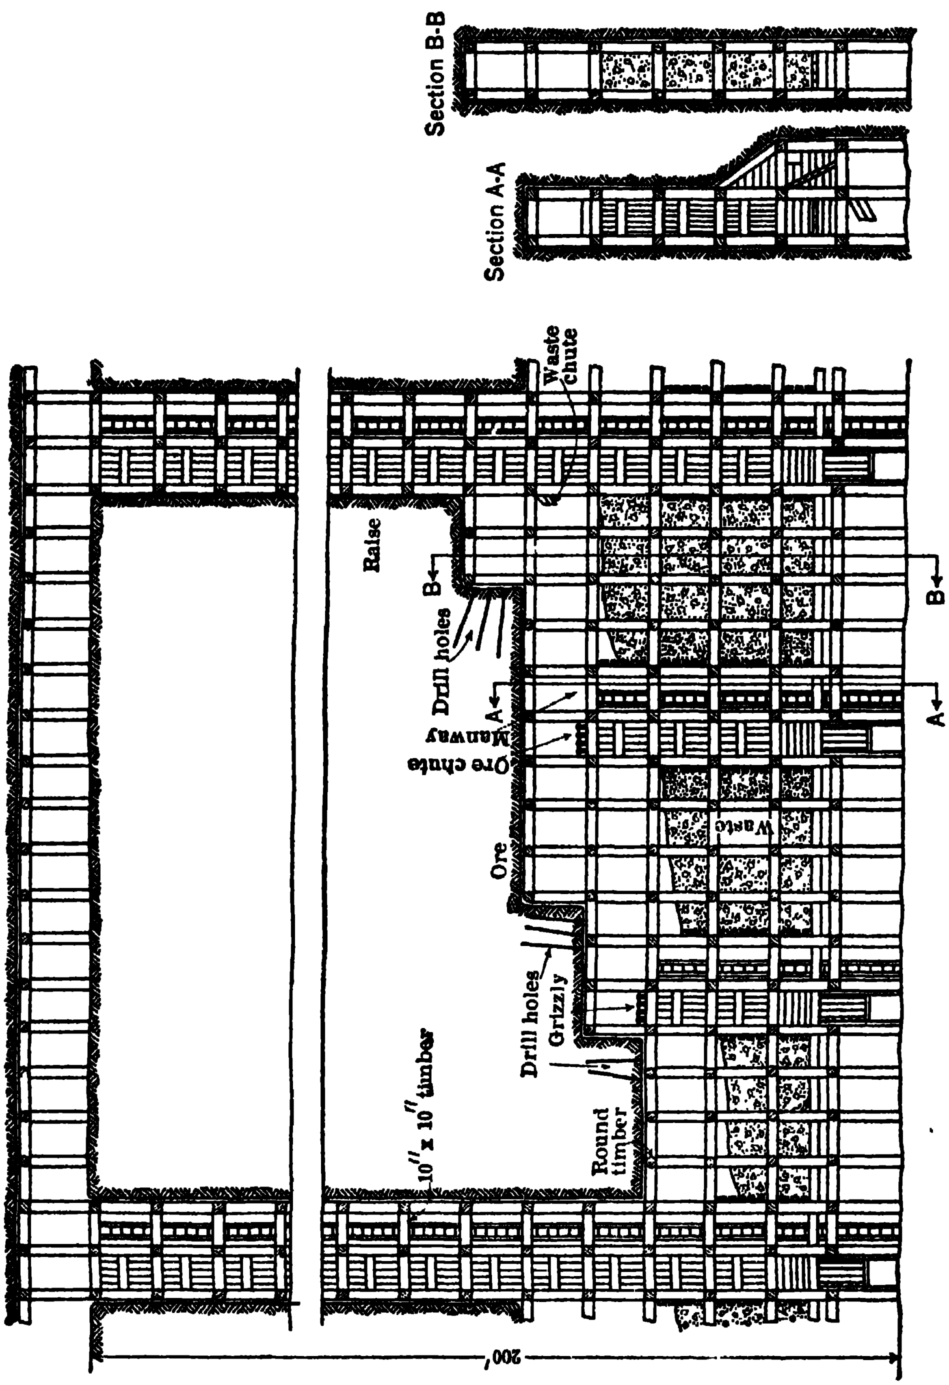


Fig 288. Flat-backed Square-set Stope, Butte, Mont

materials below the 2 800-ft level. Level interval above the 2 800-level is 200 ft; below it, 150 ft. On each level a main crosscut is driven through the orebody, and from it a 30-ft raise is put up in ore. At this point, a 4 by 6-ft drift is driven the full length of ore zone.

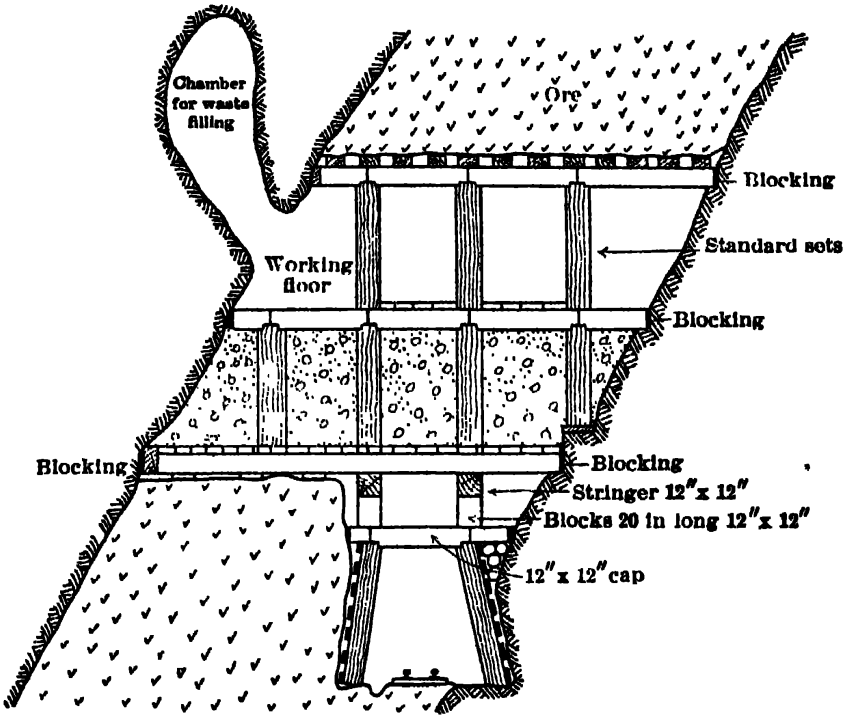

Fig 289. Obtaining Waste Fill from Hanging Wall, Argonaut Mine, Calif

From this drift, at intervals of 80 ft, horiz diamond-drill holes are driven at right-angles to general strike, to determine the ore outline. Information thus gained permits careful planning of level development, which, as shown in Fig 290, comprises a main haulageway in footwall, a series of longit drifts in ore, and connecting crosscuts about 485 ft apart. The longit (haulage) drifts are 44 ft apart to give proper chute spacing; their number depends on width of ore; they are driven 11 by 11 ft in cross-sec. timbered with 10 by 10-in

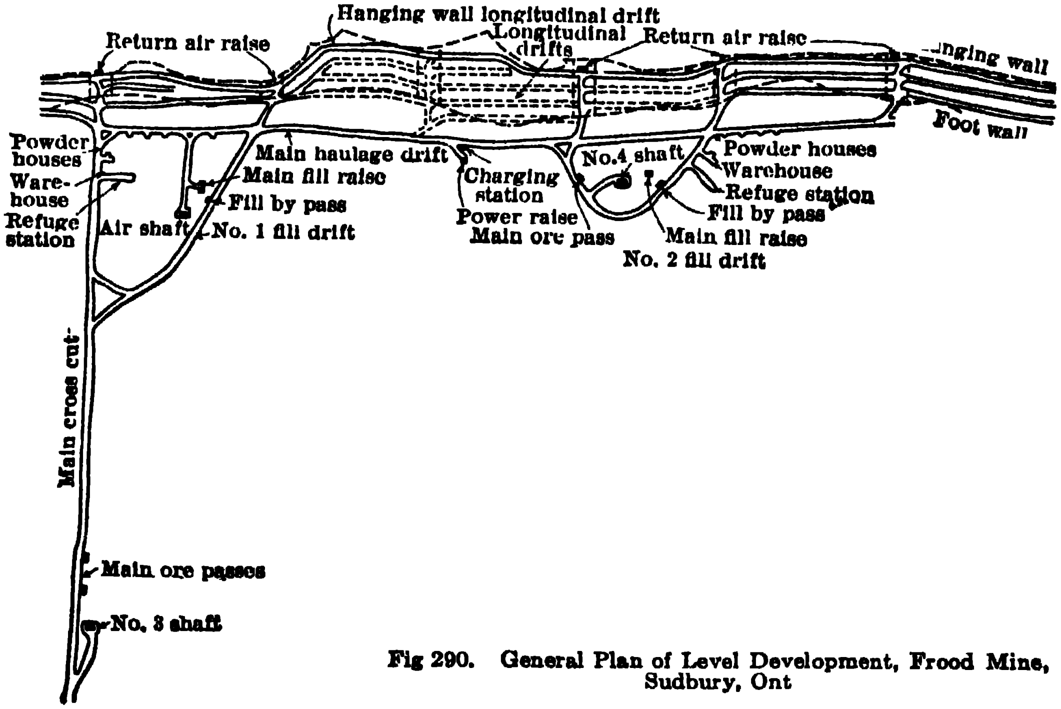

Fig 290. General Plan of Level Development, Frood Mine, Sudbury, Ont

fir sets, spaced 5.5-ft centers. Before stoping starts, back of drift is raised to height of 16 ft and a second floor, or "gangway," is timbered with square-sets having 10 by 10-in posts, 5 ft 10 in long. Chute pockets are built at gangway elevation; planking over drift sets provides footing for loaders. STOPING. Mining began below 2 000-level. Horiz cut-and-fill method (Art 62) was first tried. Stopes 45 ft wide were carried from foot to hanging wall, separated by 35-ft vert pillars. It was found that horiz cleavage planes and cross fractures in the orebody made the backs dangerous. Systematic support of backs, by cribbed bulkheads joined together by lagged stringers, was tried but proved unsatisfactory; then the present square-set system was adopted. New levels are laid out in mining blocks. In general, each block consists of 10 5-set stopes and 9 3-set pillars ("set" measure, 5.5 ft), see Fig 291. Larger pillars ("return-air-raise pillars"), each corresponding in width to a 5-set stope and 2 3-set pillars, are left between the blocks. The return-air raises in these pillars are 7 by 17 ft cross-sec. STOPING DETAILS. Distinctive feature of Frood method is use of long girts in stopes. The standard square-set is 7 ft high and 5.5 ft square, c to c of posts. Girts run at right-angles to pillar lines, or in direction of strike. Long girts give a post-spacing of 11 ft, or twice that of standard sets. Fig 292 is a plan and section of a 5-set stope, timbered with sets *S* from foot to hanging

through the center of the stope and flanked on both sides by long-girt sets *L*. Bottom of sill floor of stope is 7 ft above the rail in the haulage drifts. Cut starts by driving a 5 by 7-ft crosscut at this elevation, along center line of stope, from a gangway and extending to both walls. Ore is breasted with light drifters, drilling 9 to 11-ft holes 2.5 ft apart. Broken ore is scraped with 10-hp, double-drum hoists, directly into cars in haulage drift. First cut, about 8 ft high, is timbered with 8-in jack-pine sets placed to correspond with haulage-drift timbering, posts being 5 ft 8 in long. Where chutes are to be located, 10 by 10-in B C fir is used. Sets are kept within 10–15 ft of face, lagged booms protecting workers at face. During silling operations, a waste raise near hanging-wall end of stope is driven to connect with the hanging-wall drift on level above; raise contains a cribbed manway, serving later, for lowering supplies into stope, for a travelway, and for ventilation. Before first fill is introduced, bottom of first cut is floored with double layer of cedar plank, 2 by 10 in by 10 ft, laid on 4 by 10-in sills. Sets adjacent to pillars, on sill and all higher floors, are "gob-fenced" (lagged) before filling. Chutes are established in every fourth set, lengthwise of stope. Manways are carried up along one pillar line. Regular cycle of stoping operations commences as soon as sill floor is completed. Stope progresses upward by successive horiz slices 7 ft high as shown in Fig 293. Operating cycle is accomplished by dividing work into 3 shifts, known as drilling, timbering, and nipping shifts. Drilling-shift crew comprises 1 stope boss, 2 drillers, 1 timberman, 2 shovelers, and 1 wasteman. Two miners drill and blast the 5-set breast in 1 shift and also do any necessary blockholing. Light drifters are used; drill steel is in sets of 3-, 5-, and 7-ft lengths. From 35 to 50 holes are required for a 5-set blast; usual spacing is 1.5 ft vert and 3 ft horiz; upper row is inclined 15° upward. Explosive used is 40% gelatin; $2^1/_2$ to 3 sticks are required per hole; stemming of clay cartridges is used. Timberman on drilling-shift does miscellaneous timber work. Timbering-shift crew consists of 4 men: timberman, helper, blockholer, and shoveler. They re-blast any missed holes, stand and block new set, and, in general, put stope in shape for further drilling operations. On the nipping-shift a crew of 3 men, serving several stopes, deliver timber, steel, and other supplies to stopes in accordance with requisitions from shift bosses. ORE HANDLING. "Wing-chutes" *W*, Fig 293, 1 set high, are built over chute raises, a grizzly of 60-lb rails, spaced $14\,^1/_4$ in, covers 5 sets on the shoveling floor at top of winged chute; for detail see

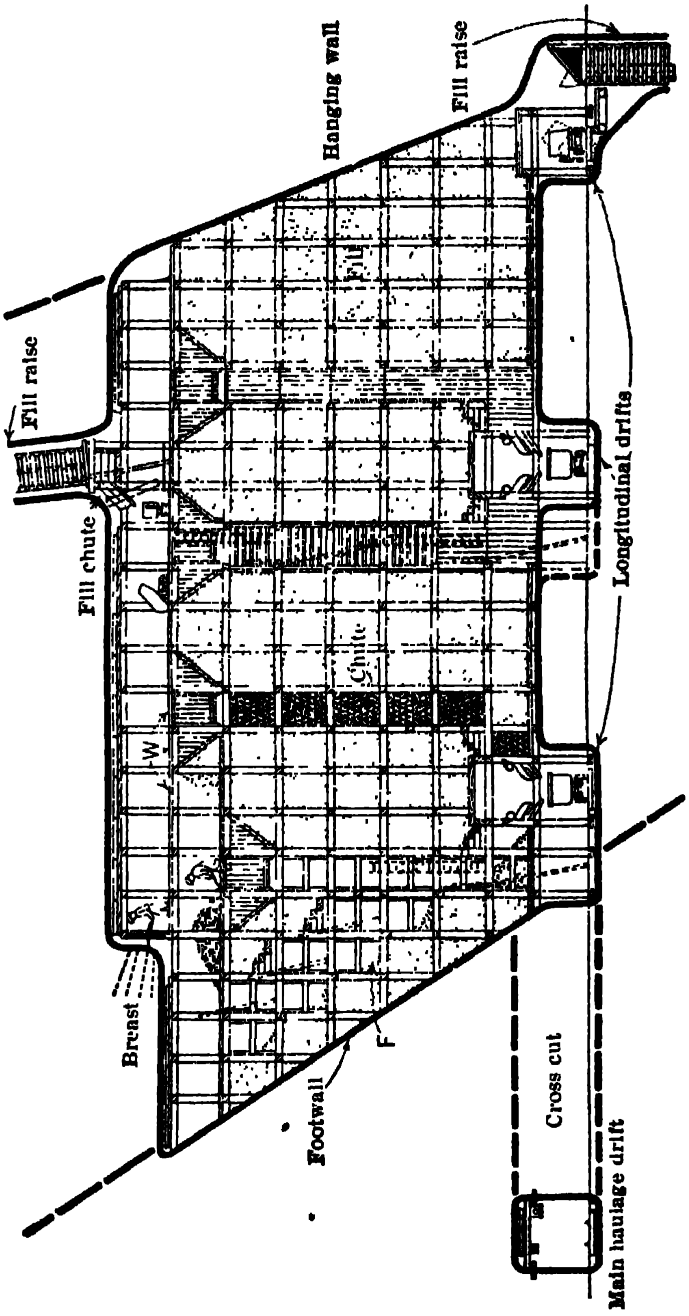

Fig 293. Standard Stope Sec, Frood Mine, Sudbury, Ont

Fig 294. This arrangement reduces shoveling to extent that bulk of broken ore is barred directly through grizzlies. Filling. Waste fill is spread in 16-cu ft end-dump cars on 18-in sectionalized track; track sections, 11 ft long, are easily laid or dismantled by one man. Fill is usually kept within 3 sets of toe of broken-ore pile. Chute construction. Vert chutes are spaced at 22-ft centers; sets are of 10 by 10-in B C fir. Plank lining has been replaced by "bricking." Timber blocks, 8 by 8 by 13 in, are placed so that butt ends project 3 in into chute opening, other ends resting against outer chute lagging. Each row is staggered in relation to rows above and below, see Fig 295; all rows are wedged tightly against inside of posts, caps, and girts; whole lining becomes tightly wedged as timbers take weight and "bricks" become water-soaked. Chutes nearest footwall are offset toward footwall as shown at *F*, Fig 293, and *H*, Fig 295, to maintain efficient chute spacing. Hanging-wall chutes eventually become useless and are filled with waste on abandonment. Pillar mining. The 3-set pillars are mined in two longitudinal slices, a 1-set slice and a 2-set slice. 1-set slice is mined first, by overhand stoping; 2-set slice is mined overhand if ground permits, otherwise by underhand stoping. Chutes at 22-ft intervals in 1-set slice serve for mining the remaining section. Manways in adjoining stope serve as manways, fill passes, and airways for 1-set block; 2 open sets carried in this block serve same purposes for 2-set block.

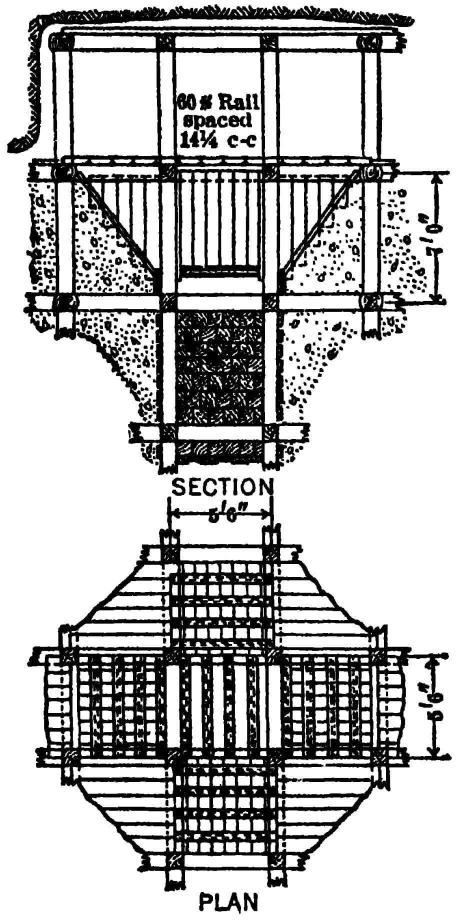

Fig 294. Wing-chute and Stope Grizzly, Frood Mine, Sudbury, Ont

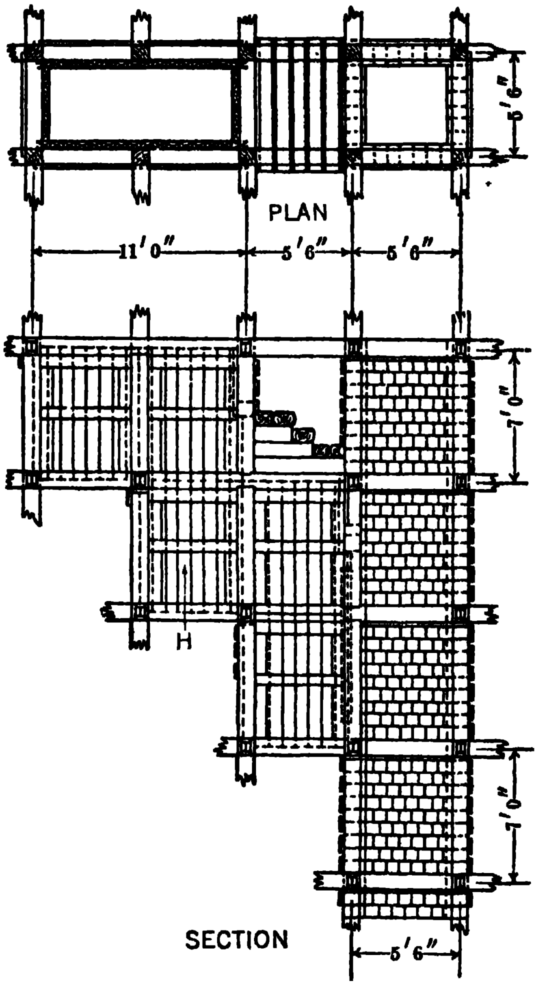

Fig 295. Method of Offsetting Chutes, and Use of "Bricking" as Lining, Frood Mine, Ont

b. Domed or Pyramid Stopes

Work is so arranged that the general outline of the stope back is dome-shaped or pyramidal. They are commonly open stopes, and have been used in massive orebodies of both strong and weak ore under strong hanging walls. The arched back is partly self-supporting and reduces pressure on timbers.

Fig 296 shows this method at Centennial-Eureka mine, Tintic, Utah, for mining an irregular chimney, 350 by 100 ft in cross-sec, dipping 45°, and over 800 ft deep. Walls were fairly strong limestone, but in many places ore could be mined with a pick. Level interval was 100 ft vert, with raises between levels near one end of orebody. Sets were of 8 by 8-in timber, with sills 2 sets long laid parallel to long dimension of orebody. Work on sill floor started at the raise, and when a square, 3 sets on a side, was completed, a 1st floor set was placed in the raise. Sill and 1st floor were then widened simultaneously; when the 1st floor was 3 sets square, the 2nd floor was begun, and so on. Crib bulkheads were necessary to keep stopes from caving (Art 51) (210).

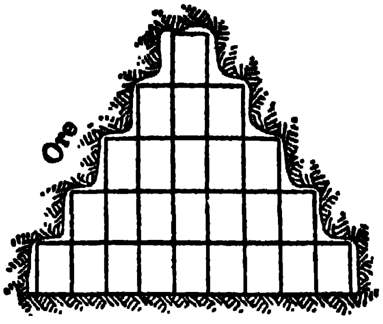

Fig 296. Domed Stope, Cross-sec

L. S. Cates describes similar work at Bingham, Utah, in irregular replacement orebodies (211). Ore was in shoots, 50–200 ft wide, 100–300 ft long, and in places 600 ft deep; dip, 0°–90°. Open pyramid stopes were used only where ore was solid and hanging wall firm. Space for only one set was excavated in advance of timbering; hence, sills were 1 set long. From a drift near middle of orebody, a row of lead sets (Art 45) was extended longit through it. Sill floor was opened from these sets to a width of 4–5 sets, then a row of lead sets was begun on 1st floor, directly over those on sill floor. Widening on any floor might begin 4–5 sets behind the lead set. Each floor was kept 2, or better 4 sets, wider than that above; extra width aided in keeping broken ore on the floors.

c. Rill Stope

This form is designed primarily for use with waste filling. The stope back on any floor is 1 or more sets ahead of that on floor below; hence, general slope of stope face roughly parallels angle of repose of filling. The fill is distributed largely by gravity; planking is laid on the filling, and broken ore slides to chutes at the toe of fill. Except for the square-sets, the stope is same as a filled-rill or inclined cut-and-fill stope (Art 65). Examples:

Butte, Mont. For ore occurrence and development, see Flat-back stopes above. Fig 298 shows an ideal longit sec of a timbered rill stope, opened up as in Fig 297. Data from H. L. Bicknell, W. B. Daly and others (534) in 1923, and checked in 1939 by officials of Anaconda Copper Mining Co.

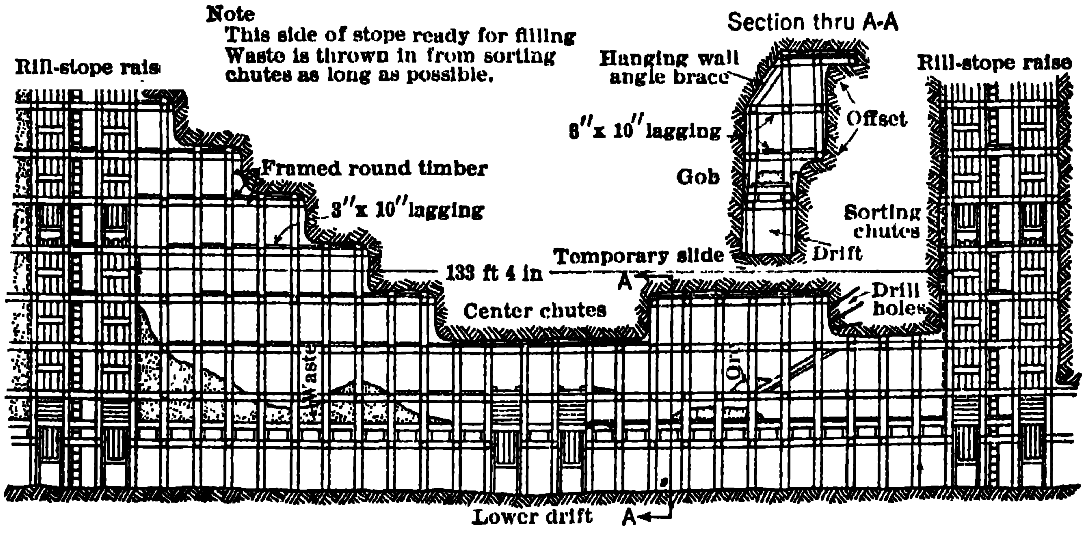

Fig 297. Preliminary Development of a Timbered Rill Stope

Method is used in veins over 10 ft wide, where back and walls will not stand in a filled-rill stope (Art 65). Level interval, 200 ft; drifts timbered with square-sets; at intervals of 11 sets, offsets 1 set wide by 3 sets long are made in footwall for raises and chutes. Drifts are made 2 sets wide every 500 ft, for a distance of 10 sets, to provide space for switches. Alternate raises (stope raises, Fig 298), comprising a central manway with chute on each side, are carried up in ore to within 30–40 ft of level above, whence they turn vertical to hole through at least 15 ft in the hanging wall on level above. As a raise passes the 1st floor, one set on each side is mined and timbered. After raises are up 5 or 6 floors, the 1st floor is mined. All sets except those at chutes and manways are of round timber (Fig 337). Stopes 2 sets wide usually cover the width of vein. After completion of 2nd floor, "center" chutes are built in the offsets half-way between the stope raises and cribbed to 2nd floor, and sides of the stope-raise sets are lagged. Fig 297 shows right end of a stope in process of development to the form reached in left end. During development of the sloping stope faces, temporary slides convey ore to the 2nd floor; waste is sorted out and piled on the floors. When the rill face has been formed in both ends of a stope, bulkheads and chute gates (Fig 297) are built in the stope raises above 7th floor, and stope is filled with waste poured down the raises. This completes development. 2 by 10 or 12-in lagging is laid on top of the waste, so broken ore will slide to a grizzly over center chute. The 3d floor (7 sets long) is then mined and timbered. Thereafter, mining and filling proceed alternately in each end of a stope. Starting at stope face in each case, 4 sets are mined successively on 4th, 5th, 6th, and 7th floors, then 3 sets on 8th and 1 set on 9th floor. This completes a "cut"; the raises are then lagged; that end of the stope in which this work has been done is filled, and the miners are transferred to other end of stope, where the same operations are repeated. Fig 298 shows a stope after such a cut has been taken in each end. Mining proceeds until the top floors are within 5 sets of the level above; then work is confined to the V until a level-pillar has been left, 5 sets thick and the full length of stope. This pillar is mined later, when drift above can be abandoned. Sorting is done at the grizzly, one of the center chutes being used for waste.

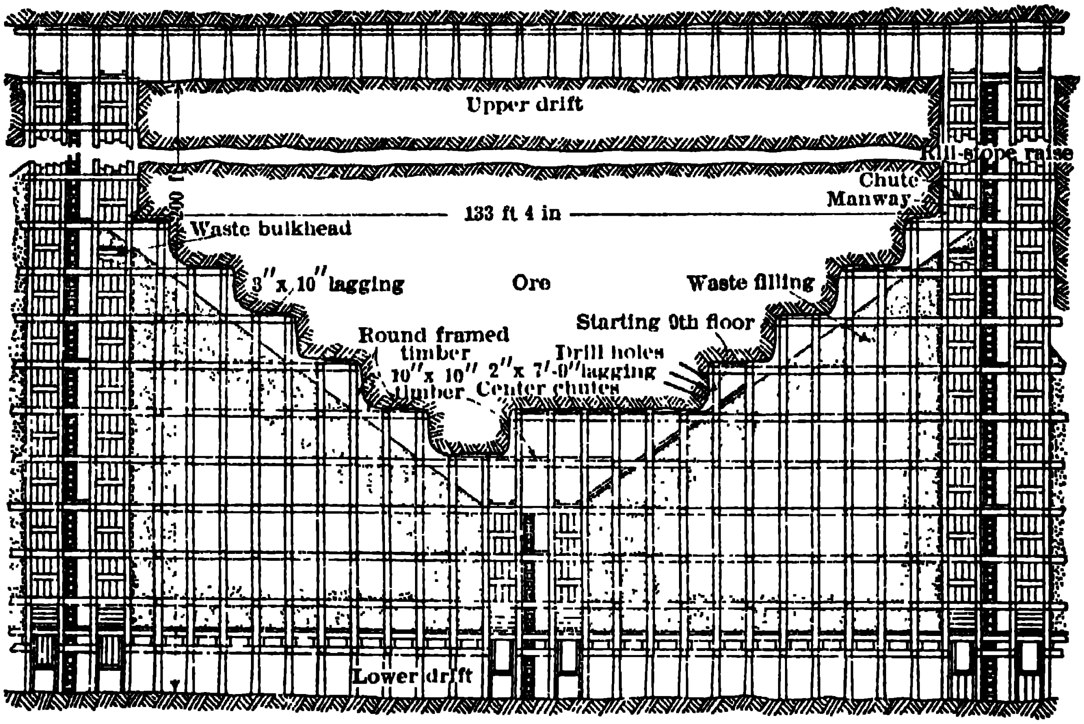

Fig 298. Timbered Rill Stopes after Development, as carried toward Upper Level

Lake Shore mine, Kirkland Lake, Ont (95). Data from W. T. Robson and L. S. Weldon in 1936. Gold ore occurs in crushed and brecciated fault zones in complex series of syenitic intrusives and in a porphyry boss. Aver grade of ore in 1934 was 0.667 oz Au per ton. Ore zone on property is about 2 800 ft long. Mining reached depth of 4 500 ft in 1936. Aver stoping width is 15–16 ft, but widths to 70 ft have been mined. General dip from surface to 4 500-level is 82°, with local dips as low as 45°. Shrinkage stoping, first employed, was discarded because of excess dilution and ore left behind in local rolls or in parallel or branching leads; horiz and inclined cut-and-fill stopes were also tried; bad ground eventually led to square-set, flat-back and rill stopes. DEVELOPMENT is by 2 vert shafts, with levels 200 ft apart to 2 200-level and 125 ft apart below. Levels are developed by drifts in the veins. SQUARE-SET RILL STOPES. Drift is widened by slabbing to full width of ore for entire length of section to be mined. Back is taken down to height of 16–17 ft above rail. Sill floor is timbered as in Fig 299; distinctive feature of sill timbering is use of double caps, with longit stringers between them, which facilitate replacement of timbers broken by pressure and aid in holding the level open when stope below is being mined through; sill-floor timbering is designed to avoid breakage through pressure from walls. A centrally located, 3-compt raise (Fig 300) is driven to the level above,

timbered with square-sets, 8 ft high and 5 ft 4 in c-c of posts; 10 by 10-in squared timber used for all members. Center compt of the raise is a manway; the outer ones are chutes. A double-rill stope is started from the raise, and carried to level above as a block 25 sets in length. Fill is introduced to each half of stope through the raise. A manway is carried at each end of the stope, next to stope chutes. On completing the first stoping block, successive single-rill sections, 12 sets long, are mined. The manway sets of the last completed section are used for conveying filling to the new section. Ground is broken by flat holes drilled by mounted drifters. A round consists of 12 6-ft holes, loaded with 70% semi-gelatin dynamite. General practice is to advance the rill 2, or even 3, cuts before filling. Entire final face of a group of cuts is drilled, but not blasted until fill is introduced, thus permitting closer filling. Purchased sand is used for fill. Flooring over fill is spiked to caps, giving a slope of 56° to surface of fill. Crew of miner and helper do all work in a stope section; 20.11 tons are broken per machine-shift; powder consumption, 0.725 lb per ton.

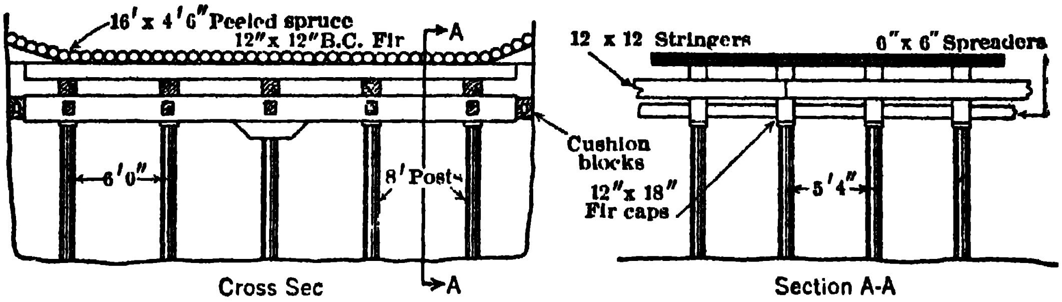

Fig 299. Sill-floor Timbering, Lake Shore Mine, Kirkland Lake, Ont

Ground Hog mine, Vanadium, N M. Data from F. W. Richard (527) in 1930. Ore, Pb-Cu-Zn, occurs in irregular lenses in a fault fissure intruded by diorite porphyry and granodiorite dikes. As post-mineral faulting caused fracturing of ore and wall rocks, prompt support of ore and walls is necessary. Ore is usually massive sulphide; mill feed runs about 8% Pb, 3.5% Cu, 15% Zn, and 6.5 oz Ag per ton. Width of ore is 3-25 ft, normal to dip. Aver dip, about 60°. Development is by vert shaft in hanging wall, intersecting vein at 300-level; inclined winze in vein from 400-level serves for mining below this horizon. Main levels are 100 ft apart vert; sub-levels half-way between main levels aid in distributing filling and make shorter lifts in raising. Stulled raises are 50 ft apart. Stoping. Rill stopes are used entirely. For ore widths less than 10 ft, filled rill stopes (Art 65) are used, with occasional timber support; for widths greater than 10 ft, square-set rills. Stoping blocks are 100 ft long, with a raise at each end and in the middle.

Fig 301. Square-set Rill Stope, Ground Hog Mine, Vanadium, N M. L

Stoping starts by breasting to full width of ore on a main level. Floor sills of 10 by 10-in timber run from wall to wall and are covered by double 2-in flooring. In ore over 10 ft wide, square-sets are placed on the sills. Sets, 5 ft sq and 7 ft high, consist of 8 by 8-in posts, and 6 by 8-in caps and girts. After mining first floor above sill, the middle raise is widened and timbered one set wide across the vein and up to level above. On second floor, 3 lines of sets are taken out on each side of raise, from wall to wall; on third floor, 2 lines of sets; on fourth floor, 1 line. This forms a pyramid of unfilled sets. Waste is then run in, filling sets close to the back; after which flooring is laid on fill. Stoping continues on either side of raise as desired until toe of rill is within 10 ft of next raise; 2 sets nearest the raise are carried flat to furnish shoveling and sorting platform. For method of stoping at the several stages, see Fig 301. A few drill holes, blasted lightly, will make room for a set; drilling is with stopers or drifters. Stoping crew comprises miner, timberman, and helper. On basis of all men underground, 1.68 ton of ore per man-shift was produced in first 3 mo of 1930; explosive for stoping, 0.63 lb per ton.

d. Vertical-face Stope

Fig 302 shows former practice in open stopes at BINGHAM, Utah (211). For ore occurrence, see Domed stopes, above. Stope faces were vertical where hanging wall was heavy, and the nature and extent of ore were not known. A row of lead sets *A* was first driven close to hanging wall, followed by row *B*. When both were complete, stoping began at *B*, and sets *C* were carried to hanging wall. Successive vert slices were taken until the stope was worked out, or, if the weight became great, the stope was caved and a new one started alongside. Sills and caps were at right-angles to strike. Advantages (L. S. Cates): (*a*) "There is always a solid breast of ore on one side of stope, which relieves press on timbers.

(b) Should stopes cave unexpectedly, only the ore on floors and in chutes is lost, for a new stope can be opened by driving a row of sets on the sill floor, next to the caved stope, and carrying them up to the hanging as before."

This method in filled stopes is illustrated at Bunker Hill & Sullivan mine, Idaho. Data here are retained from 1927 edn of Handbook. More recent data by U. E. Brown (212) in 1931 show no material change. Large irregular shoots of heavy galena ore, with little waste, occur in shattered quartzite; dip, about 40°. Stopes, 300–700 ft long and 40 ft wide, have been carried through lifts of 200 ft. Hanging wall and ore are heavy, and flat-back or stepped-face stopes expose areas of back too large for safety (214). Work begins on a level, Fig 303 (215); a vert slice, 3 or 4 sets wide, is carried up under hanging wall and filled. The face is then advanced toward footwall by mining vert slices 1 or 2 sets wide. Waste filling and timbers are dropped through footwall raise *C*, and trammed to top floor through crosscut *A*, 1 set wide. Waste is distributed in stope by temporary slides, as shown. A new crosscut *B* is driven directly over *A* to serve the next floor; crosscuts for lower floors are not shown, each being abandoned as a new floor is opened.

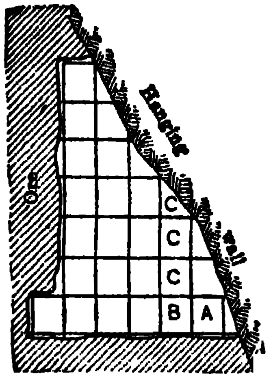

Fig 302

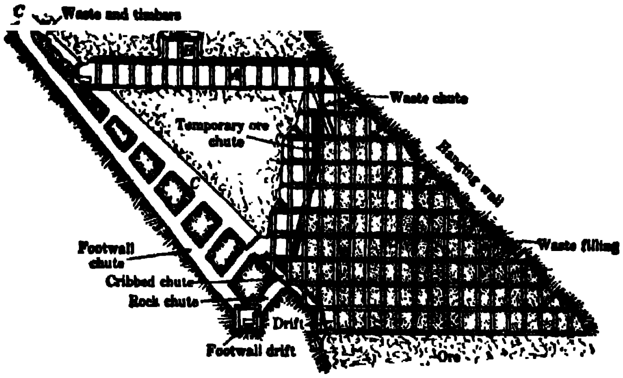

Fig 303. Vert-face Stope, Cross-sec

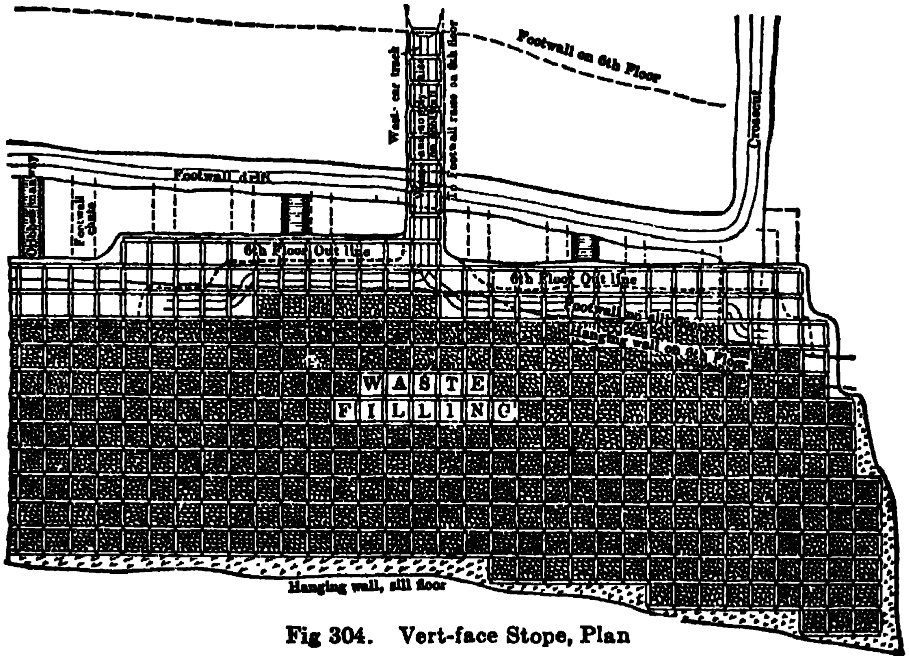

Fig 304. Vert-face Stope, Plan

Fig 304 (S. A. Easton) is a plan of a narrower stope, worked up to 6th floor, showing the relation between work on top and lower floors, and arrangement of tracks for handling filling. In some stopes, filling is dumped through a raise along hanging wall; but a footwall raise is preferable in heavy ground. Rock chutes to footwall drift (Fig 303) are 15–20 ft apart, cribbed or lagged chutes being carried up from them through the filling as stope advances. On abandoning the sill floor, a raise from footwall side of rock drift is made, a little steeper than the footwall, and branched at intervals to intersect the ore at the upper floors. This raise serves as a chute when floors are advanced to footwall, and obviates necessity for transferring ore on an intermediate floor. This method is safe and provides prompt support for hanging wall. The sharp arch developed early in the stoping stage, and maintained until level above is reached, greatly increases strength of the ground. Most of the weight of ore is carried by footwall. See also Bib (575).

e. Underhand Square-set Stopes

Stopes of this type are unusual. Employed at Broken Hill South mine, N S W, for mining chain pillars, 30 ft thick, under large filled stopes. Mining is done in vertical slices, 1 set wide, from wall to wall; when 2 or 3 adjacent slices are complete, they are filled before more ground is opened. Work starts from top of a winze, by an excavation for the set *L* (Fig 305). This undermines sets in a crosscut above, which are supported by a boom *S*. Set *L* is erected and caught up with a boom from the winze set (Fig 306). The 6 by 10-in crosspiece *A* supports the 2 caps and is itself supported by boom *B*, which rests on *C*, its rear end being wedged under *D*. Dogs *K* tie posts *F* to caps and girts. After set *L* is blocked, the ground beneath is excavated, another set is suspended by dogs and process repeated until the filled stope below is reached. The bottom set is then blocked and boom *B* may be removed. By repeating these operations a slice 6 ft wide (1 set) and 30 ft deep is carried across the level pillar. Broken ore falls to and is handled on bottom floor of the underhand stope. Mining in the slice alongside starts from a lead set (Art 45), at one end of the top winze set. Work under old stope bottoms is difficult and sometimes requires spiling. It is found that timbers fail in slices over 60 ft long; for greater widths of lode the chain pillars are sliced in 2 sections. Object of this method is to expose only small sections of old stope floors at one time.

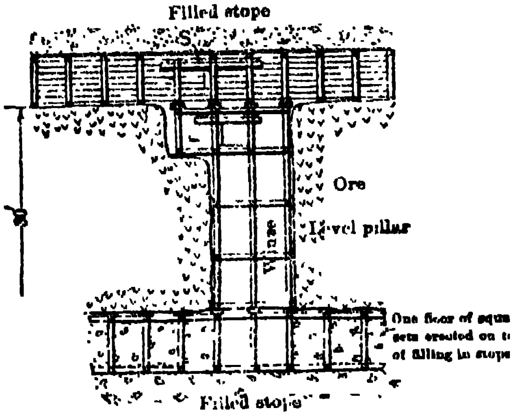

Fig 305. Square-setting for Underhand Stope

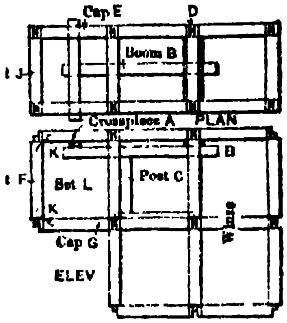

Fig 306 Details of Underhand Square-setting

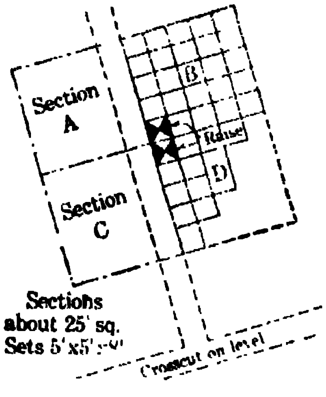

Fig 307. Plan of 5th Floor of Underhand Square-set Stope, Briggs Mine

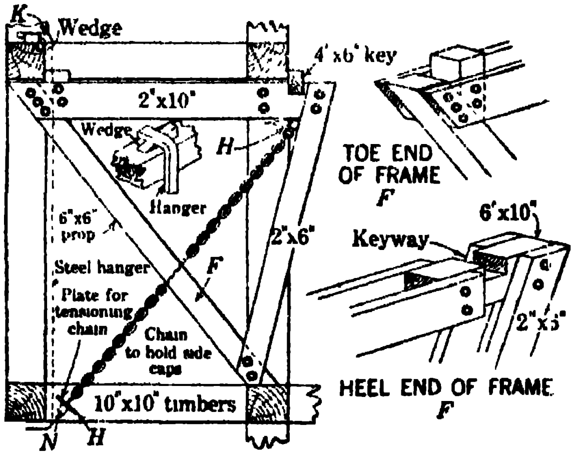

Fig 308. Mode of Support for Underhand Square-sets, Briggs Mine

It is stated that, though slices are narrow, the 30-ft depth gives capacity and considerable economy. For details, see Bib (217).

Briggs mine, Bisbee, Arizona. Data from R. H. Dickson and G. J. Young in 1923 (579). Ore was copper and iron sulphides, overlain by irregular masses of barren sandy pyrite or brecciated quartzite. Overhand square-set stoping proved unsatisfactory, and the Briggs underhand method was evolved. Ore was blocked out by crosscuts and raises into sections from 10 by 20 ft to 25 by 35 ft horiz, and extending to height of ore or to level above. Square-sets were 5 by 5 ft by 7 ft 10 in high. The sections were mined in regular sequence around a central 2-compt raise (Fig 307). The 3 sets cornering on the raise at top of the ore were first mined and timbered with regular square-sets; mining then started on the floor below. When a set was undermined it was supported by the 2 triangular frames *F* (Fig 308, 309); by the 2 chains attached to dogs *H*, driven into the timbers and tightened by screwing up nuts *N* (Fig 308); and by light bent hangers *K*, tightened by wedges. These supports transmitted the wt to the raise sets, or to sets that had been blocked into place; they were removed and reused after the set had been blocked. Stoping on top and successive floors progressed downward (Fig 309), each floor being 1 set behind floor above: the ore fell to chute below. When a section was finished it was waste-filled through a raise to level above before the adjoining section was mined.

A modified method of underhand square-setting, the Ratterree, used for mining small sections of sulphide adjoining worked-out filled square-set or cut-and-fill stopes, was also developed here (579). See also Art 57.

47. HANDLING ORE, WASTE, AND TIMBER IN SQUARE-SET STOPES

Ore is handled in flat-back stopes by shoveling directly to chutes, by transfer to chutes in barrows or cars, or by slides. Use of slides is desirable, but may be impracticable if close filling is necessary or if careful sorting is important. Close spacing of chutes tends to low handling cost, but saving may be more than offset by added cost of timbering. A primary purpose of square-set fill stoping is to reduce ore-handling cost. Scrapers are sometimes used in square-set stopes; Fig 310 (189) shows one application, at Park Utah mine.

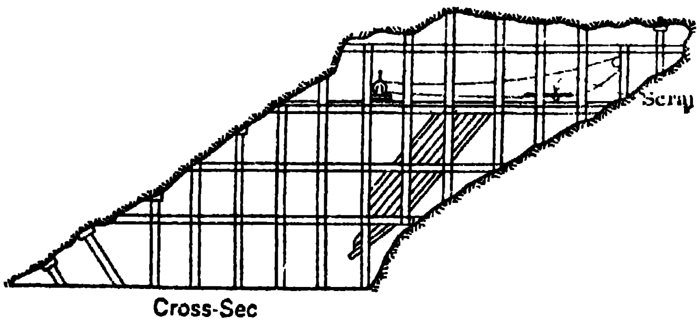

Fig 310. Use of Scraper in Square-set Stope, Park Utah Mine, Park City, Utah

Floors are of 2 to 5-in plank, long enough to cover 1 or 2 sets; the shorter length is more convenient; flooring is taken up and reused; 2-in plank is too weak to stand heavy blasting, and should be doubled, or protected by round lagging, or 3 or 4-in plank should be used. Insecure seating of flooring on caps or girts often causes accidents in square-set stopes. Cleats, 2 by 2-in, nailed along center-line of supporting members, reduce danger of flooring slipping out of place. Floor plank should be laid so that shoveling is with the grain; for barrow work, planks usually lie across caps. Over filling, tight floors prevent loss of fines, which may amount to 5% and become important with high-grade ore. Canvas may be used under flooring, but has a short life. At Goldfield, Nev, in high-grade ore, the shoveling floors were laid on 2 in of fine filling. On finishing a floor, the planks were taken up and swept. The fines below were skimmed off down to the caps and sent to chutes; this recovered all high-grade fines sifting through joints between planks (145).

Chutes: (*a*) A cheap chute for filled stopes may be made by simply lagging the outside of a vert row of sets, but set timbers or lagging are apt to be broken by falling ore; such a chute is feasible only with soft ore. (*b*) The inside of a row of sets (usually the outside, also) is lined with vertical planks. This is common in both open and filled stopes. Thickness of lining (2 to 4 in) is proportioned to wear during life of chute. A double 2 or 3-in lining may be used to secure tight joints. (*c*) Cribs of round or square timber, built independently or just inside of the sets, which may or may not be lagged outside. Independent chutes are useful for carrying through stopes at an angle to the sets. Chutes inside of sets act as reinforcement and offer strong resistance to wear and pressure of filling. (*d*) A vertical row of sets is "bricked" with timber blocks. See Fig 295; also, Black Rock mine, Art 90.

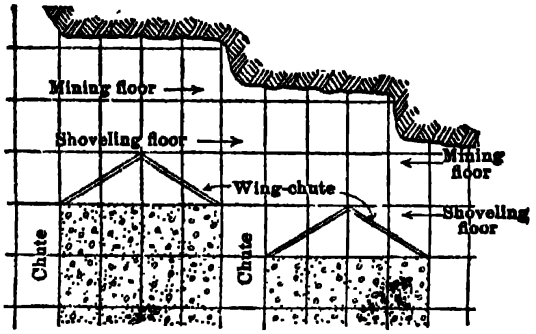

Fig 311. Wing-chutes, or Slides

Wear on chute linings is decreased by offsetting to reduce vert drop. It is also lessened by keeping chutes nearly full. For chute gates, see Art 90.

Grizzlies, of logs or square timbers or of rails set 8–14 in apart, are often placed over tops of chutes to keep out large lumps which might block chute or gate. They are especially important in this regard for single-compt chutes in filled stopes; they also reduce danger of men falling into chutes.

Distance between chutes varies from 15 to 50 ft or more; it is closely related to cost and method of handling. Cheapest handling is furnished by slides or wing-chutes (Fig 311). In upper parts of stopes ore can be thus delivered to chutes 50 ft apart. In lower parts of stopes started with this chute interval, barrows are necessary.

In filled stopes, the closer the filling to back of stope, the smaller the area served by a slide. At Leonard mine, Butte, in flat-back stopes, 50 by 25 ft in horiz section, filling was kept 2 sets below the back; chute interval was 16 ft; about 50% of broken ore could be handled on slides (80). For economical handling, flat-back stopes usually require chutes closer together than those with inclined faces (see Rill stope, Art 46). Though barrows may be used with any chute interval, their handling cost is high, increasing rapidly with distance. It is best to use slides as much as possible, and to shovel remainder of ore to chutes. Shoveling distance should be kept down to 10 or 12 ft max, which requires chute intervals of 15 to 25 ft.

Wing-chutes (slides) are sloping floors of 3 to 4-in plank, spiked to the sets. In Fig 311 the ore falls 1 set to sorting floor and thence is dropped or shoveled to the slides; filling can thus be kept 3 sets below the back. If sorting is unnecessary, both slides and filling may be moved 1 set higher. Slides may converge in 4 directions toward a chute, and many variations are possible; see Fig 294; their use does not entirely eliminate shoveling.

Pockets or bins for storage are sometimes used in open square-set stopes. They are made by putting lining around from 1 to 5 sets, terminating at the bottom in a chute; they may extend through the whole height of stope. Pockets reduce shoveling distances, and may obviate necessity for wing-chutes.

Access to open square-set stopes is by ladders from level below. In filled stopes, there may be a raise to level above, or chutes built to include 2 rows of sets, one of these compartments being a MANWAY. In heavy ground, these are harder to keep open than single-compartment or "blind" chutes, but the manway is not only a traveling way through filled sets, but facilitates repairs to the ore chute and clearing it when it clogs.

Filling may be obtained in part from sorting, or from breaking waste or low-grade inclusions in the orebody; see also Fig 289, Argonaut mine. For running in filling from outside sources, a raise to the level above is necessary. In flat-back stopes, filling is distributed by shovels, barrows, or cars, depending on size of stope and distance between waste raises; in rill stopes, distribution is largely or entirely by gravity.

Timbers are handled most cheaply when lowered or dropped through a raise from level above; 1 compt of a waste raise may be used thus. Lacking access to stope from above, timbers are hoisted from below by a windlass, or electric or air hoist. In filled stopes, TIMBER CHUTES are sometimes kept open through the filling by lagging and lining a vertical row of sets next to a manway or ore-chute; or a timber slide may be built in a corner of manway.

48. DIMENSIONS OF SQUARE-SETS

Horizontal dimensions. Table 38 shows that practice favors sets about 5 by 5 ft in plan, with floors 7 to 8 ft apart.

C. T. Rice states (80): (*a*) Posts should be far enough apart to give shoveling room; to allow for right and left-hand shovelers, they should be equidistant capwise and girtwise. A clear space of 4.5 ft is about minimum for effic shoveling; hence with 10-in timbers, posts should be at least 5 ft 4 in centers. (*b*) Strength of ore limits max size of set, as the ground must stand unsupported over area of 1 set while timbers are being placed. Heavy press from weak ore may require smaller sets (see *e*). (*c*) Sets should be proportioned so that 1 round of holes breaks room for a new set, thus allowing prompt placing and blocking of sets. (*d*) Large sets are desirable in reducing amount of timber per ton of ore, but, in large sets, timbers are heavier and cost more to handle, and a stope started with a large post interval may become unmanageable if the ground suddenly becomes heavy. (*e*) Distance between posts and the area of stope floor are related factors. By working stopes rapidly in small sections, the pressure on timbers is reduced, thus allowing use of larger sets and smaller timbers. (*f*) A compromise between all the factors usually limits the max spacing of posts to 6.5 ft and minimum spacing to 5 ft.

Probably the distance between posts could often be increased without overloading timbers. In close-filled stopes, where the weight comes onto timbers from above and is transmitted to posts through lagging and caps, a comparison of relative strength and cost of sets of different size can be made.

Minimum height of sets for headroom is about 6.5 ft in the clear; in many mines, to allow for settlement, posts are cut to give a clear 7 ft. Length and cross-sec of post must also be adjusted to withstand pressures.

At Bisbee, Ariz, a reduction in pressure due to rapid work in small stopes allowed use of 8 by 8 and 10 by 10-in posts, instead of 12 by 12-in, and also an increase in height from 6 to 7.5 ft. Increasing length of posts effects no saving in timber, unless the increase is sufficient to save one or more complete floors in a lift. Long posts probably increase cost of placing caps, girts, and blocking, enough to counterbalance the saving in timber.

In 1914, the Ariz Copper Co lengthened posts from 6.5 to 9.5 ft; this increased the extraction per set from 179 to 250 cu ft of ore, and reduced total timbering cost 15%. Crushing strength of 6.5-ft posts is so much greater than transverse strength of cap and girt, that an increase in height of post does not materially reduce strength of set. It is difficult to prevent long posts from swinging when pressure comes from the side (178).

Size and strength of timber. As stated by E. D. Gardner and W. O. Vandenburg (189), it is difficult, or impossible, to estimate accurately the strength required of square-sets. Experience is the guide in selecting the kind and size of timber for given conditions. Where filling is used, requirements of strength are usually temporary, because pressures are eventually taken up by the fill. Hence, many mines use cheaper timber for square-sets than for use where more permanent strength is required, as in shafts or on main-level workings. Use of timber preservatives may be justified in the latter case, but not in the former. On the other hand, use of square-sets in stopes tends to give a false sense of security, and strength requirements should be judged accordingly; especially in blocky ground, where sets may be subjected to sudden and heavy shocks. Tight side and head blocking tends to reduce this danger.

49. FRAMING SQUARE-SETS

General. The two general types of framing are "post-butting" and "cap-butting." In either, variations in framing are theoretically without limit. Fig 312–337 show how widely practice has varied. Diversity of framing in early days was largely due to honest theorizing, but probably in part chargeable to desire for originality. Lack of standardization today is probably due to tendency to follow custom. As far as possible, symmetry and simplicity in framing should be sought.

Post-butting *vs* cap-butting sets. Early practice was about equally divided between these types. E. D. Gardner and W. O. Vanderburg (189) show that recent practice trends to more general use of cap-butting. Choice can not be based on theoretical grounds alone, because: (*a*) unit pressures in square-set stopes generally exceed safe bearing values used for ordinary timber structures and hence there is considerable crushing of the joints; (*b*) direction of pressure is rarely parallel to caps or to posts, and its exact amount is never known; (*c*) distribution of stress in different members of a set under eccentric loading can not be calculated, because joints are indeterminate and the members do not fit exactly.

Strength of timber under compression across the grain is from 10 to 20% of its compressive strength parallel to the grain. In framing post-butting sets, the area of the post tenons is made 12 to 44% of area of the joint; in cap-butting sets, the area of cap tenons is 10 to 66% of the area of the joint. Hence, under pressures within the limit of safe bearing values, square-set joints are strongest in the direction in which the tenons butt. For such conditions of loading, post-butting sets should be used where the direction of max press is vert; cap-butting sets, where direction of max pres is lateral. Where pressures exceed safe bearing values, joints are compressed. In cap-butting sets, ends of posts bear entirely on wood in cross grain, and under vert press the rate of compression is equal over whole area of joint. In post-butting sets, under heavy vert press, the post tenons or HORNS must fail before the crossgrain wood in caps and girts can aid in transmitting press to the post. As rate of compression is not the same in all parts of a joint, settlement in a stope is often irregular. C. T. Rice cites evidence (218) to show that settlement is greater and more irregular in post-butting than in cap-butting sets, and that more auxiliary timbers are needed in the former to keep floors level. Hence, many engineers prefer cap-butting sets for heavy vert press, and practice is almost uniform in using them for heavy lateral press also, though arguments like the above indicate the superiority of post-butting sets. But, in heavy ground, filling follows mining closely and takes most of the lateral press; the smaller and more uniform rate of vert settlement of cap-butting sets is a strong argument for their use in such ground.

Square-sets may also fail by "jack-knifing"; posts swing out of line and a girt or cap may drop, allowing adjacent sets to collapse. Hence, wide seats for girts and caps are desirable in cap-butting sets. In post-butting sets, wide seats are obtainable only by reducing size of the post horn. Long horns of small cross-sec are objectionable, as they break easily. With timbers over 10 by 10 in, post-butting sets with adequate shoulders and horns are readily framed. Sometimes, to give a wider bearing for either girt or cap, horns on posts are not of square section; they require a complicated framing machine. Girts are more apt to pull away from their seats under light than under heavy press.

Empirical rules proposed for framing details: (*a*) length of the post horn should be less than its least cross-sec dimension; (*b*) girts and caps should have a seat on the post not less than 2 in wide: a wider shoulder is desirable (218). SIMPLE FRAMING is best, especially for hand framing. Post-butting sets are generally simpler and cheaper to frame than cap-butting, but the difference is small when framing machines are used. Complicated joints resist distortion better, because of the numerous shoulders, but this advantage is doubtful, as corners are points of weakness at which crushing begins, and such joints are difficult to assemble if timbers have been even slightly crushed. SYMMETRICAL FRAMING is best; costs less to place timbers when posts can be set either end up; caps and girts should be so framed that either of two opposite faces may be placed upwards.

Examples. Fig 312–319 show post-butting sets; Fig 320–327, cap-butting. Some of the mines mentioned are no longer active. In Fig 313 the post is unsymmetrical, with a 6-in horn at top and 4-in at bottom; this secures a shallower mortise at top of set, which is easier to clean out and allows "flirting" the post (Art 52) if sets have swung out of line; long, slender horns make flirting of posts difficult. Another way to reduce length of horns of post-butting sets is to cut them of equal length and short enough to leave a "squeeze-space" between them. In early days one theory was that a squeeze-space allowed a certain "give" when press came upon sets (189); the practice has lost favor, because squeeze-spaces permitted excessive settlement. Set in Fig 314 is simple and symmetrical; post horns are short and strong; and dapped down on post, so that the horn takes only part of lateral thrust. Some examples show unframed girts, with narrow seat on post; bearing on post should be broad enough to avoid the dropping out of girts in case of general movement of sets; use of one unframed member of a set cheapens cost of framing, but, as sawed timbers vary in cross-sec, unframed ends must often be dressed in the stopes. Instances of use of narrow girts are shown (as in Fig 321); practicable where girtwise press is slight, but narrow girts provide smaller support for floor plank.

Combination sets contain both round and square timbers; they are planned to avoid the difficulties incident to framing sets entirely of round timber.

Fig 328 is a cap-butting set, with round posts and square caps and girts. It is well designed, full strength of post is obtained, all members are symmetrical and the set is easily stood and reinforced (152). A good shoveling floor may be laid either cap or girtwise. Fig 329 is a similar design,

but with posts butting; its weak point is the slender upper horn of post, the bottom horn being only 3-in; it affords good shoveling floors. Fig 330 is a cap-butting set, with round post and girt. The bottom post horn is only 1.5 in long, on the theory that it is easier and quicker to stand a post

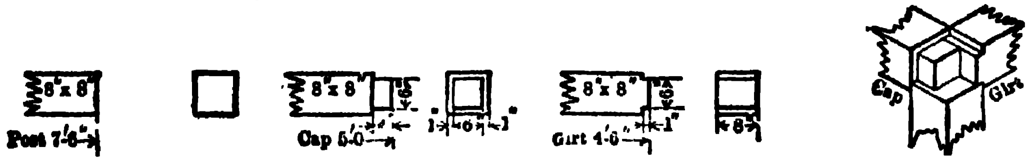

Fig 327. Esperanza, Mex

with a short horn (219). It requires an unsymmetrical cap horn, and the small round girt of this set precludes use of a floor laid girtwise.

Round-timber sets. Simplest joint is made by first squaring the ends of timbers for a sufficient length to avoid interference of their cylindrical surfaces at the joint, which is then framed as with square timber. This saves cost of squaring the whole log, an important item in hand work. Disadvantages: the joint utilizes a max of only 60% of cross-sec of the timber, and round timber weighs at least 40% more than square of equal joint strength.

Fig 331, 332 show simple framings, open to the objections stated; also, they provide a poor seat for the bottom of the post. These sets can be framed in machines of the block type.

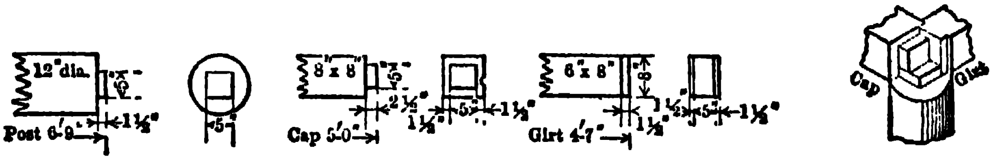

Fig 328. Arizona Copper Co, Morenci, Ariz

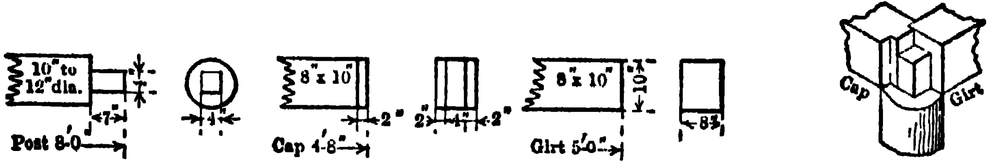

Fig 329. Cœur d'Alene, Idaho

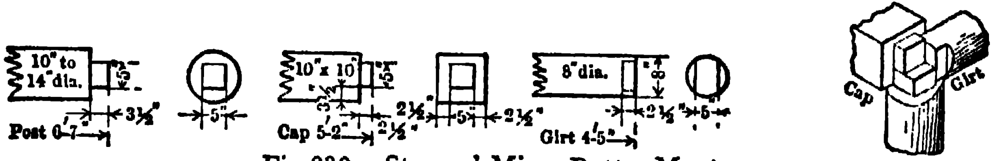

Fig 330. Steward Mine, Butte, Mont

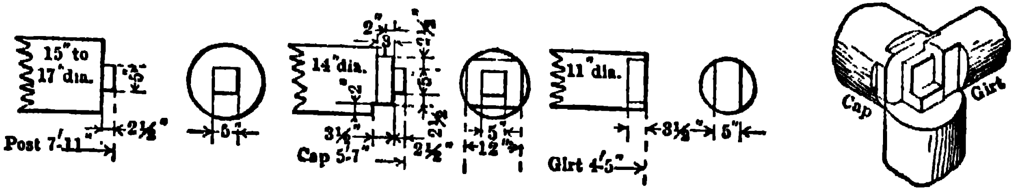

Fig 331. Sill-floor Set, Clark Mines, Butte, Mont

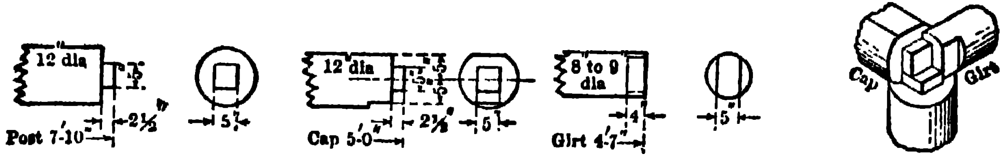

Fig 332. Gagnon Mine, Butte, Mont

Bevel or miter framing (Fig 333–336) brings the entire area of members in contact at the joint. In general, the sets are hard to stand and block, and the bevels facilitate distortion under pressure if the sets once get out of line. Post, cap, and girt of a square-set must be firmly blocked when the other members are missing. Many miter joints require blocking on top before they can be blocked sidewise, or else simultaneous blocking in 2 directions. Either case increases expense and difficulty of placing. Fig 333 has a simple miter joint, to permit hand-framing of stunted, twisted timber; caps and girts are identical (209). Fig 334 is a hand-framed set, for heavy vert pressure; a 1-in squeeze-space is left between the post tenons, giving a cushioning effect said to prevent caps from splitting (221). It may be blocked in any direction, with some of the members missing. Fig 335 is a set designed by D. W. Brunton, in which end of post is beveled. It requires top blocking, to prevent riding of cap and girt, before it can be blocked sidewise. The square and bevel joint (Fig 336) is the best bevel framing for cap-butting round-timber sets. It is easily blocked, and the cap is the only member expensive to frame (222).

The best framing for round timbers is the STEP-DOWN SET (Fig 337). It is made possible by using the cutter-head saw, and costs little if any more than simpler types cut with block framers. Full strength of timbers is utilized, the square shoulders resist distortion and make for easy blocking, and ends of posts and caps are alike. A girt more than 10 in diam is seldom used (219). In general, better joints are obtained, in round-timber sets, if posts and caps are approx of equal diam. Upper side of large caps is slabbed off, to give a flat surface for flooring if laid capwise and to avoid interference with flooring laid girtwise.

Round *vs* square timber for square-sets. ROUND TIMBER is cheaper, has lower freight rates, and is stronger per sq in, because the outer fibers are uncut, but round timber is harder to handle and aline than square; caps must be slabbed to receive flooring, though cost of slabbing may be offset by value of slabs, if used for lagging. Reinforcement of round-timber sets is difficult and expensive. Sound fallen timber, and some trees of poor grade, or too small to go to the sawmill, often furnish adequate square-set timbers at reduced cost (219). SQUARE TIMBER is best for sills. In some round-timber stopes, square timber is used for the levels, manways, and chutes, to cheapen work of reinforcement.

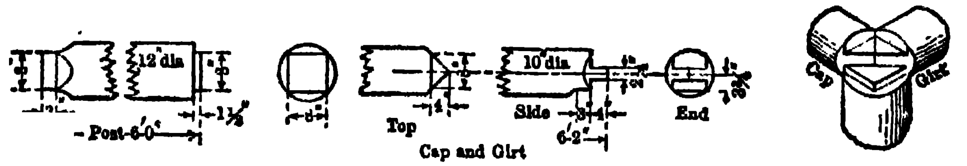

Fig 333. Chillagoe Mines, Queensland

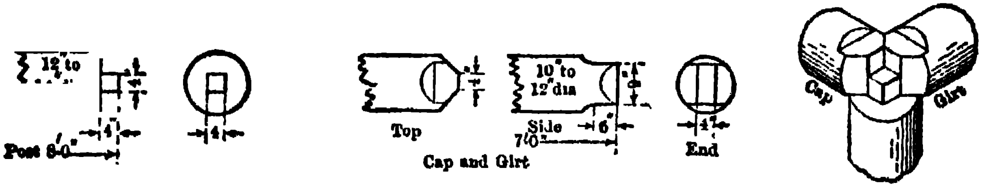

Fig 334. Chisholm District, Minn

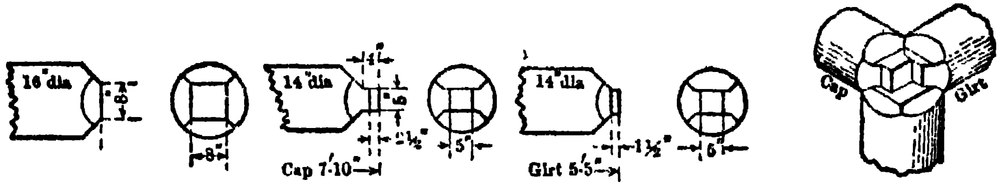

Fig 335. Brunton Bevel Set, Butte, Mont

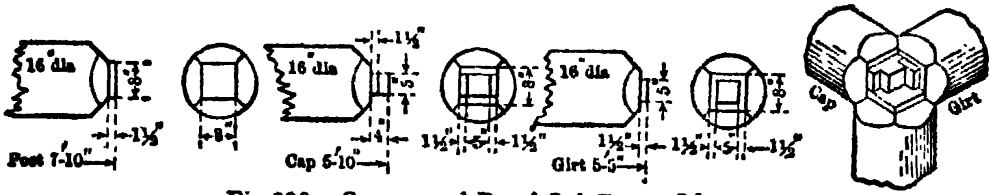

Fig 336. Square and Bevel Set, Butte, Mont

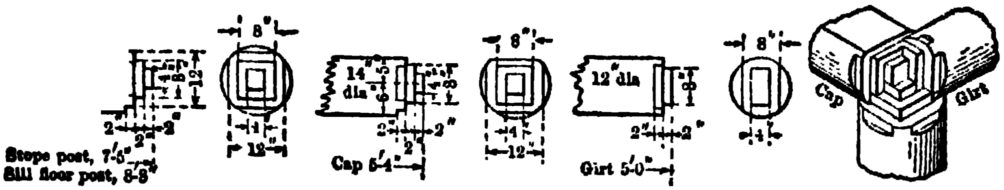

Fig 337. Step-down Framing, Anaconda, Butte, Mont

Square timber is preferred for chute-sets; it provides a flat face for spiking lining, and lasts longer in heavy ground than slabbed round timber.

P. B. Scotland states that round timber is stronger either with or across grain than square timber of same cross-sec and material. There are no data showing comparative strength of round and square timber of equal diam (*i e*, 10 in diam and 10 in square). A few transverse tests on 5-ft pieces of Texas pine at Morenci, Ariz, showed equal strength for pieces 8 in square and 8 in diam, but round timber deflected more and gave more warning of failure than square under same load. A safe estimate is that round timber between 6 and 16 in diam is as strong in both compression and bending as square timber 1 in smaller on the side. Nonobservance of this relation in substituting round for square timber destroys the saving effected by cheaper cost of the round.

Among 49 metal mines listed by Gardner and Vanderburg (189) in 1933, as employing the square-set system, 11 used round timber for all 3 members, and 10 others used round posts, with round girt or cap in 6 cases.

50. TIMBERING ON SILL FLOOR AND WALLS, SQUARE-SET STOPES

Sill-floor timbering (not always used) should be designed to give adequate foundation for the timbers above. Provision should be made for settlement, for reinforcing around traveling ways, for clearance between timbers at turnouts, and for supporting the timbering when the stope below breaks through. To meet these requirements practice varies with type of orebody, character of ore and walls, kind and size of stope, and speed of work.

Sills. Fig 338 shows a complete system, consisting of long sills (stringers), mortised at intervals to receive post tenons, and braced apart by sill-ties (girts, spreaders, or short sills). Long sills are also called 1-post, 2-post sills, etc, depending on number of posts they support. Sills are braced to stope walls by short pieces (butt-sills) cut to fit from sill-ties. Joints between long sills are usually made under posts, with butt or halved joints. For simpler framing, see Fig 339. Length of long sills depends on the ground; some ores will not stand unsupported over more than 1 set, thus requiring 1-post sills. In strong ground, convenience in handling determines max length, which usually covers 2 or 3 sets. Size of sills is from 5 by 10-in to 12 by 12-in or larger, depending on size of posts.

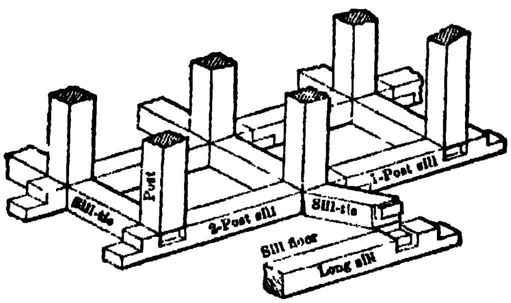

Fig 338. Sill-floor Timbering

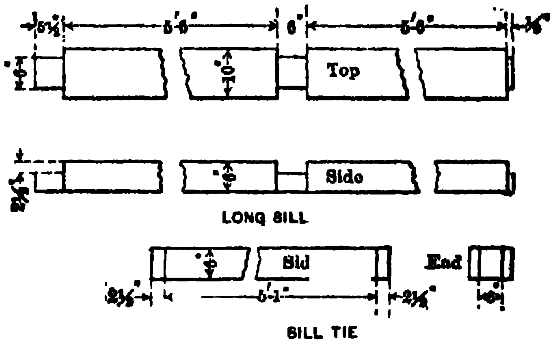

Fig 339. Sill Timbering, Homestake Mine

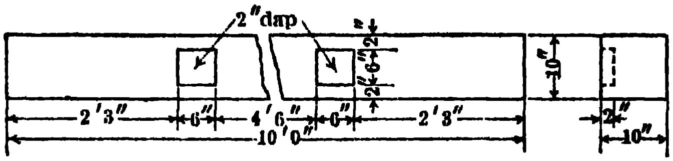
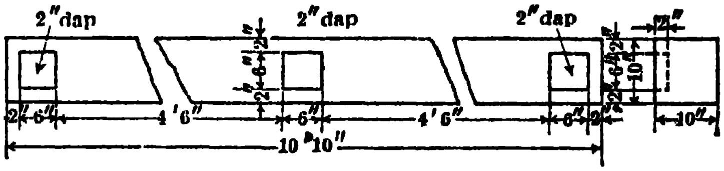
Long sills, firmly braced, are good in open stopes, where the floor is in ore. Sills extending over 2 or 3 sets will bridge a considerable opening, when the floor is subsequently mined, and are easily picked up on posts from stope timbering below. Framing for sill-ties (Fig 338) prevents them from dropping out when this work is going on. Wedging is relied upon to hold simpler framing (Fig 339). Sills distribute pressure and reduce settlement on a soft floor. In open stopes, sills are covered with plank or poles for shoveling. in filled stopes, a floor prevents runs of filling into stope below. Attempts have been made to set sills in line with corresponding sills on level above, but it is unnecessary, as stope timbers may swing 1 or 2 ft out of alinement before the level above is reached. Size of stope and speed of work should be adjusted so that sills will not rot before stope from below breaks through. See Bib (224) for replacement of rotted sills. Simple forms of sill often suffice. A 3-post sill of 5 by 10 timber is common for 10 by 10 posts, which have flat bottoms and are braced capwise by 2-in plank spiked on top of sills; light sprags brace the post and sill girtwise.



10"x 10" 2-Post Sill



10"x 10" 3-Post Sill

Fig 340. Details of Stope Sills, Bisbee, Aris

Examples. Bisbee, Aris (practice in 1939, contributed by H. M. Lavender). Timbering of sill-floor sets depends on nature of the ground. If floor is waste, flat-bottom posts are usual, resting on small blocks with 4 by 6-in spreaders between the posts. If floor is ore, to be mined from below, general practice is to use regular caps and girts; 2-, 3-, or 4-post caps, and posts supported on special " stope " or " mud " sills, of 10 by 10-in or 4 by 10-in timber, dapped 2 in deep to take the post's 6-in square horn. Length of sills is for 2, 3, or 4 posts, and 5- or 6-ft sets; Fig 340 shows sills for 2- and 3-post, 5-ft sets. In very soft ground, even though the floor is waste, regular caps and girts are used with the special sills, as they afford better foundation for the sets above. Goldfield, Nev. Sill-floor posts (10 by 10-in) have a flat bottom and stand on 8 by 10 sills; 2-in spreaders are

spiked to sills between posts, but there are no braces between sills. Lateral bracing for feet of posts is furnished by a floor of 2 layers of 2-in plank spiked to top of sills (145). Butte, Mont. Amalgamated Copper Co often omits sills (80). Flat-bottom posts stand directly on stope floor, or on foot-blocks; 4 by 10 spreaders brace feet of posts capwise, 2-in braces, girtwise. This practice is largely due to time required to level off rough points on stope floor, for placing sills properly. In some camps, sills are bedded on a layer of muck for quicker placing and because the muck protects them when the floor is mined from below. Floor is sheathed with poles or old plank laid across the spreaders. Filling is well compacted by the time the stope comes up from below, and this type of sill floor is picked up as readily as if sills were used. Sills are omitted under round-timber posts also, though the latter are then difficult to aline. G. D. Moulthrop (219) states that, with round timbers, sills are often of 2-in plank, set to grade with a carpenter's level and alined by plumb-bobs from centers of caps already in place. Sudbury, Ont. (Data from H. J. Mutz, in 1938.) International Nickel Co does not put framed sills under first-floor posts in Frood mine (Art 46). Where 4 by 10-in sills have been used under posts, they have been so badly squeezed as to offer no support during mining of underlying ore. Present practice (Fig 341) is to stand square-bottomed posts on solid ore, lay 4 by 10-in sills between rows of posts, and cover these with 2 layers of 2-in plank. There is no difficulty upon coming up under sill floors thus prepared.

Fig 341. Sill Flooring, Frood Mine, Sudbury, Ont

Sill-floor posts are often longer than standard stope posts if tramming ways are to be maintained within the sets (Fig 317–319 and 337). Posts should be long enough to afford enough headroom if settlement occurs, and to permit repair or reinforcement of timbers. Posts along tramming ways may be of greater cross-sec, or of stronger timber than stope posts. Generally, regular still-floor posts are used, and reinforced by added posts or doubling-up sets (Art 51). Such reinforcement is good insurance if there is possibility of excessive weight as stope progresses upward.

Drift sets with battered posts are sometimes used for sill floors in narrow or moderately wide veins, with heavy lateral press, as shown in Fig 342 (219). Posts are selected timbers, 14 to 23-in diam. The large batter (1 : 4) gives strength against side pressure and postpones repairs. False caps, placed over the set caps, receive sheeting on which the filling rests; space between sheeting and caps aids in repairing or replacing timbers.

At Leonard mine, Butte (Fig 343) (80), drifts, 1 set wide and sunk 1 set below stope floor, have been used. This simple plan reduces pressure on the level timbers, unless in very weak ore. Such stopes are somewhat harder to take up from below than those with flat floor. The level is called the sill floor, and the floor on which the stope is opened, the bedrock floor; sills are omitted on both. Sill-floor posts are 7 ft 11 in long and from 12-in diam up. Bedrock and stope posts are 7 ft 5 in long, 12 and 10-in diam, respectively. See also Argonaut mine, Fig 289.

Turnouts from main drifts into crosscuts require special timbering, to avoid short-radius track curves and for clearance between car and posts. At such points a double length cap (and sill) is used, with a flat-end post under its center. Later a truss set (Fig 356) may be built over the long cap and the post removed. At Bingham, Utah, an arch set (Fig 344), built on the sill floor, was used for reinforcing long caps (226). Its applicability depends on height and width of sets and size of car. Special timbering for turnouts is avoided by using turntables; most engineers prefer timbering.

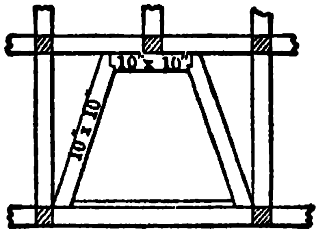

Fig 344. Arch Set at Turnout, Bingham, Utah

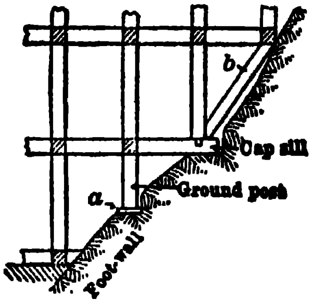

Fig 345. Timbering against Sloping Footwall

Timbering on walls. Standard sets are often impossible in mining along irregular walls of dipping orebodies. Square-sets must have firm support on the footwall and follow the hanging closely enough to allow proper blocking of timbers.

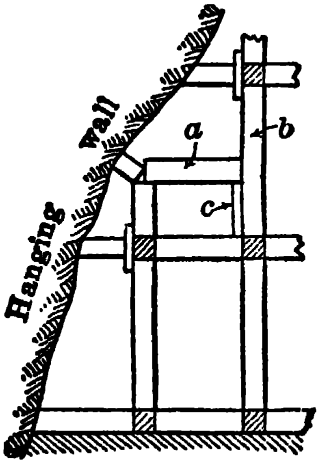

Fig 346. Timbering against Inclined Hanging Wall

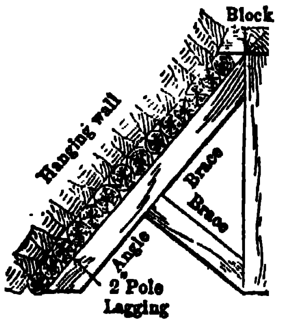

Fig 347. Angle Set (*E & M Jour*)

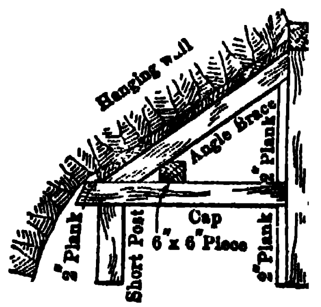

Fig 348. Half-angle Set(*E & M Jour*)

In firm ground, short posts, caps, or girts are used along the walls, with their ends in hitches or wedged against the rock. Short posts on the footwall are GROUND POSTS

(Fig 345). Use of the bearing block *a*, and depth of hitch depend on character of ground. Cap-sill (butt-cap or butt-brace) is used on flat dips or soft rock, to tie the foot of the post to stope timbers and distribute pressure from the post over a larger area than that of the ground post. Short sets are common on hanging-wall side. Fig 346 shows a form used by L. S. Cates at Bingham, Utah (211). Cap *a* is not framed into post *b*, but is spiked to it and supported by a piece of 2 by 8-in lagging *c*, spiked to *b*. Lateral motion of the cap is prevented by a brace of 2 pieces of 2 by 8 lagging, spiked in place and reaching to next set. In soft ground, a good but rather costly bearing for sets is secured by cutting into the walls far enough to allow use of full-size sets at points where the dip requires an offset in the floors. Angle sets (Fig 347), or half-angle sets (Fig 348), are for following the hanging wall and supporting lagging. Angle braces and sets may also be used to support sets on footwall (*b*, Fig 345). Details of wall timbering are varied locally. In open stopes, lagging may be used on either wall over areas of shelly ground. In close-filled stopes, area of walls exposed at one time is small, and lagging is rarely necessary. In block systems (Art 46) walls of blocks which will be exposed when adjacent block is mined are often lagged as the stope goes up, to prevent runs of filling; such lagging is often called "fencing."

51. REINFORCING SQUARE-SETS

Complete reinforcement was secured in the original Deidesheimer system by wall-plates and angle-braces (Fig 349). Some very large open stopes were thus made in soft ore. But no system of timbering will support heavy rock pressures for any length of time. Wall-plates and complete angle-bracing have been discarded because of their cost; also, bracing interferes with traveling ways and chutes.

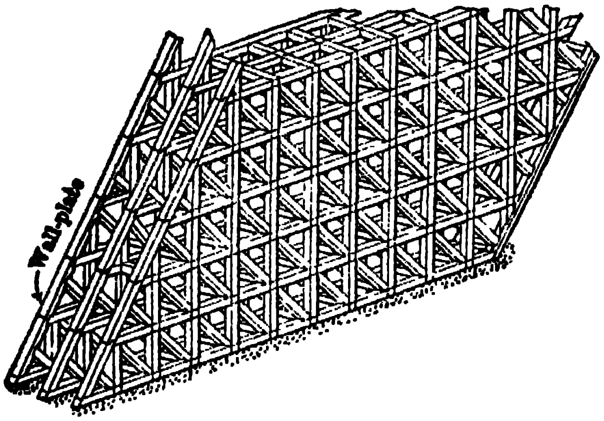

Fig 349. Complete Reinforcement, Deidesheimer System

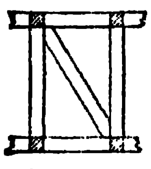
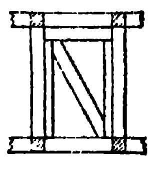
Modern practice in heavy ground regards the timbers as temporary supports, final support being furnished by filling, kept within 2 or 3 sets of the back. The need for costly reinforcement is further reduced by rapid working in stopes of small area. Even with these precautions, timbers fail or swing out of line and require reinforcement. Reinforcing timbers are common on sill floors, where haulageways must be kept open under heavy press from filling in stope above (Art 50). Reinforcement is used also in open square-set stopes in amounts varying widely with local conditions. When such stopes are in strong ground, the sets serve merely to support slabs, and as staging for miners and broken ore; in that case, no reinforcement may be needed.

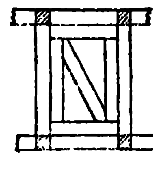
Angle-braces or diagonal braces (Fig 350), either round or square, have no tenons; thin wedges may be used to tighten them, but a driving fit is better.



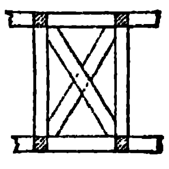
Angle-brace
Fig 350



N-frame brace
Fig 351



N-frame set
Fig 352



Diamond brace
Fig 353

Theoretically, the brace should be at right-angles to hanging wall; practically, this is impossible. Angle-braces applied to sets tending to swing out of line are effective only in cases of incipient distortion and light pressures. If used in the upper sets of open or filled stopes, they may cause caps or girts to "ride" off the posts when the sets above are unblocked by mining operations. Tenons on posts at the ends of an angle-brace must be strong. When timbers or joints begin to fail, modified braces may be used, as the N-frame brace (Fig 351) or the N-frame set (Fig 352). The X-frame, or diamond brace (Fig 353) is uncommon. Angle-braces are also used to take weight off a post showing signs of failure (*b*, Fig 356); this is good for reinforcing drift posts on sill floors, as it does not decrease cross-sec of traveling way. The same bracing, with post *b* omitted, is placed over long caps at turnouts, or, with the post *a* omitted, it will take the weight of stope filling off center post of a haulageway. Sets thus braced are truss-sets; their use on the 1st floor to relieve sill-floor timbering is uncommon, as it involves keeping 1st-floor sets open. Truss-sets also support stope floors, where a post is removed to allow an angling chute to pass.

Reinforcing posts, stulls, or helpers (Fig 354) are convenient for picking up failing ends of caps and girts; they are round or square; size, from a 2-in plank to a post.

Doubling-up sets (false sets) are 3 or 4-piece reinforcing sets, like the N-brace (Fig 351) and N-frame (Fig 352), with angle braces omitted. The timbers are usually of same size as set timbers, but joints are not framed. They may be used to stop distortion, instead of angle-braces; like the latter, they are inadequate for heavy pressure or bad cases of swinging.

Cribs and bulkheads, next to rock filling, afford strongest reinforcement. Cribs, of round or square timber, are built between the posts of sets (Fig 355). They may be of timbers only, or filled with rock. Bulkheads, of criss-crossed timbers, skin to skin, are stronger than open cribs, but cost more. When used in open stopes to arrest swinging or crushing, or to prevent runs of filling, the bulkheads or cribs extend from wall to wall and from floor to back. In close-filled stopes, trouble from swinging sets may be stopped by building one or more cribs 4 sets square, on top of the filled sets and rarely more than 2 or 3 sets high. Each layer of the crib is of 6 pieces equal in length to 2 sets. At Centennial-Eureka mine, Utah, continuous cribs, 1 set wide, were built at intervals of 5 to 10 sets to support a domed stope (Art 46), about 100 ft wide by 350 ft long; they were of 8 by 8 timber and required about 1 300 bd ft per set.

52. MISCELLANEOUS DETAILS OF SQUARE-SETS

Fire protection. Some disastrous mine fires have started in square-set stopes. Careless use of open lights and discarding of cigarette ends are common causes of fire; some mines prohibit smoking entirely or place limitations. Use of elec miners' lamps reduces the hazard. Clean, orderly stopes are safer from fire than disorderly ones. Filling reduces danger of fire spreading through square-set areas; but fire sometimes travels along lines of posts, caps, or girts even though surrounded by fill. Frood mine (Art 46) provides fire breaks by removing entire lines of girts concurrently with filling. Ability to control ventilation is essential feature for fire-control in any timbered mine.

Crowning floors. Trouble from settling of timbers is not serious in low or narrow stopes, nor where the dip is such that sets are repeatedly offset along the footwall. In high, wide, vert stopes, timbers settle considerably, and faster in middle of stope than along walls. These troubles increase with height of lift. Small movements are often met by SPECIAL POSTS, 1 or 2 in longer than regular stope posts and kept in readiness. At Morenci, Ariz, with block-system stoping, the sill floor of each block was arched or crowned to compensate settlement. Length of posts increased gradually towards middle of stope, where the posts were 2 in longer than those on the walls. Crowning was repeated in one of the upper floors as soon as the arch effect was lost.

Flirting posts. When sets are slightly distorted, a new post may sometimes be properly placed by cutting off part of the bottom horn, or cutting out the corresponding mortise; this is known as flirting posts. It is usually done more readily in cap-butting than in post-butting sets, because posts of the former have short horns (Art 49).

Blocking, if carefully done, materially reduces swinging of sets. It is also intended to crush under the initial creep of walls or back, thereby saving the main timbers. Sets should be blocked at joints, to avoid bending strains in timbers. If a long block (sprag) is necessary to reach a wall, it should have a headboard, so that the press will come onto the timbers through wood in cross grain. Good blocking is especially necessary over the posts at back of stope, as it alone holds the timbers when the side blocking is removed to make room for new sets. Sets on the floor alongside of an advancing face tend to " ride " toward the face, because the side blocking is blasted out on each round. Riding of sets is sometimes prevented by standing the posts with a slight pitch away from face; subsequent stoping tends to straighten them.

Recovery of square-set timber is rarely attempted. Where feasible, it points to the possibility of mining by some system requiring less timber. In NEW IDRIA mine, Cal (Art 46), timbers are

usually recovered from unfilled square-set stopes after mining is completed. At Frood mine (Art 46) long girts are recovered after filling each floor; primary purpose here is reduction of fire hazard, but saving in timber also results. At Calumet & Arizona mine, Ariz, some timber was formerly recovered from stopes in flat orebodies, mined in small sections. Recovery took place during the filling period, which was delayed until a section was completed. Each section was carried up as a flat-back stope 4 sets wide, and of height and length of the orebody. When finished, 6-in stulls, unframed and held by wedges, were placed diagonally between the middle points of caps or girts on 1st and 2nd and 2nd and 3rd floors (*a* and *b*, Fig 357). The corner sets of a floor required 2 stulls, each being set off center to avoid interference. Under their support, sill-floor timbers were removed from 3 rows of sets, *X*, *Y*, and *Z*. A girt was first taken out, by sawing it in two; remaining pieces were pried out with a bar or by using a drill column as a jack. Then sets *V* were lagged, filling was poured in through chutes *c* and *d*, stulls *a* were knocked out and replaced between 3rd and 4th floor timbers, and the process repeated. Some stulls were left in, if pressure were heavy. Top-floor timbers were removed under protection of vert posts set between the filling and back, and filling was packed under the roof by hand. A vert row of sets *V* was left on side of stope, to furnish a point of attack for adjacent block and a place to store recovered timbers, which were reused several times. Caps were run across stope, as 3 cross members were recovered for 2 longitudinal ones. Haulageways, sometimes run as blind levels from a raise, were required on top and bottom floors. This method was found applicable in irregular orebodies.

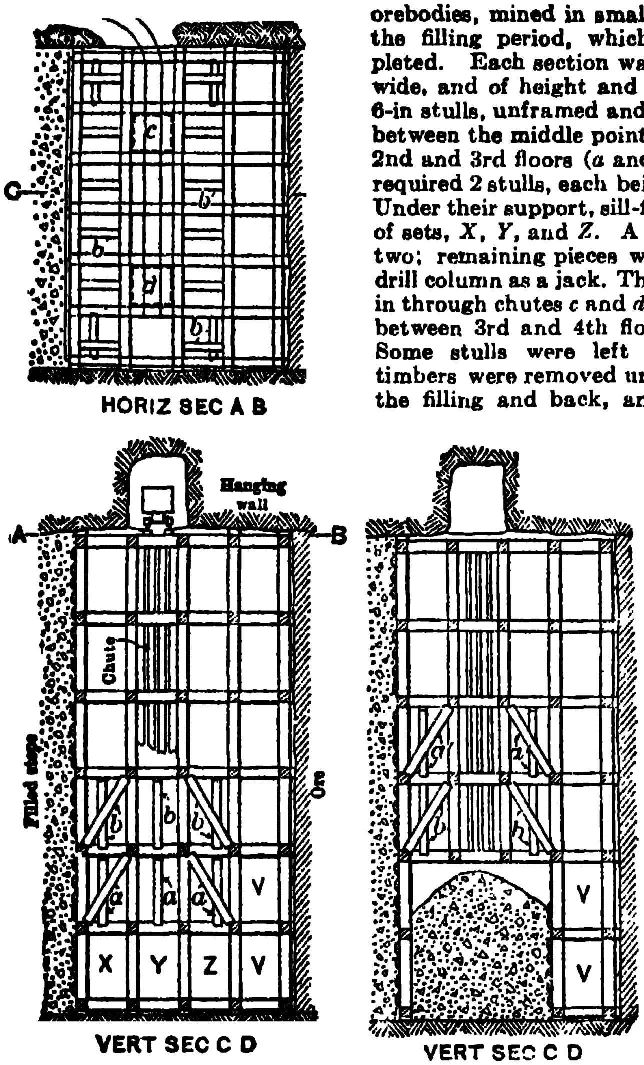

Fig 357. Recovering Timber from Square-set Stope

53. DATA ON SQUARE-SETS

To find total timber required in any stope, consider all sets as corner sets (1 post, 1 cap, 1 girt) and add posts, caps, and girts required along 1 wall and 1 end of the stope. Since amounts of timber used per ton vary with the specific gravity of the ore, figures per cu ft are better for making comparisons. Timber for floors, chutes, lagging, sill-floor sets, reinforcement, etc, is not included in Table 38; the amounts for these vary with size and form of stope. M. J. Elsing (213) estimates amount of timber for a set as stated in Table 37; posts 7 ft 2 in long, spaced 5 ft c-c both ways; aver number of pieces per set over a whole stope, 1.2 posts, 1.1 caps, 1.1 girts; size of posts and caps as stated; girts, 5 by 8 and 6 by 12 in; flooring used repeatedly. Elsing also records that square-set stopes in Copper Queen mine, in 1907, produced 565 600 tons of ore, required 31 400 sets, and consumed 8 950 000 cu ft of timber and 475 000 pcs of 5-ft lagging; or, 285 bd ft of timber and 15 bd ft of lagging per set yielding 18 tons of ore.

Table 37. Bd ft for a 5 by 5 by 7.17-ft Square-set

Size posts and caps	8″ by 8″	10″ by 10″	12″ by 12″
1.2 posts	51	80	115
1.1 caps	27	42	59
1.1 girts	19	21	30
Stope lagging	18	18	18
Chute lining	10	10	10
Blocking	7	11	16
Flooring (aver over its life)	2	2	2
Misc, wedges, breakage	9	11	13
Total bd ft	143	195	263

Examples following show wide variation, and indicate necessity for making liberal allowances in estimating total timber requirements. Morenci, Ariz. Approx total consumption was 15 bd ft per ton; a corner set, without reinforcement, took 8 bd ft per ton (178). At Cananea, Mex, a corner set requires about 8.4 bd ft per ton; total stope timber is 27 to 31 bd ft per ton. At Rossland, B C, about 100 bd ft of lumber was required per round-timber set for chutes, floors, ladders, and railings; aver diam of members, 16 in; a corner set contained 280 bd ft (209). BUTTE, Mont. W. B. Daly, in 1939, states that the amount of AUXILIARY TIMBER in a square-set stope depends on number of sets and width of stope. Where chutes and manways are 25 ft apart, general figures for the bd ft required for sets 5.33 ft square are: top lagging (3-in) for 1 set, 86; chute, 1 floor high (2-in lagging, 277; 3 by 10-in lumber, 84; 2 by 6-in lumber, 12), 400; manway, 1 floor high, 2-in lagging, 224; timber slide, 1 floor high, 53; total, 736 bd ft.

* These figures are for a corner set (1 post, 1 cap, and 1 girt). † Bd ft in round timber is computed by QUARTER-GIRTH RULE; area of cross-sec = 1.97 × square of radius, which gives cross-sec of largest square timber that can be sawed from a given log.

Data on framing. At ROSSLAND, B C, in 1903, round timbers averaging 16-in diam were framed by hand. Aver work for 1 carpenter per 9 hr was 21 posts, or 21 girts, or 16 caps. Cost per set was about 55¢ (wages, $3.50). Cost of same set, machine-framed, not over 30¢ (209). At HOMESTAKE MINE, So Dak, in 1903, some 12 by 12 timbers were framed by hand at 60¢ to 65¢ for a cap, girt, and post (wages, $3). Posts cost about 2¢ more than caps or girts. Costs indicate that 1 man framed 13 or 14 posts, or 14 to 16 caps or girts, per day (104). At SUDBURY, Ont, in 1938 (data from H. J. Mutz), 2 men with a single-end framer could make 170 posts, or 200 caps, or 300 girts in 8 hr. With a double-end framer, 3 men could frame 310 posts, or 500 girts, or 420 caps; while framing caps, 2 extra men were required for axe trimming.

Table 39. Machine Framing, Square-sets (Ibex Mine, Leadville, 1902)

Single-end, block-type machine, Denver Eng Wks	Posts 10 by 10-in, 6 ft long	Caps 10 by 10-in, 6 ft long	Drift posts 10 by 10-in, 6.5 ft long	Drift caps 10 by 12-in, 4 ft long	Sills, 6 by 8-in, 6 ft long	Raise cribbing, 4 by 8-in, 6 ft long	Wedges
No pieces framed	1 158	20	144	97	48	1 156	16 800
Total hr	68 25	2	6.75	8 75	2.5	24.75	28.75
Cost per piece, ¢	1 93	3 35	1 52	2 93	1 69	0.73	0.05

In a 166-hr run by above machine, delays were 0.75 hr. According to P. B. Scotland, a Denver Eng Wks double-end, block-type framer, used by Ariz Copper Co, run by 2 men, framed 160 round posts in 8 hr. Square caps and girts (Fig 328) were cut in a single-end framer; 2 men made 600 girts or 300 caps in 8 hr.

Erecting sets. P. B. Scotland stated, concerning mines of Ariz Copper Co, that aver duty of 2 men in placing and lagging stope sets was 2 to 3 sets per 8 hr. B. H. Dunshee stated from Butte, that, if a stope were ready to be timbered, 2 miners would place 4 posts, 2 caps, and 2 girts, block down and cover the top with lagging in about 1 hr. Ordinarily this work took 2 hr or more, as loose ground often had to be picked down or poorly fitting timbers adjusted. In FROOD MINE, Sudbury, Ont (data from H. J. Mutz, in 1938), 2 men can stand a square-set (1 post, 1 cap, 1 girt) in 1 hr. In a standard stope (Art 46), where usual blasting makes space for 5 sets per shift, remainder of 8-hr timbering shift is spent in scaling, extending booms, blocking and lagging the back, and laying floor for the 5 sets.

Miscellaneous. Mining on sill floor costs 2 to 3 times as much as on upper floors, even for contract work. Breaking is by flat holes, the face is not undercut, and shoveling is on a rough rock floor. At Leonard mine, Butte, a standard crew consists of 2 machine men (stope-drills), 3 or 4 shovelers, 1 man on filling, and timbermen and blockers who look after several stopes. This crew carries up a 25 by 50-ft stope, 100 ft in 4 or 5 months, or in 1 year to a height of 200 ft, extra time being required in the 2nd 100 ft for repairing and reinforcing timbers and for crowning floors (80).

54. APPLICABILITY AND LIMITATIONS OF SQUARE-SETS

In early days, square-setting was almost standard for underground mining of large orebodies in the U S. Later, increasing cost of timber, and introduction of shrinkage, filling, and caving systems narrowed its field of use. Square-set stoping is a comparatively high-cost method and therefore best applicable to high-grade ores. It is used where ground conditions require closely spaced support of ore or walls, as in soft ground, or in harder ground which sloughs or slabs; and as an adjunct to methods for recovering pillars.

Open stopes. Experience shows that open sets do not afford permanent support for weak ground; timbers rot, or more often crush under pressure caused by the extension of stoped areas. This is serious, as the caving of large stopes may set up a slow crushing action ("creep"), which extends into adjacent unmined blocks and renders their extraction difficult and costly. The field for open square-sets is in orebodies too wide for stulls, and where the ground is strong, but requires prompt support to prevent slabs falling from back and walls. These conditions preclude use of shrinkage stoping; the alternative is a filling method, the choice being governed by relative advantages of these systems, as stated below and in Art 66, and by their relative costs.

Filled stopes. Conditions jointly justifying complete filling for square-sets are. (*a*) necessity for permanent support of the surface or of overlying ground containing other orebodies; (*b*) weak ore requiring complete and immediate support of stope backs.

If subsidence can be allowed, some caving method is often cheaper than and preferable to square-setting; but caving methods are limited to certain types of orebody (Art 82). If temporary cribs and stulls will support the stope back, straight filling is usually better than square-setting. Choice is further governed by the advantages and disadvantages outlined below; see Art 46 for advantages of different forms of square-set stope.

As auxiliary to other methods, square-sets have a wide field of use (Art 68).

Advantages of square-setting, not covered above: (*a*) reliability; properly applied, it is dependable for mining almost any kind of ground; (*b*) safety, since the area of ground open at any time may be adjusted to its strength; (*c*) flexibility; stopes can be expanded or contracted at will, irregular stringers followed into walls at any point, dikes or waste inclusions left unmined, and prospecting drifts driven from any floor; (*d*) good facilities for sorting in stopes; important where ore must be separated from waste, sulphide from oxide ore, or smelting from concentrating ore; (*e*) good facilities for handling ore and supporting men in the stopes; (*f*) good ventilation; (*g*) walls alongside of old stopes can be mined if desired.

Disadvantages of square-setting, not covered above: (*a*) high cost, due to use of much framed timber of good grade; (*b*) danger of fire, which has occurred in nearly all large districts where the method is used. Fire risk is greater in open than in filled stopes (see Fire prevention, Art 52).

Summary. Notwithstanding its cost, square-setting is necessary and useful for certain types of orebody, and as an adjunct to other mining systems. Following practice tends to reduce costs (T B. Scotland): (*a*) use round timbers instead of square; (*b*) use second-class and smaller timbers where possible, instead of one size for all kinds of ground; (*c*) purchase logs partly seasoned, aver say 550 bd ft per ton; (*d*) accept mixed shipments, *i e*, ship as cut; (*e*) install slabbing saws and use slabs for lagging; (*f*) install mechanical devices for handling timbers on surface and underground; (*g*) frame at the lumber camp, thus reducing freight charges; (*h*) discard sills in all but soft, wet ground; (*i*) recognize the fact that accurate alinement of timbers is unnecessary, especially where filling closely follows mining.

55. MITCHELL SLICING SYSTEM (220, 228, 580)

This modification of square-setting was apparently first employed in mining soft hematite at Queen mine, Negaunee, Mich (136). It was further developed, in form described below, at Calumet & Arizona mine, Bisbee, Ariz, for mining flat, bedded bodies of heavy sulphide ore in limestone. Hanging wall was well defined and easily supported; orebodies contained little waste and rarely exceeded 50 or 60 ft thickness. Ordinary square-sets failed under the weight of soft, heavy ore. Mitchell system has also been successful at Magma mine, Superior, Ariz, in a steeply dipping sulphide vein, averaging 20–30 ft wide.

General plan is to mine by square-setting along the sides of a small block of ore; top of pillar thus formed is then mined, and hanging wall timbered. Under this protection, the rest of the pillar is sliced downward by underhand stoping.

Development. A main drift was driven, preferably along one wall of deposit; from it crosscuts (*c, c*, Fig 358), called slice-leads, were driven to opposite wall on 20-ft centers and timbered with sill-floor square-sets. A vert square-setted raise to level above, over first 2 sets of each slice-lead, served as a timber and manway, and later as a waste chute. On sill floor a small manway *a* gave access to manway side of raise on first floor. Small excavations, *E*, on sill-floor plan, were shot out at top of alternate sill-floor sets in slice-leads, and a chute built in each; these cuts were kept small and on same side of adjacent crosscuts, otherwise they weakened base of the pillar between 2 slice-leads. Cars could not always be run into slice-leads; if not, the first set alone served as a chute for loading cars in main drift. Two adjacent slice-leads were next carried to hanging wall, as flat-back square-set stopes, 1 set wide, called lead-stopes; broken ore formed its own slides to chutes; little mucking was necessary. This preliminary work cut out a pillar 15 ft wide; ordinary pillar lengths were 25 to 50 ft; greater lengths were mined as separate sections. Max vert height for safe mining was about 60 ft; heights of 100 ft were mined in two 50-ft sections, the upper one first (220).

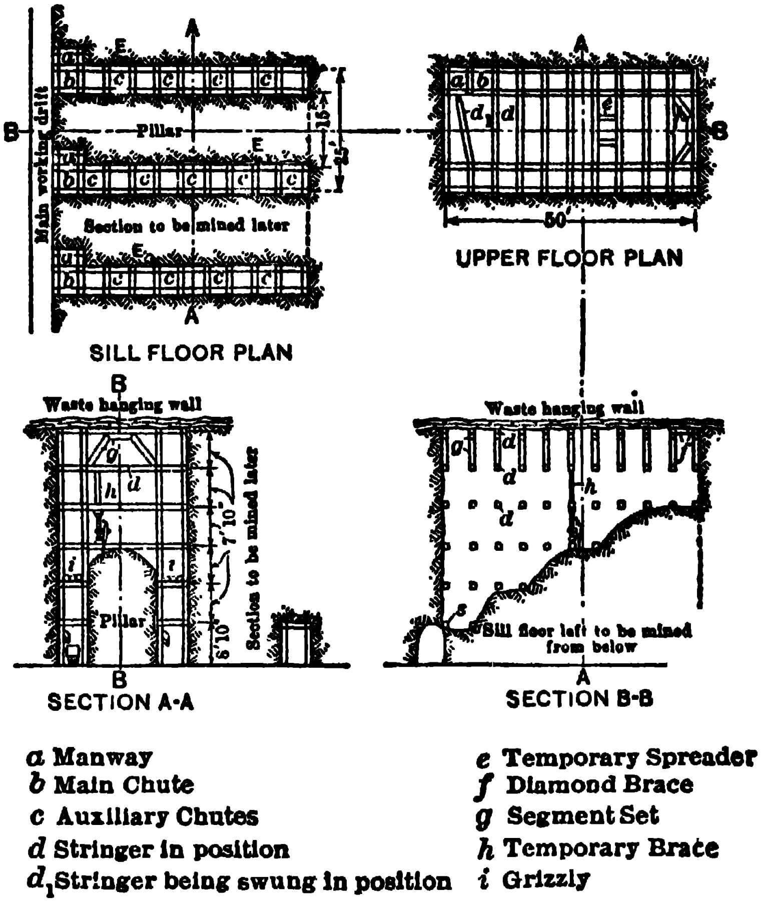

Fig 358. Mitchell Slicing System

Slicing began from the end set on top floor of a lead-stope, by drifting across the pillar to the corresponding set in opposite stope, directly under the hanging wall. Ore ran out by gravity through an inclined drift from each lead-stope to center of pillar; successive drifts were run until the whole top of the pillar was cut off.

Stringers (*d*, Fig 358) were placed under hanging wall as soon as there was room, with enough lagging and blocking to secure back of stope and timbers. A cut must be made in a lead-stope cap or girt at one end of stringer, for swinging its tenon into place (*B*, Fig 360). Topmost stringers were supported temporarily by stulls resting on the pillar. When enough ore was broken to allow placing stringers between next lower run of square-sets, stulls were replaced by 3-piece segment sets *gg*, of 10 by 10 timber (see *AA*, Fig 358). This braced the sets in lead-stopes and transmitted to them pressure from hanging. Rest of pillar was stoped underhand in successive slices. Most of broken ore was thrown into lead-stopes and chutes, little mucking being necessary until 1st floor was reached. Slicing was continued to 1st floor, leaving sill floor to be mined from below. A plank floor was then laid on top of bottom stringers *s*, the inside of the square-sets in both lead-stopes was covered with 2-in lagging and the stope was filled with waste through the raises to the level above. This left lead-stopes open and ready for attacking adjacent blocks.

Campbell mine, Phelps Dodge Corp. Data on 1939 practice from H. M. Lavender. Mitchell slicing system at Bisbee, Ariz, is practically limited to the Junction, Campbell, and Cole mines, for recovering ore left in pillars between cut-and-fill or square-set stopes. It is confined to mining ores that are fairly dry, stand reasonably well, are uniform in composition (contain little waste that must be sorted out), are free from very heavy top or lateral press, and do not require heavy blasting. Special development work is usually unnecessary; ore is extracted through same drifts and crosscuts used for adjacent stopes worked previously, and fill is introduced through existing drifts and crosscuts on level above. The pillars in one area in Campbell mine, the original sections of which have been mined by inclined cut-and-fill methods (Art 65), except a small part that was square-setted, are now being mined by Mitchell slicing. Following description, see Fig 359, covers operations in that area.

Orebody is roughly circular in section, about 200 ft diam, and has been extensively worked to a height slightly more than 100 ft. It was cut by drifts and crosscuts on the haulage level into blocks approx 50 by 70 ft, in roughly checkerboard fashion. The orebody, not uniform in strength and hardness, varied from a hard siliceous ore and siliceous massive sulphide to sugary pyrite and broken material alongside a weak porphyry wall.

The pillars being mined are usually 15–24 ft wide by 18–36 ft long; bounded on 3 or 4 sides by filled stopes, above by a firm hanging wall or filled stopes, and below by ore in place. Existing lines or " panels " of square-sets, along the long dimension of pillar and extending from bottom to top vertically, are used for extraction when possible. Square-sets are of 10 by 10-in timber, 8.5 ft high, with posts 6 ft c-c. In a few cases timbers were 8 by 8-in. In wider pillars, the old panels are lagged off, filled with waste, and new panels are set beside them. After the panels have been provided, 10 by 10-in grizzlies are installed on top floor. Alternate sets in the panel, both horiz and vert, are floored over (*p*, Fig 359), and act as ore passes. One set *r* at corner of the panel may be lagged off and left for a manway or to start a new section.

Actual mining is started on top floor, and the entire section is cut off to the hanging wall or to bottom of section above, if that section has been mined out. Where the hanging wall is not flat, one side of the stope may be carried higher than the other, and the top stringers are put in, blocked, and lagged. After top floor has been cut off, stringers *s*, 8 by 10 in or 8 by 8 in, are placed across the stope so that each corner of each exposed set in the panels is well braced. Framed stringers are used when they will fit the sets; otherwise, their ends are left square and held in place by planks scabbed to posts and caps. When enough ground has been removed, corresponding 10 by 10-in stringers are then installed on floor next below. Top floor is then lagged and the back secured by blocking if this has not already been done. Segment sets *t* (3-piece " doubling sets " framed in the stope as in Fig 359, 360) are then installed to transmit the top press from middle portion of the stringers more or less directly to the stope walls.

Mining is continued by underhand slicing; the grizzlies are moved downward as required. Temporary braces, made by notching 6-ft pieces of 2 by 12-in lagging, are placed between the stringers near blasts, or where stringers are bowing slightly, as at *b*, Fig 359. Bottom of stope is sloped toward the panels to minimize mucking, and, as shown, would also be sloped toward the manway, to give better support to the weaker end of the section next to the old filled stope. As mining descends, the solid end of the stope is lagged off vert outside of the end sets to protect men working below. It may be necessary to place angle braces *c* at either or both ends, to withstand the thrust of the adjoining filled stope or of ore in place. It is customary also to lag every third or fourth floor, as at *f*, for safety of men working below. If the stope should suddenly take weight, the entire stope may be waste-filled above the lagged floor, after which, mining is resumed with new segment sets. These operations continue down to first floor above the sill. Stringers, covered with lagging, are placed there, and waste-fill is introduced, at center of top floor, if possible, rather than from one end or corner. The panels are also filled with waste, unless they are to be used again. Most of the stringers and much flooring are salvaged as the stope is filled. The ground below the bottom stringers is left to be mined from below. In some cases the square-set below the segment set must be reinforced by a diagonal brace (*d* in Fig 359). If the wall is ore in place, instead of waste fill as shown, this diagonal may pass over the top of cap below, and rest in a hitch cut for it in the solid, which takes the weight independently of the lower square-set. Should a stope be shut down after being partially cut, it is important that the lowest stringers in place are not resting on the solid, as slight movement of the sets at either end will bend or break them.

Fig 361. Mitchell Slicing applied to Mining of Vert Pillars, United Verde Ext Mine, Jerome, Ariz

ADVANTAGES of the system, in general, are a saving in labor and timber as compared with square-sets. Special advantages are: obvious safety, rapidity of mining, and large tonnage per man-shift. The square-set panels at the side of a stope may be prepared in advance of actual mining needs. Direct STOPING COSTS, covering 25 000 tons from this area: labor, 44¢; explosives, 13¢; timber, 35¢; total 89¢ per ton. Output per man-shift, 14.44 tons. Wages for miners, $5.48, for muckers, $4.84. Comparisons between cost of mining by Mitchell slicing system and by square-setting are apt to be misleading, due to differing conditions under which the methods are used. However, recent direct costs of mining 17 000 tons by square-setting in the Bisbee mines were: labor, 65¢; explosives, 12¢; timber, 38¢; total, $1.15 per ton. Output per man-shift, 9.87 tons.

United Verde Ext mine, Jerome, Ariz. Mitchell system, as formerly applied to mining of vert pillars, was described by R. L. D'Arcy in 1930 (90). Orebody, now exhausted, was a large lens of high-grade copper sulphide ore; max length, 500 ft; max width, 300 ft. Level interval, generally 100 ft. Principal method of mining was a block system of square-setting, in which vert pillars, usually 6 sets wide, were left temporarily over main extraction drifts. These pillars were later found to be badly broken by movement, and so had to be mined in small sections. Fig 361 shows general plan. A small square-set section (2 sets wide and 3 sets long in Fig 361) was carried up to level above, the 2 end sets *B*, next to unmined ore, serving as chute and manway. Sets *C* are open sets of the adjacent previously mined square-set section. On completing a section, one of the outer sections alongside was removed by Mitchell slicing. Because of the broken nature of the pillar, the ore could frequently be barred down into the chute, without need of drilling or explosives. A series of 10 by 10-in stringers, braced as required, were placed between the square-sets and the old pillar fencing as mining progressed downward. The section was filled after completing mining, and the section on opposite side of the square-set stope was then mined and similarly filled. Thereafter all sets in the section were filled, except the chute and manway on the advancing side, these being kept open for access and introduction of fill to the next 3 sections (2, 3, and 4 in Fig 361).

56. MISCELLANEOUS TIMBERING SYSTEMS

Moore system (232) is a modification of square-setting, employed at one time in Tonopah Belmont mine, Nev, wherein the posts were replaced by diagonals in the vert plane of the caps. This formed a series of triangular frames, placed parallel to direction of max pressure and braced apart by girts at the joints (Fig 363). In Fig 362, a force applied at *M* resolves into components along lines *AC* and *AB*. Sets were designed on the principle that if a member *mn* fails, the force acting through it is taken by diagonals *mq* and *mp*; a corresponding failure in ordinary square-sets might cause collapse of several sets.

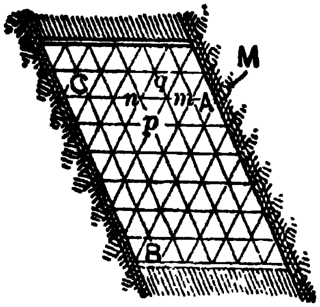

Fig 362. Diagram of Moore System

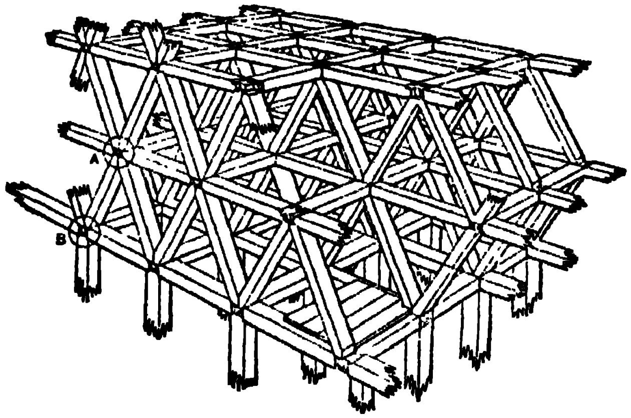

Fig 363. Moore System at Tonopah Belmont Mine

F. S. Bradshaw furnished Fig 363 to 365, showing details. Sets were 8 ft high, 7.5 ft capwise, and 5 ft 11 in girtwise. Diagonals were inclined 65° (theoretical angle should be the dip of

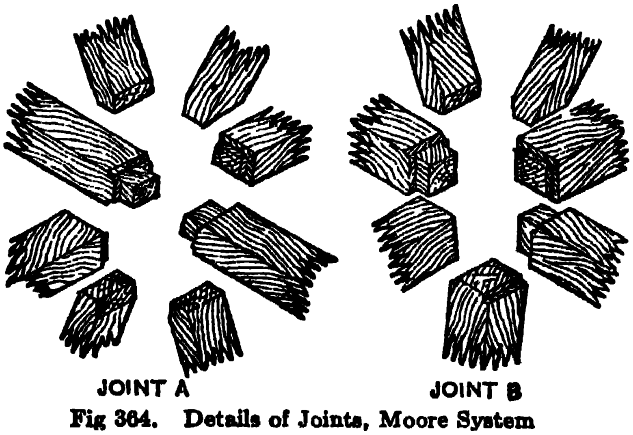

Fig 364. Details of Joints, Moore System

hanging wall, but is not practical; 65° is suitable for most cases). **Fig 363 shows framing of triangular sets and their junction with ordinary square-sets. Fig 364 shows joints *A* and *B*, Fig 363.** All timbers were placed flatwise in the set; caps were butted for convenience in framing; it is needless to make joints stronger in one direction than another. Drift sets were formed by substituting 10 by 10 vert posts for 2 diagonals on sill floor. Along vertical end faces of stopes a half-cap was put in on alternate floors, supported at wall end by a 4 by 10 upright. On inclined walls, the angle of diagonals could be changed to fit, or in strong ground ends of caps might be set in hitches.

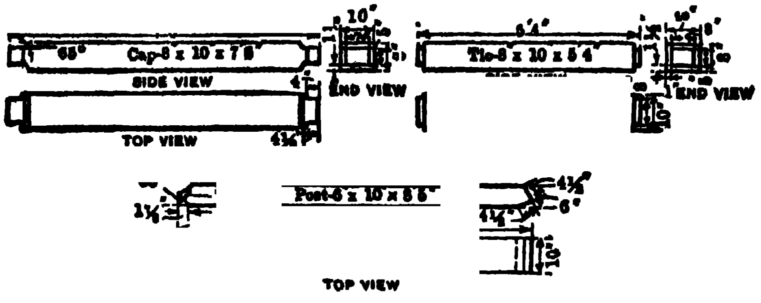

Fig 365. Details of Timbers, Moore System

Table 40. Comparison of Corner Sets

	Dimensions of set, center to center	Bd ft per corner set	Cu ft ore per set	Bd ft per cu ft	% timber across lode
Moore (cap, girt, 2 diags)..	7 ft 6 in by 5 ft 11 in by 8 ft	169.5	355	0.48	79
Square-set *........... ...	7 ft 6 in by 5 ft 11 in by 8 ft	161.1	355	0.45	78
Square-set †........... .	5 ft 4 in by 5 ft 4 in by 7 ft 10 in	137.7	222	0.62	77

* Corresponding to Moore set. † Ordinary set, 10 by 10 post and cap, 8 by 10 girt.

Under direct vert or horiz pressure, the strength of a Moore set (of 8 by 10 and 6 by 10 timbers) is about the same as that of a square-set of same dimensions with 10 by 10 cap and post and 8 by 10 girt. Under oblique stress, it is stronger, due to the triangular panels, but, to utilize this strength, joints must be held from swinging girtwise. Moore set has no advantage over square-sets of equal size, in either timber consumption or amount of timber placed in cross-frames; but the timber in cross-frames is better placed to resist distortion. Advantages claimed: (*a*) greater strength than square-sets for same amount of timber; (*b*) lighter timbers to handle; (*c*) on account of greater strength, filling is not required in some stopes, or where required it need not be kept so close to face; (*d*) flexibility, since the angles of diagonals can be varied; (*e*) drift set construction is very strong; (*f*) chutes can be run diagonally or vertically; in latter case, one dimension of chute is limited to about 3 ft in sets of the size shown.

Moore sets were used with some success at Tonopah Belmont mine, for dip of vein between 45° and 75°, and width of 15 ft or more. They were not well adapted to stopes where there was lateral movement of one vein wall with respect to the other, as they were not readily reinforced with angle braces. They were not adapted to running ground requiring close timbering, but rather to ground which would stand over full width of stope, 1 set long; hence, it was necessary to change from triangular to square-sets about 2 sets before reaching a level above. Cost of framing was slightly greater than for square-sets. Caps were framed in a single-end machine, after being cut to length by a swing crosscut saw, with same number of operations as square-set caps; bevel cuts were made by hand. Posts were framed by a swing saw, with one less operation than for square-set posts. Girts required same framing as for square-sets. With skilled men, cost of erection per ton of ore was no greater than for square-sets.

Inclined square-sets. A modified square-set, with posts at right angles to hanging wall, was formerly used at Calumet & Hecla mine, Mich, on dips of 35° to 40°. Object was to avoid oblique strains on timbering. The system was complicated and was abandoned in favor of stulls (Art 39) (20).

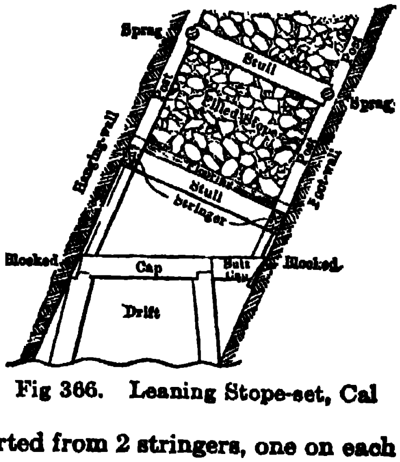

Fig 366. Leaning Stope-set, Cal

Leaning stope-sets (Fig 366) are sometimes used in narrow veins with soft walls affording no support for stulls. At Argonaut mine, Cal, they have been used instead of square-sets in stopes less than 16 ft wide (230). Advantage claimed was that posts could be set directly above each other. Dip of vein was such that square-sets could not be placed with posts superposed in the short time that the ground will hold. Stull timbering without posts would not hold; walls swelled and often required lagging. Round timber was used; posts were 8 ft long, and 4 ft apart along strike; joints between posts and stulls were braced longitudinally by unframed sprags. Stope timbering started from 2 stringers, one on each wall, blocked up from drift-set below, and separated by lagged stulls carrying filling. Swell of walls tightened timbers, so that they supported filling even when drift sets were destroyed by mining the chain pillar from stope below.

Stringer sets (formerly used in Ontario mine, Utah, in wide parts of a steep vein) consist of a horiz cap (STRINGER), from wall to wall, carried by posts 5 ft apart. Caps are braced by girts opposite posts. No framing was done, 60-d spikes being used at joints. Max length of stringer, 16 ft; for wider stopes, 2 stringers were butted, with a post under the joint. These sets suited the solid quartzite walls at Ontario mine, but gave trouble when tried in weaker ground elsewhere. They require nearly as much timber as square-sets, and as much labor, when latter are framed by machine.

Similar timbering, called STULL SETS, is used in the Cœur d'Alene district, Idaho. Fig 367 shows practice at MORNING MINE (231). Wall rock swells, causing side pressure great enough to broom out the ends of 24-in red fir caps, which are therefore protected by soft-wood blocking. At HECLA mine (data from C. H. Foreman in 1930), caps of stull sets are at 5-ft horiz and 9-ft vert intervals (223). Max length of cap that can be handled is 16 ft; sometimes 2, rarely 3, caps, placed end-to-end, are necessary to span stope. Head blocks are about 12 in thick, of 3-in by 5-ft boards of random width. For mode of recovering a caved stope at this mine, see Art 57.

57. RECOVERY OF CAVED STOPES

General. Caving of stopes may be caused by: (*a*) attempting to mine blocks of too large an area; (*b*) failure to block sets properly, or reinforce them prior to blasting; (*c*) failure to keep fill close enough to back; (*d*) destruction of timber by fire; (*e*) abandonment of stope for a considerable time. After a cave, special timbering may be needed to reclaim the caved ore and so to control the stope that regular methods may be resumed.

Usual method of attack is to start at one side and, if possible, on top of the cave, placing supports under the solid back before removing the caved ground. Unnecessary breaking or shaking of the back should be avoided. Selection of mode of recovery depends on: (*a*) dimensions of stope; (*b*) normal method of mining; (*c*) manner in which the back is caved and amount of arching that has occurred (see Subsidence, Art 112–116).

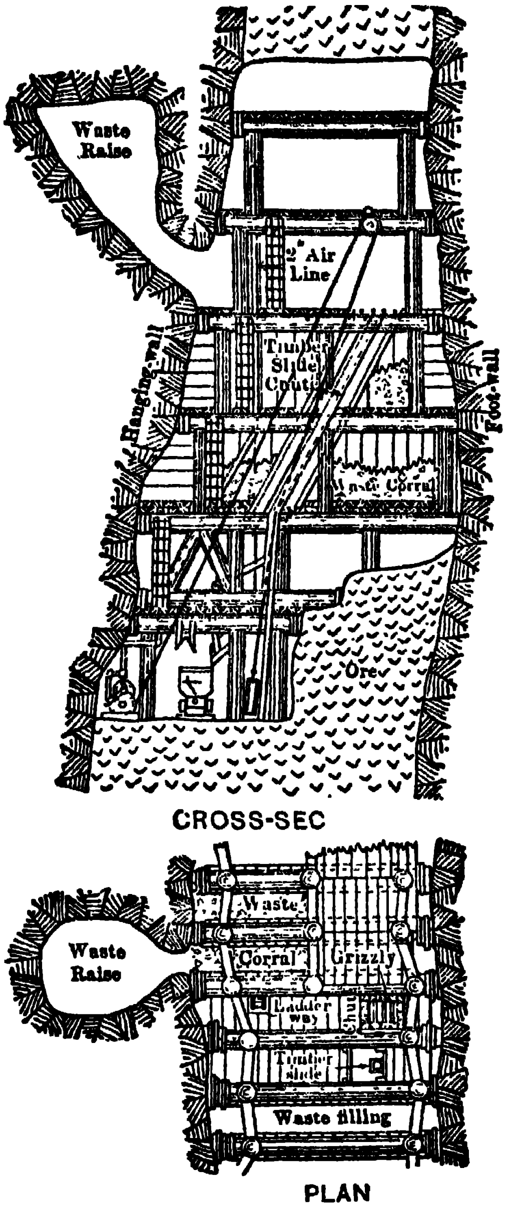

Fig 367. Stope Timbering, Morning Mine, Idaho

Examples follow of practice in recovering square-set and stull-set stopes.

Butte, Mont. H. L. Bicknell in 1922 (534) gives method in wide square-set stopes. Where back over cave is approx horiz, underhand square-setting as in Art 46 (Fig 305, 306) is started from nearest open set on the floor just below the cave, but using 2 booms instead of one. Booms 10 by 10 or 12 in by 9.5 ft are placed below the caps and between the posts of the open set, and extended into caved area (Fig 368). The booms are supported by 2 posts under the lead cap, with 4-in blocks between booms and caps. Next to the 4-in blocks on forward end of the boom is laid 4 by 10-in lagging *L*, to support the 2 girts. Caps and girts are then placed and held in position by cross lacing to the sets already in. The back above the set is then steadied by sprags, blocking or cribbing. Enough caved ground is removed to repeat the operation in next set below, and posts between the 2 sets are placed and fastened to the existing sets. The sets are thus carried down the face of the cave to the standing sets below. Successive vert rows of sets alongside the first are then similarly worked down, until the entire face has advanced 1 set into the cave. This work continues until whole stope is recovered. The same general method is used in narrow square-set stopes.

Fig 369 shows a square-set where a cave left the solid back of vein sloping up at a steep angle from the undisturbed timbers. The caved ore was too high above the timber to start a boom-set until space was made ahead of the highest set *C* by spiling (Sec 6). The top spiling was driven first, then side spiling starting at the top; breast boards were placed between ends of side spiling, to prevent caved material from running into space below. Under protection of the spiling, the top booms were placed and blocked, also the upper caps and girts; top spiling was then blocked or cribbed to back. Part of the broken rock below was removed, and booms *F* were placed supporting the cap, girts, and posts on floor below. Fig 369 shows this work starting next to one of the walls; after 2 sets are in, those alongside were placed in order until opposite wall was reached. Meanwhile the posts between standing sets below and the sets resting on the booms were put in, and all timbers blocked to walls. Then a start was made on floor *G* of the raise, and the brow of rock between raise and cave was removed by barring or light blasting. Sets between raise and cave were timbered and blocked to the back above. Work continued over sets *C* and *D*, and in advance of them using spiling to make room for boom-sets.

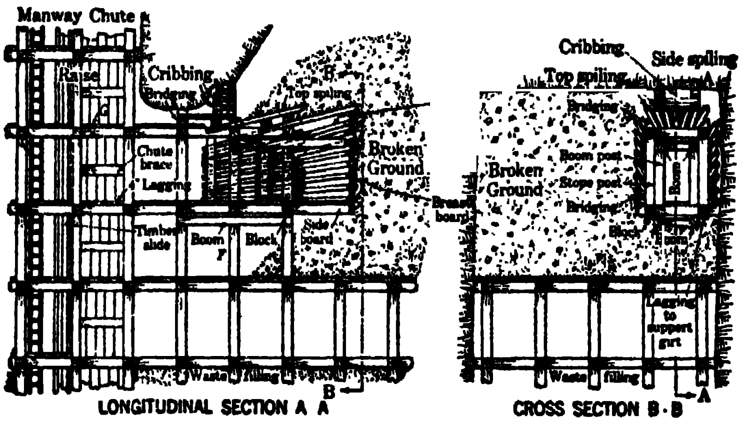

Fig 369. Recovering Square-set Stope, Butte, Mont (534)

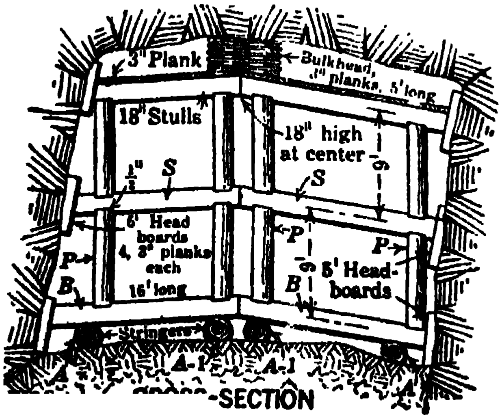

Fig 370

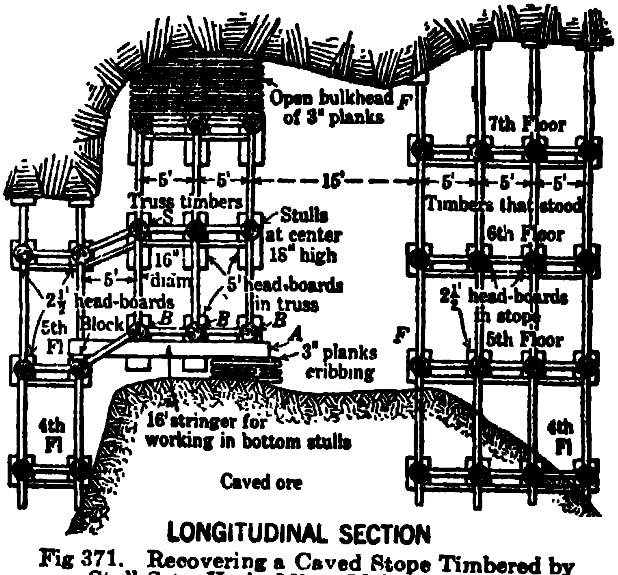

Fig 371. Recovering a Caved Stope Timbered by Stull Sets, Hecla Mine, Idaho (581)

Hecla mine, Cœur d'Alene, Idaho. Data from Ç. T. Rice in 1918 (581). Stull sets are used for mining (Art 56). Caved stopes are recovered as shown in Fig 370 and 371. Work is started from highest standing timber; 4 stringers *A* (Fig 371) 16 ft long, slabbed top and bottom, are laid parallel to the walls, one end being supported by the standing stope timber, the other by the caved material. Stringers *A*–1 (Fig 370) are blocked up 6–18 in higher than the outside stringers *A*. Three pairs of stulls *B* are placed at 5-ft centers and 5 ft from last standing stull. The raised stringers *A*–1 make each pair of stulls form a flat saddleback (Art 38, Fig 229). Head-blocking of 3-in plank is used in each wall (Fig 370) and temporarily wedged. Posts *P* are then stood in 0.5-in daps cut into the stulls. A second series of stulls *S* is placed, blocked and braced girtwise to prevent swinging. Other stull sets are placed above, until the timbers are high enough to permit building a cribbed bulkhead between them and the back, after which the whole structure is tightened evenly with wedges. In the case in Fig 371, the remaining 15 ft of open stope was similarly timbered, starting from standing timbers *F*, *F*. The back was then picked down, ore drawn, stope filled with waste, and mining resumed (581).

58. PRESERVATIVE TREATMENT OF MINE TIMBER

General. Data from Bib (585, 586, 587, 588). Preservative treatment, by method most common at mines, adds about 30% to initial cost of timber; hence should be confined to that timber, estimated at 15–20% of all consumed, which is desired to outlast the normal life of untreated timber; latter may be as short as 1 yr; aver, 2–4 yr, rarely reaching 5–10 yr. Properly treated mine timber may be expected to resist decay for at least 15 yr; in a Penn anthracite mine, gangway posts treated with $ZnCl_2$ by open-tank method in 1906 were still sound and retained ample margin of protection in 1931, whereas adjacent untreated posts had all failed within 4 yr. Knowing the life of untreated timber under given conditions, and costs (in place) of timber treated and untreated, and estimating life required of treated timber, the respective annual charges (excluding cost of replacements, but providing for amortization of first cost) can be compared by applying the formula: $A = \frac{Pr(1+r)^n}{(1+r)^n - 1}$, where A = annual charge; P = initial cost, in place; r = interest rate, expressed as decimal; n = life, in years. CHIEF BENEFITS OF TREATMENT: (1) saving replacements, each of which usually costs 50–100% more than initial erection; some timber, as sill flooring and fencing in filled stopes of a block system (Art 46) can not be replaced and its failure causes trouble when mining adjoining blocks or pillars; (2) permits use of smaller timbers for a given load, since safety factor need make no allowance for loss of strength by decay (treatment itself has no effect on strength of timber); (3) a cheap, local wood of suitable strength, but prone to rot, may be substituted (after treatment) for more expensive timber; (4) where the mining method permits salvaging timber for re-use, resistance to rot is an obvious advantage. TIMBERS MOST ADVANTAGEOUSLY TREATED: (1) framed sets in shafts and haulageways required to stay open, say, 4 yr or more; (2) stringers supporting chute bottoms; (3) chutes and pockets, especially in dead ends; (4) cribbing in all permanent manways; (5) fence posts and lagging in filled stopes of block systems; (6) sills and flooring on sill floors in filled stopes above blocks of ore to be recovered later; (7) shaft guides (especially subject to rot at joints and bolt holes).

Cause and prevention of decay. Fungi causing decay grow inside of wood; visible parts are fruits, discharging spores which may be carried by air currents if not transmitted to adjoining timbers by direct contact. Growth is possible between about 40° and 100° F, is most vigorous at 70°–90° F, and is promoted by moisture; continuously dry or completely wet timber is immune; a post with one end in water is very susceptible. Wood can be sterilized by heat alone, at 150° F, but retention of a chemical antiseptic to depth of 0.5–2 in is required to prevent re-infection and the growth of fungi. Among numerous compounds and mixtures, $ZnCl_2$ has proved best adapted for treatment of mine timbers, its only drawback being possible leaching out of the wood in very wet places; usually this objection is slight. Minimum amount of $ZnCl_2$ is 0.35% by wt, or about 0.12 lb per cu ft for most woods; common specifications are 0.5–0.75 lb per cu ft, up to 1 lb for wet places. In Rand gold mines, $ZnSO_4$ (a cheap byproduct of cyanide plant refineries) is used, with addition of NaF and dinitrophenol. Large Nova Scotia coal mines submerge props in hot, strong solution of common salt; satisfactory results are probably due as much to the heating as to the salt. Creosoted timbers, though more lasting in resistance (also more expensive) and better suited for wet places, are nasty to handle; their added inflammability can be almost completely overcome by 6 mo seasoning after treatment, but fumes from burning creosote are dangerous, and its normal odor can arouse suspicion of a smouldering fire. Round timber must always be peeled, and framed or dimensioned timbers should be completely shaped, including bolt holes, if any, before treatment; new surfaces of any subsequent cutting may be painted with preservative with some slight advantage. Green timber is regularly treated, but results are best with timber seasoned as rapidly as possible without causing severe checking; the sooner the moisture in sapwood is reduced to below 20%, the less chance for infection before treatment.

Open-tank or hot- and cold-tank process is simplest and cheapest to install (a plant for $ZnCl_2$ treatment of 1 000 props per yr costs about $1 000), but is slower in operation and is best limited to round and seasoned timbers. In almost all woods, except hemlock and spruce, sapwood absorbs solution faster than heartwood, whence open-tank treatment may give a round stick all the penetration required. Wood is submerged in solution and heated to 175°–180° F (never over 200°) for 1–2 hr by direct heat of fire or steam coils. Expansion causes most of the air (of which dry wood may contain up to 50% by vol) to escape. Upon cooling while still submerged, either in same tank after withdrawing heat or in another tank filled with cold solution to which the wood is quickly transferred, solution is drawn into cells by contraction of air remaining in them. When cool, wood is stacked for drying. Suitable strengths of solution are same as for pressure treatment.

Pressure or closed-tank system is good for all sawn timber and, in general, whenever the desired output demands speed; pressure method gives the same or better results than open-tank in about 1/3 the time. Green timber can be well treated only in closed tanks. Rate of treatment is slower with round than with squared timber, as a smaller volume of rounds can be packed into a given tank. A small pressure-tank plant, to treat 5 000 props per yr, costs $10 000–$15 000. ESSENTIAL EQUIPMENT includes: (*a*) horiz, cyl tank with hinged or removable door at one end, with gasket and bolts for tight closure; in small tanks, the wood may be inserted and withdrawn in individual pieces; larger tanks usually have rails for receiving trucks loaded with timber. Tank contains steam-heating coils, and inlets for live steam, comp-air, suction, and solution, and outlet for return of latter; also vents at top and bottom, controlled by valves; (*b*) tanks for mixing, storing, and measuring solution, latter equipped with some form of calibrated volume indicator; (*c*) air compressor, vacuum pump, and pumps for transferring and applying press to solution (which may be done by comp air); (*d*) steam boiler. USUAL PROCEDURE: (1) admit live steam, avoiding temp above 250° F; with seasoned timber, this step may be omitted; for green timber, it is essential, and may require 1–4 hr; (2) drain tank and apply suction (20-in or better) for 0.5–1 hr; (3) admit solution, containing 3–5% $ZnCl_2$, and apply press of 150–180 lb per sq in, heating with steam coil, and continuing until the previously calculated vol of solution to give desired penetration or desired wt of $ZnCl_2$ per cu ft of timber (examples below) has been absorbed, as indicated by the measuring tank; (4) return solution to storage tank, by comp air or pump; (5) apply suction for 0.5 hr to extract excess solution; (6) remove timber and store for drying, preferably about 6 mo.

Examples. INSPIRATION MINE, Ariz (586) consumes about 10 450 M bd ft of timber per yr, mainly sawn Douglas fir, on which freight constitutes over half the delivered cost. Plant for $ZnCl_2$ press treatment, designed and erected by mine employes, began operation in Jan, 1930, and in 11 mo treated 522 430 bd ft, working 1 shift with 1 operator and laborers for loading and unloading trucks. Typical charge of 162 cu ft was impregnated to depth of 2 in, or with 0.6 lb $ZnCl_2$ per cu ft (using sol of 4.7% strength) in 3 hr over all. In dry, summer weather, preliminary steaming and evacuation were omitted, without affecting results. Treated timber is given 6 mo to dry. UNITED VERDE MINE, Jerome, Ariz (587), consuming 8 700 M bd ft of timber in 1929 (about 75% local pine, remainder Oregon pine), is generally well ventilated and decay is not excessive. Chief difficulties have occurred in fencing and flooring square-set filled stopes, some of which are not finished in less than 10 yr, and for which nearly half of all timber is used. Plant for $ZnCl_2$ press treatment of 1 000 M bd ft per yr was finished in May, 1929, at cost of $12 184, and in succeeding 7 mo treated 882.6 M bd ft (or 17% of all consumed in same period) at following cost, per M bd ft: labor (1 operator, 2 helpers), $3.980; power, $0.020, steam, $1.349; $ZnCl_2$ (@ $5.34 per cwt), $2.710; misc supplies, $0.394; repairs, $0.547; total, $9.00. Press tank, 5.5 ft diam by 32 ft long, treats aver charge of 3 700 bd ft in 8 hr (sometimes 3 charges in 2 shifts), never allowing more than 3 hr for impregnation at 180-lb press, sol contains 3% $ZnCl_2$, vol is calculated to give penetration of 0.75 in for heavy timbers, 3/8 in for lagging and flooring, corresponding to aver 0.61 lb $ZnCl_2$ per cu ft. HOLLINGER MINE, Timmins, Ont (588) finished $ZnCl_2$ press plant at mid-1934 and in next 6 mo treated 2 500 M bd ft, both green and seasoned, or all timber except lagging, track ties, and stulls. Consumption of $ZnCl_2$ (applied in 5% sol) averaged 0.53 lb per cu ft, with penetrations of 2–2.5 in at 150-lb press. Tank is 50 ft long and takes 700 cu ft of timber. Total time per charge: spruce, 4 hr; dry, sawn lumber, 2.5 hr, B C fir, 7–8 hr. COMMERCIAL TREATMENT PLANTS are located in many lumber centers and offer advantages to small mines not equipped to treat their own timber. Orders and specifications should be placed as long in advance as possible (say, 6 mo), to insure adequate seasoning before and after treatment. As a rule, specifications as to $ZnCl_2$ content and penetration for mine timbers may be less rigorous than for RR and structural timber, and price should be shaded accordingly. In southern Ill coal field in 1932, cost for treating with 0.5 lb $ZnCl_2$ per cu ft was 12¢ for sawn and 16¢ for round timber, per cu ft. For advice on this and related subjects, the Service Bureau of Amer Wood-Preservers' Assoc, Chicago, Ill, may be consulted.

FILLED STOPES

59. GENERAL

Definitions and general plan. Filled stope, as term is used here, is one in which: (*a*) support for walls and men and, at times, for back of ore is furnished by waste rock, tailing or sand, which materials are called filling or gob; (*b*) filling is an integral part of stoping; generally the orebody is excavated in small sections, filled wholly or in part before adjacent ground is attacked; (*c*) excepting the crosscut method (Art 64) use of timber, if any, is for temporary support of slabs or back and is not systematic as in square-set stopes (Art 46, 47). Most filled stoping is done in overhand flat-back, stepped-face or rill stopes (Art 38). Surface of fill is kept roughly parallel to stope back. As the stope progresses upward, chutes (usually of timber) are carried up through the fill, giving access to the stope and delivering broken ore to level below. Height of section mined before filling depends on character of ore and walls; details vary with size and shape of stope and source of filling; modes of arranging haulage ways and of mining level pillars vary with strength of walls and ore and width of orebody; for examples see following articles. In overhand filled stopes, the operations of breaking or cutting a slice from back of stope, and then filling the excavated area, have led to the wide use of the term cut-and-fill. A flat-back filled stope is called a horiz cut-and-fill stope; a filled rill stope, an inclined cut-and-fill stope; these terms are used in the following articles. The term filled stope is also applied to a stope mined by some other method and then filled with waste to prevent caving or subsidence. This is delayed filling, and may be used in open, shrinkage, or timbered stopes after completion; such work is described by adding the words " with delayed filling " to name of stoping method used, for example shrinkage stoping with delayed filling. Examples of delayed filling in different forms of stope are: Hollinger, Wright-Hargreaves, Coronado, and Homestake mines, Art 68; Horne mine, Art 43; Calumet & Arizona, Art 52; New Jersey Zinc, Golden Queen, and Carson Hill mines, Art 87.

Source of filling. Usually, cheapest filling is waste rock, unavoidably broken with the ore, which is sorted out in the stope (Art 60); amounts of waste produced by sorting are usually insufficient, and must be supplemented by other material.

Excess filling may be supplied by: (*a*) Shooting down walls of lode; this obtains filling with little or no handling, and is feasible if wall rock is strong; in weak rock, such excavations expose a strip of unsafe ground alongside of ore in back of stope (see Resuing, Art 61). (*b*) Driving crosscuts into walls; the waste produced is distributed in stope by barrows, cars or scrapers (Sec 27). Inclined raises in walls serve same purpose, discharging filling into the stope by gravity (Nevada Wonder mine, Art 60). Crosscuts and raises serve to prospect the walls, and hence are preferable for obtaining filling where parallel stringers are apt to occur. Methods (*a*) and (*b*) are used mostly in flat-back stopes, for relatively small amounts of filling required in excess of that from sorting. (*c*) Using waste brought from surface; it may consist of mill tailing, sand, or waste rock which can be broken cheaply in an open cut. Such filling, usually sent underground through filling or waste raises, is transported laterally along levels in cars (occasionally by belt conveyers) and dumped through raises into the stopes. Fig 372 shows mode of obtaining waste rock at Los Pilares mine, Nacosari, Mex (150). Glory-holes (Art 99) were opened in barren ground on the surface around raises *R*, which were 15 ft sq. Rock was broken with deep holes and heavy charges, and fell by gravity into the raise, at bottom of which was an offset connecting with drift *T*, and main waste raise *W*. Top of *W* was covered by

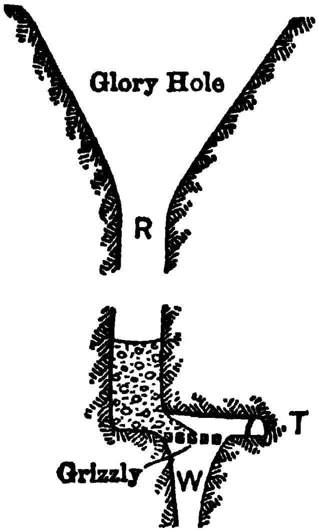

Fig 372

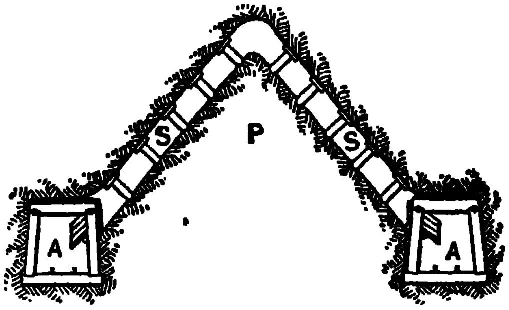

Fig 373. Caving for Waste. Diagrammatic Cross-sec

a grizzly of heavy timbers 18 in apart, faced with steel, on which large boulders were broken. These raises terminated in bins, from which waste was distributed to stopes by electric haulage. There are many similar plans for obtaining waste for filling. Old dumps may sometimes be utilized by driving drifts and raises under them. (*d*) Utilizing waste from development work, thus saving or reducing cost of hoisting it; this is an important element in planning effic work in large-scale mining with numerous filled stopes and extensive exploratory and development work, as at Bisbee, Ariz. (*e*) "Caving for waste." Under proper conditions, this gives cheap filling. Two parallel timbered drifts *A* (Fig 373) are driven in country rock at a safe distance from the mine workings. Inclined stopes *S*, 3.5 to 4 ft wide and timbered with stulls, leave a V-shaped pillar *P* between the drifts. Chute gates (Art 90) are erected in drifts, say 6 or 8 ft apart. By blasting out the stulls, the back of *S* caves and the material is drawn as needed into cars. Obviously this method is feasible only in rock which will cave when thus undermined (259). Waste filling for Frood mine, Sudbury, Ont, is supplied by drawing caved hanging-wall rock from nearby Creighton mine (Art 68). At McIntyre mine, Schumacher, Ont (171), a large block of wall rock near the orebody is mined by sub-level stoping as source of waste supply (Art 43). (*f*) Drawing filling from upper stopes and reusing it in lower ones: feasible where it is unnecessary to support walls of orebody permanently. Allowance for swell of broken rock must be made in estimating cost and amount of filling material.

Other details as to filled stopes: see Art 60 to 65.

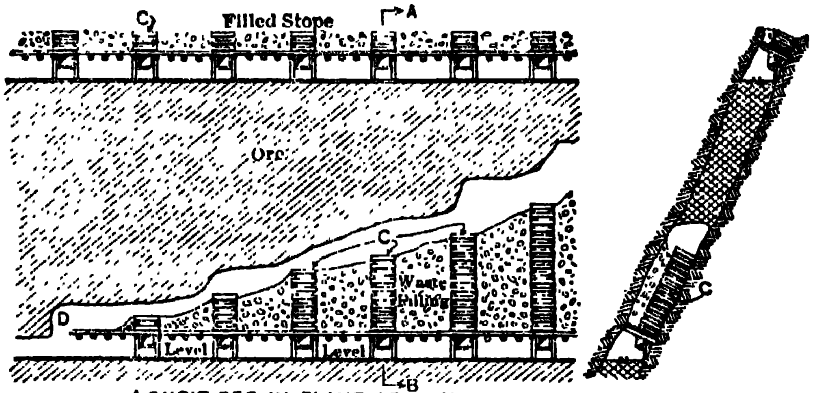
60. FILLED FLAT-BACK AND STEPPED-FACE OVERHAND STOPES OR HORIZONTAL CUT-AND-FILL STOPES, NARROW VEINS

Suitable orebodies are steep-dipping veins of strong ore, up to 15 or 20 ft wide; walls may be either weak or strong (Art 66).

Development follows practice in narrow veins (Art 14). If filling comes from outside sources, raises are necessary for delivering it into the stopes; main raises for passing filling to different levels should be continuous through successive lifts.

Breaking ground (see Overhand stopes, Art 26 to 28).

Stoping and filling. Fig 374 shows common practice in western metal mines. Stopes are started like open overhand stopes (Art 38). Ore from drift and cutting-out stope is sorted, and the waste used for filling other stopes. Level is timbered with lagged stulls or drift-sets (for choice, see Art 38).



LONGIT SEC IN PLANE OF VEIN CROSS-SEC AB

Fig 374. Filled Stope, Narrow Vein

First back-stope is usually a thin slice, broken with light shots to avoid damage to level timbers; waste is sorted out and left on timbers; ore from first back-stope is often loaded into cars on level through holes formed by removing 1 or 2 pieces of lagging. Before starting a second back-stope, timbered passages *C* (Fig 374), called CHUTES, MILLS, MILL HOLES, or ORE PASSES, are built 20 to 50 ft apart along the stope (Art 90). Work then proceeds as in ordinary overhand stoping. Chutes are built up periodically, to keep their tops at about the level of the filling.

Access to stope may be provided by timbered passages, like chutes; usually, manways are formed by putting ladders in one side of 2-compartment chutes. Openings *D* (Fig 374) serve as auxiliary chutes during early work in stepped-face stopes. This description assumes that enough waste is rejected in sorting to fill the stope; if this be insufficient, excess filling is obtained as described in Art 59.

Sorting in stopes is usually possible only when ore minerals are easily recognized, where ore and waste differ markedly in appearance, or ore occurs in distinct bands or patches. Underground sorting is not feasible where fine breaking is required to separate ore from waste.

Sorting diminishes amount and increases grade of ore secured. This may reduce plant and operating costs for handling and milling an ore, and give more profit than is obtainable by treating entire contents of vein; it also reduces amount of outside waste required for filling. Sorting may result in a profit from ore of apparently too low a grade to work, as illustrated by following figures from a western silver mine. An 8-ft vein was mined as shown in Fig 374; about 40% of material broken, carrying $2 per ton, was left in stopes as waste; remainder was sorted and sent to a concentrating and cyanide plant; mill extraction, 90%; total cost of mining and treatment, about $9.90 per ton milled. Sorted ore had to assay $9.90 ÷ 0.9, or $11 per ton, to pay expenses; minimum aver value of vein matter which could be broken to produce sorted ore of this value was (60 × $11) + (40 × $2) ÷ 100, or $7.40 per ton. Calculations to determine advisability of sorting are similar to those given under Resuing, Art 61.

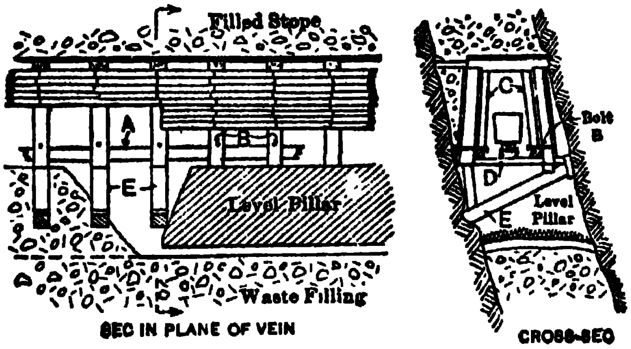


Fig 375. Mining Level-pillars, Waihi Mine, New Zealand

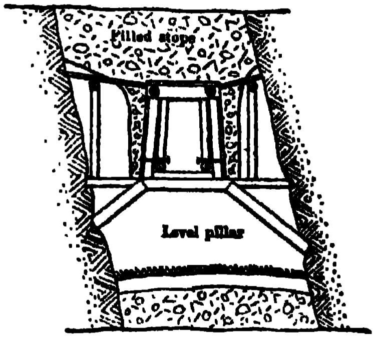

Fig 376. Mining Level-pillars, Vein widths 15-20 ft, Waihi Mine

Mining level-pillars presents no difficulties if ore is strong, and if level is timbered with stulls to support filling in stope above. Work is same as that of breaking a back-stope with uppers; in weak ore, vertical posts or cribs, resting on filling, are required to support level-pillars, and prevent falls of ground as work progresses; such ground may be broken by holes drilled in floor of level above. If the level is required for haulage, etc, filling from outside source is necessary to replace ore in level-pillars.

Fig 375 shows method at WAIHI MINE, New Zealand, of mining pillars under timbered levels (233). Work begins by placing heavy stringers *A*, 15 to 20 ft long, on each side of track close to posts; 1.5-in bolts *B* are then driven into each post, their projecting ends resting on the stringer and supporting the posts when ground below is removed. Timbers *C* are wedged between bolts and caps; spreaders *D* are placed at each set. The underlying pillar is next broken down, each drift set laid bare being blocked up from stulls *E*. When 3 or 4 sets have been thus picked up, the open space is filled and stringers are moved on another length, their forward end always resting on solid ground. This method is used for vein widths up to 15 ft; for greater widths, stulls *E* would be too long to handle. Saddle-back sets (Fig 376) are used for widths of 15 to 20 ft. Fig 377 shows method at NEVADA WONDER MINE for supporting stull and post timbering; other variations are feasible. See also McINTYRE PORCUPINE MINE below.

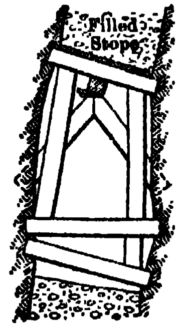

Fig 377. Support for Stull and Post Sets while mining Level-pillars, Nev Wonder Mine (Fig 379)

Examples of practice given below illustrate details of filled flat-back or stepped-face stopes in narrow veins; see also Resuing, Art 61.

Block P mine, St Joseph Lead Co, Hughesville, Mont. Data from W. O. Vanderburg (577) in 1931. Fissure vein carrying Pb–Ag ore occurs in large syenite chimney or stock, cut by rhyolite dikes. Vein has known length of 4 000 ft. Ore is 1–4 ft wide, but stopes aver 5 ft. Dip, 65°–88°. Mineralization is distributed in lenses throughout vein. Walls usually well defined and stand well for the short time they remain unsupported; occasional stulls used in blocky ground in rhyolite. Ore breaks well; about 95% broken in primary blasting will pass an 8-in grizzly. DEVELOPMENT. Entry to deeper part of mine is through a 2-compt vert shaft, 1 200 ft deep (1931); first 350 ft was sunk in vein, next 300 ft in hanging wall, remaining 550 ft in footwall. Below 400 ft, level interval is 200 ft. Drifts run along vein in both directions from shaft; timbered with drift sets. Raises, 690 ft apart, are driven for exploration and ventilation. Length of stopes aver 400 ft, sometimes reaching 750 ft. Drift sets are 5 ft c-c, except every ninth set, where spacing is 6 ft to accommodate chute and manway. STOPING is started by removing lagging over drift sets and taking a 5-ft cut from back, the ore being shoveled into cars. Lagging is replaced, chutes built, and horiz cut-and-fill mining starts (Fig 378). Cuts, 5 ft high, are broken by uppers drilled with hand-rotated stopers; 1 miner drills about 15 holes per shift; blasted with 30% gelatin dynamite. Selective blasting and

hand sorting are used to obtain high-grade product and minimize loss of ore. Amount of waste thus produced is more than enough for filling. Following methods of breaking depend on ore occurrence: (1) where ore and waste are in alternate bands across the vein, they are blasted together and waste sorted by hand; (2) where ore occurs as single strong band, the waste is first blasted, then the ore; (3) where ore is weak and in one band, ore is first blasted and then the waste. Before blasting, flooring is laid over fill to prevent mixing of ore and waste; flooring is of 3-in planks, 8 and 10 in wide, 5 ft long. Sorted ore is shoveled into chutes by hand. Stope crew usually consists of miner and shoveler. Chutes and manways are of framed sets of round timber and are built up periodically by timbering crews; chutes are lined with 3 by 10-in plank, 5 ft long, and are 26 in square inside lining; manways, 32 by 26 in. Single-compt chutes without adjoining manway were formerly used, but were unsatisfactory; repairing was difficult and it was dangerous to start ore running when hung up in chutes; manway gives safe and easy access to any point along chute. At end of a stope section, fill is lagged off from unbroken ore by row of stulls 5 ft c-c, laced with pole lagging 3–5-in diam. Horses of waste are left unmined (Fig 378). Stopes are carried through to level above. About 5 ft below level, stulls are placed 5 ft c-c and lagged with poles. Waste is run onto lagging to support track on the level. If walls are weak, stulls are also placed under drift sets before floor pillar is removed. Vanderburg cites following advantages of cut-and-fill mining at this mine: (1) complete extraction of ore; (2) very little timber is required; (3) ore is not held in stopes for long periods; (4) decreased use of timber and use of waste for filling reduces traffic in shaft; (5) a high-grade product is obtained by careful hand sorting; (6) good ventilation is obtained; (7) safe working conditions; (8) fire hazard is small. Table 41 gives operating data for year 1929.

Nevada Wonder mine, Wonder, Nev (234). Operations were suspended in 1919, but example illustrates present-day practice in many small mines and in portions of some large ones. Gold-silver ore occurred in fissure vein 5–6 ft wide. Ore was fractured; walls, weak. Following the cutting-out stope, level was timbered as in Fig 379, with 3-in plank lagging. Chutes of 2-in plank (Art 90) were at 25-ft intervals. A raise was then started in one wall, close to back of stope and at a pitch of 40° to 50°; enough waste was broken to cover timbers to depth of 2–3 ft. Waste was leveled off and covered with a plat of 2 by 12-in plank, upon which ore from first back-stope fell; the plat aided shoveling and reduced loss of fines in filling. Breaking ground began at one end of stope, 5-ft uppers being drilled with stope-drills. Before removing all ore broken from first back-stope, holes were drilled for the second, but were not charged. Ore was then cleaned up, some running to the chutes, the remainder being shoveled or handled in barrows. Plat was removed, chutes and manways were built up and braced temporarily, and stope was filled by waste to within 3 or 4 ft of back. Waste raises were driven alternately in foot and hanging walls between every 2 chutes; a raise served 2 or 3 back-stopes and was seldom over 30 to 40 ft high.

McIntyre Porcupine Mines, Schumacher, Ont. Data from H. G. Skavlem and D. E. Keeley in 1933 (229, 171). Gold ore occurs in quartz veins and in irregular replacement bodies. Wall rocks are generally lava-schists or porphyry; veins frequently along contact of these rocks. Aver width of ore is about 10 ft, but widths to 100 ft occur; length of ore varies, up to 1 200 ft. Dips, 60° to vert. In early years all stoping was by shrinkage; dilution from weak walls and need of sorting caused change to cut-and-fill and square-set methods. Mine is developed by vert shafts; levels, at 100-ft intervals to 1 000-ft level and at 125-ft intervals below. Raises for stope filling and ventilation are 250–300 ft apart. Fig 380 shows cut-and-fill practice. Chute-spacing at 35–150 ft was tried, but standard interval in 1933 was 50 ft, with manway alongside every third chute. Cuts are 8-ft high; breast is broken by mounted drifters drilling 10–12-ft flat holes. Powder con-

sumption, about 1 lb dynamite per ton. In strong ground breast may be 50 ft or more ahead of muckers. In stopes under 12 ft, scaly backs are supported by stulls. Handling of ore to chutes is by hand shoveling, or scrapers with air-driven hoists. Where scrapers are not used, ore beyond shoveling distance from chutes is loaded into 1-ton cars and trammed to chutes. Same type of car is used for spreading waste; for handling ore and spreading waste, sectionalised track of 16-lb rail in 10-ft lengths is used. As stope approaches level above, cut-and-fill mining is stopped, to leave floor pillar of a thickness depending on width of vein and ground conditions; thickness of floor pillar rarely exceeds 20 ft. Level pillar is mined by square-setting, to preserve haulageway above (Fig 381). Sources of waste rock for filling are: (1) development and shaft sinking; (2) sorting in stopes; (3) old fill from finished stopes; (4) waste cross-cuts driven in walls of stopes; (5) regular waste stopes. Use of waste crosscuts is confined to stopes remote from waste passes. Mode of obtaining waste by sub-level caving is described in Art 43.

Fig 382. Filled Flat-back Stope, Butte, Mont

Anaconda Copper Mining Co, Butte, Mont. Data from J. A. O'Neill, Eng Research Dept, and J. J. Carrigan, Gen Supt, in 1939. For ore occurrences and development, see Art 46. Fig 382 shows detail of method. Through raise-chutes *R* to level above, driven 125–200 ft apart along the veins, are later used for supplying filling from crosscuts in levels above. Sheeting caps and sheeting *S* (pole lagging or small stulls) support filling over sill or haulage level. A chute and manway *T* is carried through filling for extracting

broken ore from stope. One double-drum hoist scrapes both sides of stope into the chute, and also handles filling from through raise-chutes. Ore is shoveled on 2- or 3-in flooring on top of filling. Stulls with headboards support the walls when needed, and are salvaged before beginning each fill. In addition to low timber costs, the stope has the advantage of the good working conditions secured in all flat-back stopes, combined with close filling.

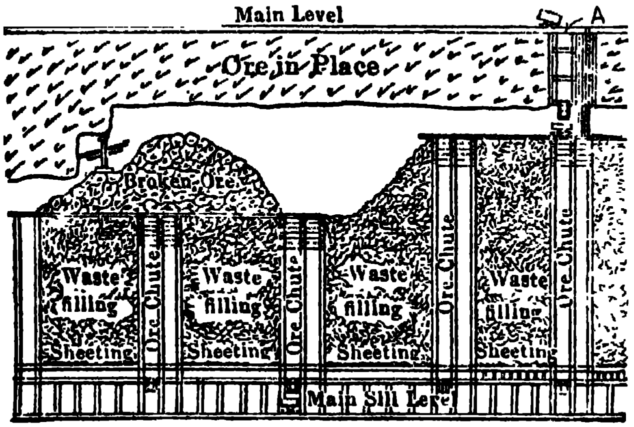

Fig 383. Back-filling at Butte, Mont

Butte, Mont (219). Fig 383, from B. H. Dunshee, shows a sometimes useful adaptation of flat-back filled stopes, used at Butte in moderately wide veins with strong ore and strong walls. Stope breast was carried about twice the usual height, in 2 benches, broken-ore pile being 15–20 ft high. Waste was run into stope through raise until it would no longer distribute itself by gravity; thereafter, it was spread by cars on track laid on filling about 6 ft below back. Chutes were raised to level of filling track as toe of fill approached them. Surface of fill was covered by 2-in plank before breaking down ore, to avoid admixture of waste and facilitate shoveling. Method locally called "Back filling."

Filled stope in weak ore. J. E. Harding describes a method of mining a block of shattered ore, 300 ft long, 100 ft high, and about 20 ft wide, at Mina Santa Francisca, Mexico (236). An open square-set stope, 4 to 6 sets high, had caught fire and caved. The stope was reopened several years later; ore had come down in huge slabs, and it was important to prevent surface subsidence. Square-setting was not deemed feasible, because of cost and scarcity of timber. Waste filling was obtainable cheaply from a nearby raise, connecting with a surface quarry. As shown by Fig 384, a drift was driven on 200-ft level through the caved area, and timbered with sill-floor square-sets with posts 4 ft apart; little spiling was necessary. A chute and manway were started in every 4th set; a cribbed raise *A* was put up to 100-ft level at each end of stope. Starting on sill floor, at both ends of stope and both sides of drift, a room as high as the sets was taken out across the vein; as fast as ore was removed, the back was caught up with vert posts and headboards. Filling, drawn through raises *A*, was kept close to face and stowed close to back, the stulls being buried. Waste was trammed to advancing face of rooms through a small drift in the back directly over the sill-floor sets; cars were loaded from temporary gates built into raises *A*. When the sill floor was mined and filled, successive slices, 10 ft high were similarly mined above. In any slice, rooms were started at the end chutes *B*, and connected with waste raises *A*; filling was drawn in and rooms advanced halfway to chutes *C*; chutes *B* were then built up, waste drifts *E* started, and the rooms completely filled. Rooms were then opened from tops of chutes *C*, carried halfway to chutes *D* and filled, the process being repeated until slice was removed. Distance between fill and face of a room never exceeded 10 ft; less in bad ground. Stulls for supporting back on sill-floor and upper slices were 10 ft long and 8-in butt diam, turned in a lathe and tapered to 6-in diam at other end; they were placed large end up, and were easily pulled out of filling with a hydraulic jack when uncovered in mining the slice above. This is a variant of the Crosscut method, Art 64.

CROSS-SEC X Y

Fig 384. Filled Flat-back Stope in Weak Ore

61. RESUING (also called " Stripping ")

Field of use for resuing is in working very narrow veins or paystreaks.

General plan of work (Fig 385). *P* is a narrow high-grade streak, separated from a low-grade or barren portion *AB* by gouge *C*. A flat-back overhand stope of minimum width is first opened alongside of a portion of the paystreak, as at *AB*; the broken material is used for filling *F*. Exposed part of paystreak is then broken down clean and sent to level through chutes *M*, spaced 15 to 50 ft apart.

Alternative methods: (*a*) Mine the vein from wall to wall, and sort out as much waste as possible in the stope; this produces more and lower-grade ore than resuing (compare Art 60). (*b*) Carry a stope of minimum width (Art 27, 28), to include streak *P*; this gives amounts and grades of ore intermediate between plan (*a*) and resuing. (*c*) Soft ore may be picked out before breaking to full stoping width. Choice of method depends on amount of sorting possible in stopes, and costs of breaking, handling, and treatment. Resuing often yields larger profit than any of these alternatives.

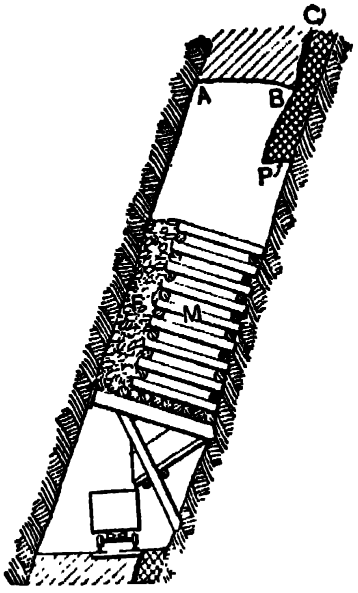

Fig 385. Resuing

Requirements for the successful application of resuing: (*a*) A well defined plane of weakness, as a clay seam or slip on one side of paystreak. (*b*) Steep dips are desirable. (*c*) High-grade ore is necessary for mining narrow deposits with profit.

Cold Springs mine, Nederland, Boulder County, Colo. Data from W. O. Vanderburg (290) in 1932. Tungsten ore (tungstate of iron, $FeWO_4$) occurs as lenses in fissure veins; wall rock is chiefly granite, frequently gneissoid. Aver width of ore-streak mined, 8–10 in; aver length, 80 ft. Aver dip of veins, 70°. Walls tend to slough when exposed more than 6 ft along dip. Ore and waste are easily distinguished by visual inspection. Mine is developed by 2-compt shaft 40 ft in footwall and inclined about 71°; upper 3 levels are 50 ft apart, lower 3, 100 ft apart. No raises are driven in advance of stoping, but some timbered chutes and manways through old stope fills are maintained as openings between levels. Cribbed chutes are 25–30 ft apart; chutes at ends of stopes have manways alongside. Stope is advanced by successive cuts 4–6 ft high. Method of breaking ground varies with character of vein. Where ore occurs as a single band, resuing or " stripping " is used; waste is blasted first, usually on hanging-wall side, and leveled off by hand. A sheet-iron plat is then laid on the fill and exposed ore carefully blasted down with small charges of explosive, or taken down by hand moiling. Where ore and waste are too intimately associated for resuing, they are blasted down together and sorted by hand. Amount of waste thus obtained is more than enough for filling; excess is shoveled into chutes and hoisted to surface. In 8 mo of 1931, an aver of 0.445 ton of ore was recovered per man-shift of all labor; 4.48 lb of 40% dynamite were consumed per ton recovered.

Molybdenum Corp of America mine, Questa, N M. Data from J. B. Carman (492) in 1931. Veins carrying molybdenite (MoS_2) occur in zone of branching and interfingering fractures in porphyry. Width of mineralization varies from fraction of inch to 6 ft, but vein walls are sometimes 10 ft apart. Streaks of high-grade ore not over 6 in wide are commonly mined, but for whole mine aver width of material taken as ore is probably 12–18 in. Veins are commonly 200–500 ft long, extending down dip about one-third their horiz length. Average dip is 60°, but wide local variations occur. Both vein and wall rock drill and break easily; molybdenite is very friable and must be blasted carefully to avoid loss in fines. Ground usually requires support given by filling, but in places open stopes are used. Mine is developed by several tunnels at various elevations; level interval, 40–100 ft. No raises are driven for stoping only. Fig 386 gives a cross-sec of a typical stope, showing variation in width of ore and occurrence of included waste. Stopes are started by taking out from back of drift, placing drift sets, and building chute-pockets 50 ft apart; manways are carried alongside of alternate chutes. Chutes and manways are of round cribbing or stulls laced with split lagging; chutes are 3 ft square inside; no grizzlies are used. Stopes are flat-back. Ground is broken by uppers, rarely over 3 ft deep. Both machine and hand drilling are employed; hand drilling favored in soft ground because recovery of ore is cleaner and more complete; hand-rotated stopers used for harder ground. Explosive is 40% gelatin dynamite. Method of breaking ore varies according to ore occurrence and is carefully supervised. Resuing is used where possible, waste portion of vein being mined before ore is broken down by picking or very light blasting. Plank flooring is sometimes laid on fill before breaking down ore, but usually fill is simply leveled off. Ore is shoveled directly to chutes without use of wheelbarrows, in spite of wide chute spacing. Double handling of ore is necessary in any case because of sorting. Enough material for filling is generally provided by waste necessarily broken and sorted out in stoping. In 1930, about 0.6 ton of ore was recovered per man-shift of all labor; explosive, about 3 lb per ton of ore.

City Deep mine, Johannesburg, So Africa. For data on resuing in this deep mine, see Art 33.

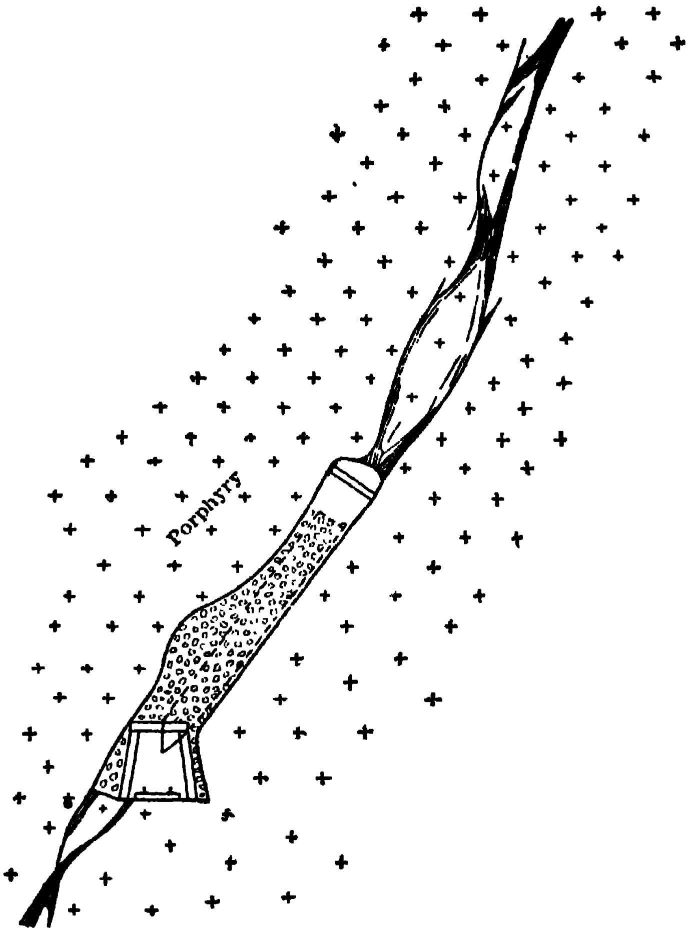

Fig 386. Vert Cross-sec through Typical Stope, Molybdenum Corp of America, Questa, N M

Resuing *vs* other methods for mining a narrow, high-grade, gold-quartz vein; data from F. C. Roberts (238). In all examples, dip of vein is 85°, wall rocks contain no values, and as there is a clean slip on footwall, stoping can be done there without disturbing vein; general charges cover items of amortization, pumping, and general expense.

Example A	Tons	Cost per ton	Total
Mining	104	$3.60	$374.40
Tramming	104	0.36	37.44
Hoisting	104	0.18	18.72
Milling	100	1.44	144.00
General			198 00
Total			$772.56
Value of gold from 100 tons			749 00
		Loss	$ 23 56

Example A. Width of vein, 6 in; value, $48 per ton. Vein and wall rock are broken together in a stope 30 in wide; broken material contains 20% ore and 80% waste; aver value, $9.60 per ton. 5% of the waste is sorted in stope; 5% of 80 = 4, hence 96% of tonnage of ore and waste broken is sent to mill, with a value of $9.99 per ton. Mill recovery, 75%, or $7.49 per ton. Cost per 100 tons milled is shown by accompanying statement.

Example B. Width and value of vein same as in Example A. Mining is done by resuing; a 30-in stope is carried in footwall and the vein broken down clean after about 3 600 sq ft are stripped; some waste from footwall stope had to be sent to surface. Mill recovery, 75% or $36 per ton. Statement shows cost per 100 tons milled.

Example C. Resuing a 12 in vein; value, $28.80 per ton. Mill recovery, 75% or $21.60 per ton. Method same as in Example B. Statement shows cost per 100 tons milled.

The same vein mined in a stope 30 in wide, where ore and waste are broken together, shows $124.38 profit per 100 tons milled, where 5% of the waste can be sorted in stopes; if 20% of the waste can be thus sorted, profit is $196.50.

Example B	Tons	Cost per ton	Total
Mining waste.....	500	$2.40	$1 200.00
Mining ore.......	100	3.60	360.00
Handling waste...	110	0.48	52.80
Tramming ore....	100	0.36	36.00
Hoisting waste...	110	0.18	19.80
Hoisting ore......	100	0.18	18.00
Milling ore.......	100	1.92	192.00
General.........	......	....	252.00
Total.........	......	....	$2 130.60
Value of gold from 100 tons....			3 600.00
		Profit	$1 469.40

Example C	Tons	Cost per ton	Total
Mining waste.....	250	$2.40	$ 600.00
Mining ore.......	100	3.60	360.00
Handling waste...	23	0.48	11.04
Handling ore.....	100	0.36	36.00
Hoisting ore......	100	0.18	18.00
Hoisting waste...	23	0.18	4.14
Milling ore.......	100	1.92	192.00
General.........	......	....	240 00
Total.........	......	....	$1 461.18
Value of gold from 100 tons....			2 160.00
		Profit	$ 698.82

62. FILLED FLAT-BACK STOPES OR HORIZONTAL CUT-AND-FILL STOPES, WIDE OREBODIES

Field of use. Ore should stand unsupported over back of stope or with no greater support than is afforded by posts or cribs resting on filling. Strong walls are not a requisite. General dip should be steep, but local variations in dip of foot- or hanging-wall. contacts are not serious handicaps. For use of filling methods in weak ores, see Art 64.

General plan of work is same as for narrow veins (Art 60). Filling for wide stopes may be obtained in part from sorting or by breaking into walls, but generally it comes from outside sources and is delivered to stope through raises. Wide orebodies often call for more than one haulageway under stope to afford proper chute spacing. Rib pillars between stopes are usually necessary to limit size of stope; in wide orebodies, narrow dimension of stope is usually in direction of strike. Examples of practice are given below and in Art 63, 64.

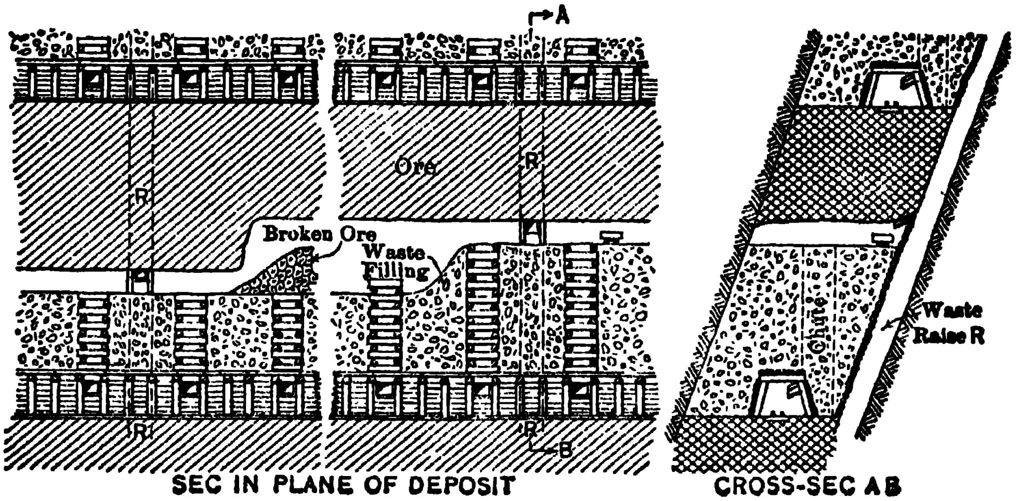

Fig 387. Filled Flat-back Stope, Minnesota Iron Co, Soudan, Minn

Minnesota Iron Co, Soudan, Minn (35, 153, 183, 239). This is a classic example of early practice in U S. Orebodies were overlapping lenses of hematite, varying in length from 200 to 1 000 ft, in width from a pinch to over 100 ft, and in vert height from 250 to 500 ft; dip, 65° to 75°. Ore was very hard and strong; walls, weak and soft. Method of mining (Fig 387, 388). Overhand, flat-back stopes were carried with alternate ore-breaking and filling; timbered gangways were kept open through the filling; an occasional crib supported loose slabs in back of stope. Entry was by several inclined shafts in foot-wall; level interval, 80 ft. Levels were opened by driving wide crosscuts from shaft to hanging wall; a 7 by 8-ft drift was driven through center of lens, followed by a breast stope (Art 30), which took out full width of deposit to a height of 15 to 20 ft. Gangways, following advance of breast stope, consisted of 3-piece round-timber sets (Art 20), with 9-ft posts, 11-ft caps; the sets were 3 ft apart, close lagged and held in place with sway-braces. Fig 388 shows plan of gangway. At chutes, sets were of 20 to 24-in timber. Top lagging was 6 to 8-in diam, side lagging 3 to 5-in. Cribbed ladder-ways, 5 ft square, were built up on hanging-wall side of gangway at 50-ft intervals, and similar chutes every

25 ft along footwall side. When timbering was finished, stope was filled with waste to a depth of 12 to 15 ft; there should be at least 5 ft of fill above gangway sets. A 10-ft slice was then broken from back of stope, the ore being thrown into chutes; as stope advanced, chutes and manways were cribbed and a new layer of filling was put in, leaving a 6-ft space between fill and back of stope. Successive back-stopes about 15 ft high were taken as long as the back would stand safely under the filling in stope above; level-pillars were usually 6 to 10 ft thick (153). Waste for filling was admitted through 6 by 6-ft raises *R* in the footwall, with one side following contact between rock and ore. Raises were about 100 ft apart and terminated in an open-cut at surface; the side exposed by stoping was timbered before filling was run into the stope; this allowed filling to be drawn into stopes at any elevation and maintained raises for future service in lower lifts. Filling was distributed in small cars, loaded from temporary chute gates erected in raises. For upper lifts, filling was obtained by blasting walls of open-cut; the filling in exhausted upper lifts was drawn downward and used in lower stopes; in narrow parts of deposits, filling was done with lower handling costs by breaking down the walls.

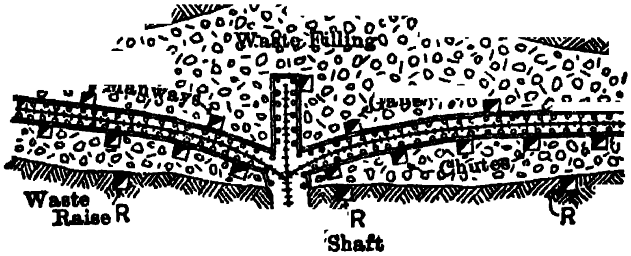

Fig 388. Plan of Part of Level, Minnesota Iron Co

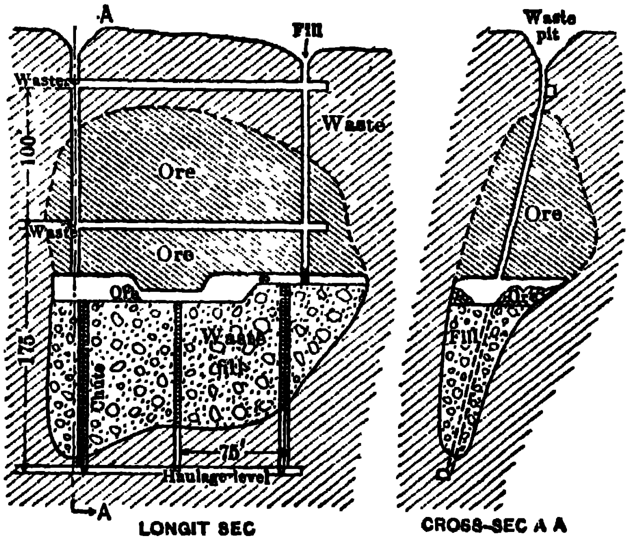
Arizona Copper Co, Morenci, Ariz; data from P. B. Scotland (178, 152). Sulphide ores occur as disseminated deposits in quartz porphyry and as fault fissure veins in granite. Oreshoots to which this method was applied carried 2.5 to 2.8% Cu, and were irregular in outline; lengths, 450 to 1 750 ft; widths, 6 to 200 ft; commercial ore extended to depths of 450 to 800 ft. Hard ore which stood well was mined in flat-back filled stopes (Fig 389); locally called open stoping and filling. A slice, 15 to 20 ft high, was taken over whole area at bottom of shoot; one or more raises were driven to surface or to level above for ventilation and filling; chutes and manways, about 75 ft apart, were erected from tramming level and the stope was filled to within 8 ft of back. If orebody was on an important haulage level, stope was opened 10 or 15 ft above it. Back-stopes were 15 to 20 ft high. Filling was distributed in cars; experiments with mechanical scrapers were unsuccessful. Excepting a few cribs or square-sets to support loose slabs, the only timber required was for chutes. Several stopes in Metcalf mine were so wide (up to 300 ft) that pillars amounting to 5% of orebody were left to support walls and back. Danger from unsupported backs limited use of method to the firmest ground. Filling was obtained cheaply from surface quarries or glory-holes. (For other methods at Morenci, see Art 35, 46, 65, 68, 73.)



LONGIT SEC

CROSS-SEC A A

Fig 389. Filled Flat-back Stope, Morenci, Ariz

United Verde mine, Jerome, Ariz. Data from T. W. Quayle (227) in 1931 and W. W. Lynch, formerly Mine Supt. Large body of pyrite occurs in a steeply dipping inverted trough, with diorite hanging wall, schist and porphyry footwall. Bodies of copper ore occur within the pyritic mass and usually extend into the footwall. The walls are generally commercial limits of massive sulphide on hanging-wall side and of schist or porphyry on footwall side. Main orebody is about 1 200 ft long, varying in width from a few ft to 200 ft. Except in some schist zones, ore is strong and stands over large areas without support except occasional cribs. Massive sulphide hanging wall is generally very strong. Footwalls of schist or porphyry usually require prompt support. Much ore is high enough in grade to be smelted without concentration and hence must be mined to give high extraction with little dilution from waste. These conditions, combined with irregularity of

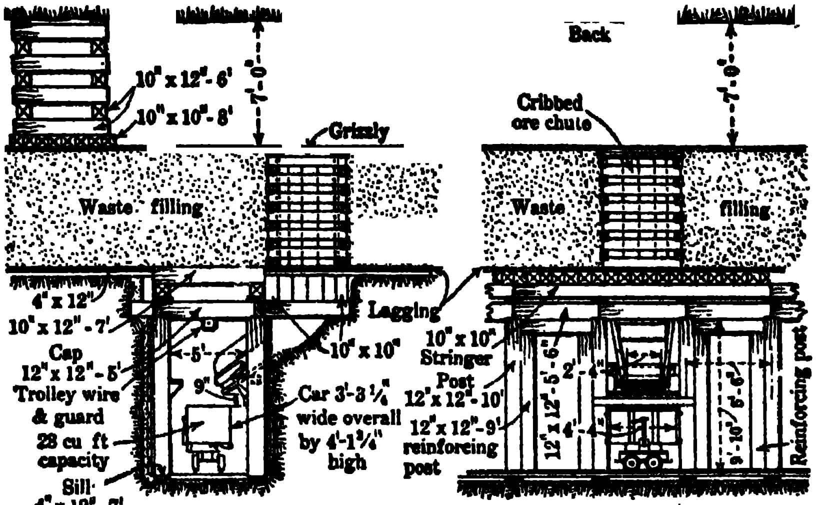


Fig 390. Chute and Gangway Timbering, United Verde Mine

walls, were reasons for favoring horiz cut-and-fill method in the past, although some shrinkage and inclined cut-and-fill stoping were used. (Future plans call for wider use of inclined cut-and-fill. Author, 1939.) Development. There are 3 vert footwall shafts, and 2 adits, on 500- and 1 000-ft levels. Level interval generally 150 ft. On each level a main crosscut intersects middle of orebody, and drifts near the sulphide-schist (or porphyry) contact determine the length of ore. Width, shape and characteristics of ore on a level are determined largely by diamond drilling (Fig 48); these data guide the planning of stopes, additional haulageways and raises, and spacing of rib pillars. Stoping. Original practice in cut-and-fill work was to sill out stopes on levels and then establish timbered gangways, but gangway timbers required costly maintenance. In later practice, cutting-out floor was 13 ft above level, which also involved timbered gangways (Fig 390); timber maintenance was reduced, but still high. Still later practice was to sill the stope 21–25 ft above level, avoiding timbering of gangways altogether. Stopes were laid out to give max size consistent with safe mining; dimensions, 30–160 ft across the orebody and 60–200 ft along strike. Stope dimensions were also affected by necessity for maintaining regularity in the vert-pillar system. Raises were 6 by 11 ft, with a cribbed manway compt, the chute side being untimbered. For stopes 100 ft or more long, 2 waste raises were driven, one at one end and the other near center of stope; smaller stopes had only 1 fill raise. Where 2 fill raises were used, the timber was stripped from both; with only 1 raise, its timber was left in place to hold the raise open for ventilation. Silling operations were usually started from one waste raise 21-25 ft above rail; sill-floor cut, 7 ft high. Chute raises connected the haulageways with the stope at 16.5-ft intervals in massive sulphide, and 22-ft intervals in schist or porphyry. After sill reached pillar lines and ore limits, a second 7-ft cut was started from a waste raise. In stopes having 2 raises, the cut was started from the one near end of stope. Two rows of 7 to 8-ft flat holes were drilled by drifters; loaded with 50% gelatin dynamite. Before starting filling, sill flooring was laid, of 4 by 12-in, 5 ft 4 in c-c, and a double floor of 2-in planks, 10 ft 8 in long, placed to break joints; purpose of flooring on a solid floor was to aid level-pillar recovery. "Pillar fencing" was built along faces of the vert pillars, of 6 by 8-in posts 8 ft long, spaced 3 ft 7 in c–c and covered with 2-in plank 7 ft 2 in long, with staggered joints. Chutes were of 5 by 8-in cribbing, 5 ft 3 in long, lined with 4-in pine and sheathed outside with used 2-in flooring. Where manways adjoined chutes, construction was as in Fig 391. Grizzlies over chutes were of inverted

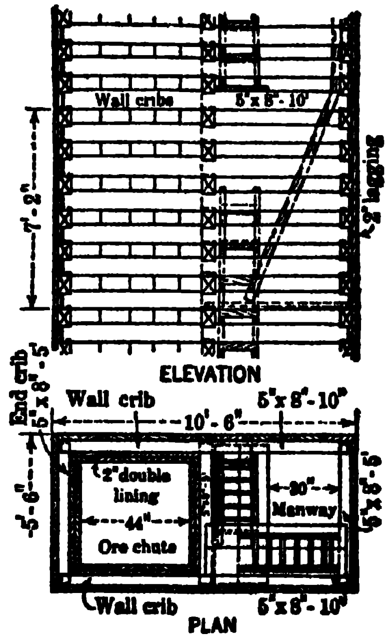

Fig 391. Cribbed Chute and Manway, United Verde Mine

60-lb rails with 11-in openings. Waste was distributed from temporary chute pocket under waste raise by 18-cu ft scoop-body cars on 18-in gage sectional track. Track sections were of 8-ft straight lengths, curves of 9-ft radius, and standard switches; rails riveted to $^3/_8$ by 4-in steel-plate ties; sections connected by slip-joint tie and a spike; no bolts necessary. Fig 392 shows stope procedure. Stope continued upward by horiz cut-and-fill to within 20–30 ft of level above. Both floor and vert pillars were later mined by square-setting. For further details and other methods, see Bib 227, 524.

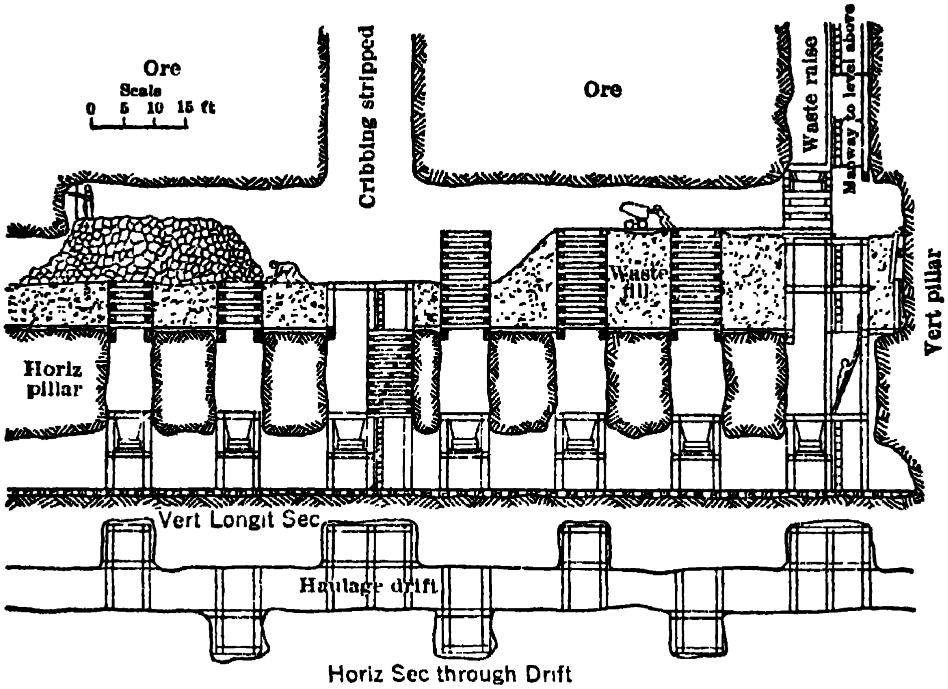

Fig 392. Typical Cut-and-fill Stope, United Verde Mine, Jerome, Ariz (227)

Hollinger mine, Porcupine, Ont. Data from A. W. Young (306) in 1935. For geol features, see Art 68. Orebodies range from narrow single veins to groups of veins forming ore zones to 100 ft width. Horiz cut-and-fill method is used for wide orebodies, irregular and often erratic systems of closely spaced, branching and connecting veins, newly developed lenses between old stopes, and narrow veins having bad walls. Fig 393 shows application to a branching orebody. Level interval, 150 ft. Ore is silled out to height of 17 ft and timbered haulageway is built. Combination chutes and manways, 6 by 12 ft, are 200 ft apart; they are of cribbing, either 8-in round or 10 by 10-in sawed timber. Chutes of round cribbing are lined with 3-in plank; unlined if of squared timber. Fill raises to level above are midway between chutes; cuts 10 ft high are started from them and run in both directions. Three rows of flat 8-ft holes are drilled with mounted drifters. Ore is hand shoveled into 1-ton rocker-bottom cars and trammed to chute; same type car used for spreading fill, which is leveled off to within 10 ft of back; flooring of 3-in fir or 2-in elm is laid on fill to prevent mixing of ore and waste and aid shoveling. As breast advances, timber sets are erected on the new fill and kept close to working face; caps or stringers of 12 by 12-in are set on round posts resting on sills. Cribs of 12 by 12-in timber supplement the sets in bad ground. Fill is kept close to advancing breast and miners usually set up on filling rather than on broken ore. Nearly all stope timber is recovered and reused. Before blasting, sets below that may be broken are removed. Power-scraping is used in some stopes for delivering ore to chutes and distributing fill. Filling comprises development waste, plus sand and gravel excavated by dragline scraper from deposits about 3.5 miles distant and transported to mine by aerial tram (235). RECOVERY OF LEVEL PILLAR. Depth of this pillar depends on width of stope and nature of ground. Fig 394 shows a retreating method of removing a 20-ft pillar. Aver figures for all cut-and-fill stopes during 1934 are: tons broken per hole drilled, 3.613; direct stoping labor and explosive costs, per ton broken: breaking, 31.1¢; timbering, 10¢; filling, 12.2¢; mucking, 36.4¢; stope and sub-level development, 7.8¢; total labor, 97.5¢; explosives, 12.2¢; total, $1.097.

Creighton mine, Ont (93). Geol features and former mining by shrinkage are described in Art 68. As ground conditions are no longer suitable for shrinkage, recent (1937) methods are horiz cut-and-fill and square-set. Much of square-set operations is to recover level and rib pillars. Horiz cut-and-fill stopes, running longitudinally, are used where possible. "Silling" (cutting-out stope) is on the level or 30 ft above rail. A permanent flooring of cedar plank is laid on sill floor before fill is begun. Chutes at 22-ft centers are cribbed, have 4-in plank lining, and incline to conform with general dip of footwall. Grizzlies are of 60-lb rails, inverted and spaced for 11-in openings. Breast drilling is done from the ore pile. Flooring on top of fill for hand mucking is of 3-in plank. Fill is carried within 6–7 ft of back. Waste raises are 7 by 11 ft; cribbed manway used in driving raise serves for ventilation and handling supplies into stope.

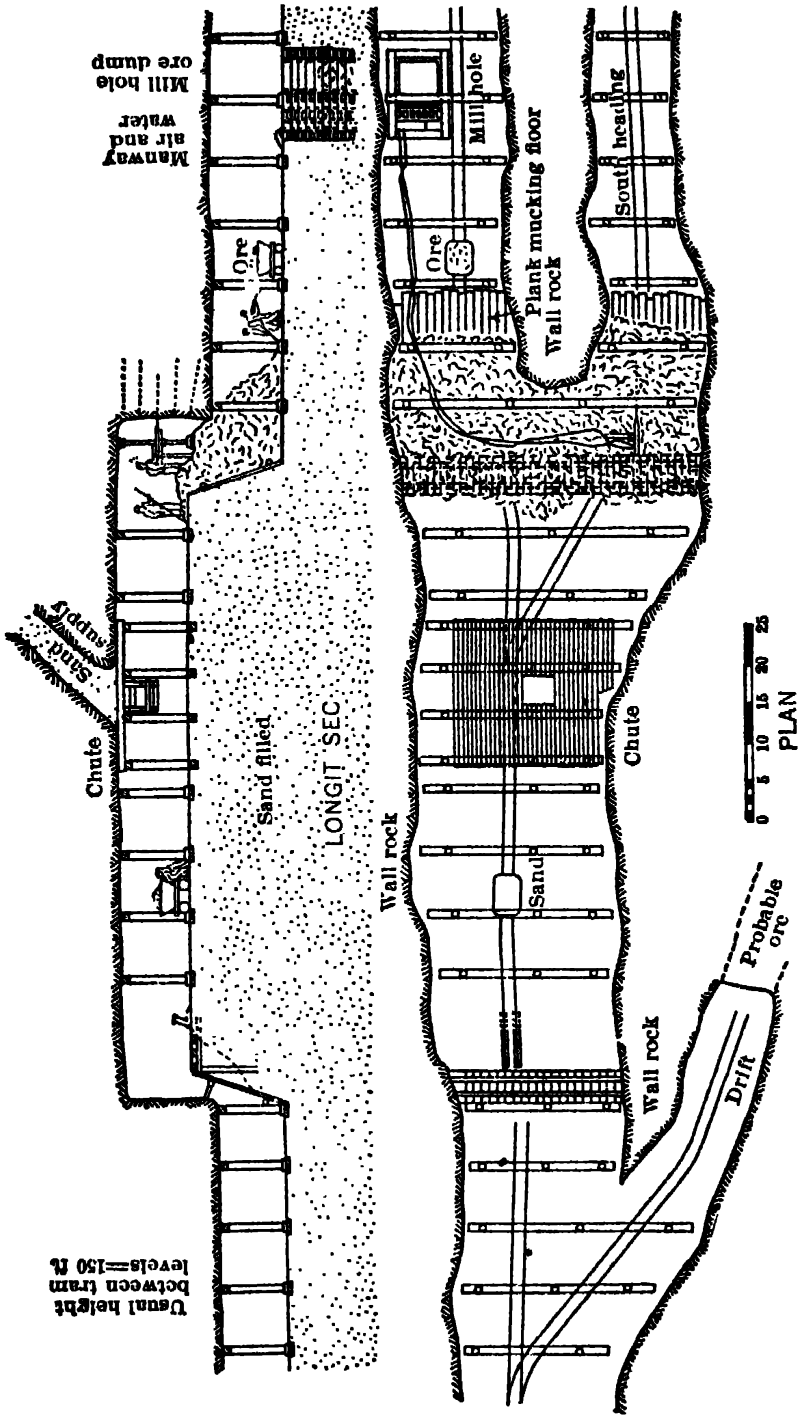

Fig 393. Cut-and-fill Stoping, Hollinger Mine, Ontario

Matahambre mine. Pinar del Rio, Cuba. Data from G. L. Richert (237) in 1929. Tabular bodies of ore, averaging 4.25% Cu in chalcopyrite associated with pyrite and quartz, occur in 1 prominent and 2 less important fracture zones across sediments, chiefly

shale and metamorphosed sandstone. Dips, 42°–45°. Footwall, usually quartzite, stands well; hanging wall, usually shale, requires prompt support. Level interval has been increased from 100 ft to 150 ft. Development is by vert shaft; haulageways are drifts or crossouts. Stoping is by horiz cut-and-fill; unusual feature is manner of filling with mill tailings. Bottom of sill-floor cut is 14 ft above rail; cut, 12 ft high. Chute raises are 50 ft apart, with manway alongside each third chute. Fill raises to level above are 100–150 ft apart; at least one raise per stope has ladders. Flooring of hardwood slabs and poles is laid in sill-floor cut before filling. Chutes are of 8-in round timber, framed to obviate use of nails. Cuts are started with stoper drills in center or at end of the stope and continued with jackhammers. Ore is usually hand-shoveled to chutes; or wheelbarrows, if chutes are far apart. After stope has advanced to within 15–20 ft of level above, square-sets are used to remove level pillar. Filling. Mill tailings are pumped to a 30-ft bowl classifier situated on surface near a raise leading to mine (Fig 395). Slime overflow goes to tailings pond; water is added to rake product and delivery to mine is through 2.5-in rubber-lined pipe. Pipeline system extends to stopes, where sand is distributed by hose. By building up small sand dams, any part of stope can be filled. Before filling, the chutes and manways are wrapped with burlap to prevent washing of sand through cribbing. Water seeps through the burlap and out of stope in about 12 hr; surface of fill is level and hard. Advantages of classified mill tailings over previously mined surface waste are: ease of handling; no spreading; flexibility; fewer raises required; better support of walls. For further details, see Art 92.

63. FILLED FLAT-BACK STOPES, WIDE OREBODIES

(Baltic Dry-wall Method)

Champion mine, Painesdale, Mich. Data from A. Mendelsohn (488) in 1931. Ore occurs largely in brecciated cappings of tilted lava flows, which dip at 30°–70°. Lode is nearly straight for long distances along strike. Hanging wall of a lode is the bottom of next succeeding lava flow; footwall is the trap lying under amygdaloidal top of flow.

In some places lodes outcrop; in others they are covered with glacial drift. Lode at Champion is in the brecciated top of "Baltic" flow; length on property, 8 000 ft; dip is uniform at 70° for 3 000 ft in depth, then flattens slightly. Aver width of ore mined in 1930 was 17 ft. Lode rock is very hard. Hanging wall is seamy lava requiring prompt support. Footwall is irregular and becomes more "trappy" at depth. Native copper occurs in irregular patches and must be sorted. Ore shipped in last 5 mo of 1930 ran 46 lb Cu per ton; before sorting, 25 lb per ton. Development is by 4 inclined shafts in the lode. Main levels are 100 ft apart along dip. Drifts follow the ore as far as possible, but avoid sharp curves for haulage reasons; they serve to explore as well as to develop. Stoping. Recent mining is largely by a retreating system (see below); earlier method, the "Baltic Dry-wall," is still used in upper levels (1931). Distinctive features of "dry-wall" method, devised by F. W. Denton, are: (*a*) use of dry stone walls to maintain gangways and chutes through filling; (*b*) mode of mining level-pillars; (*c*) devices for distributing sand filling in stopes. According to A. Mendelsohn, Gen Supt, following description from earlier editions of the Handbook is correct as to current use of the method. Description based on notes by author in 1910, by C. W. Crispell, 1916, data by C. T. Rice (141) in 1912, and by W. H. Schacht (555) in 1923.

Dry-wall gangways; drawings from C. T. Rice (141). Copper rock (ore) from drift and cutting-out stope is sorted in the level, waste being thrown aside. Building of gangways follows at a convenient distance behind the sorters; Fig 396 shows type form and dimensions.

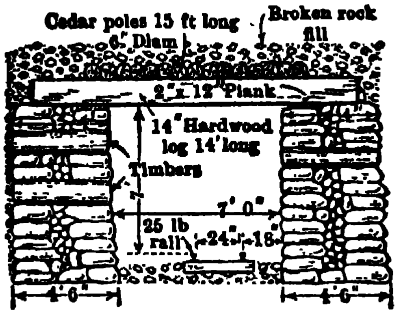

Fig 396. Dry-wall Gangway, Baltic Method

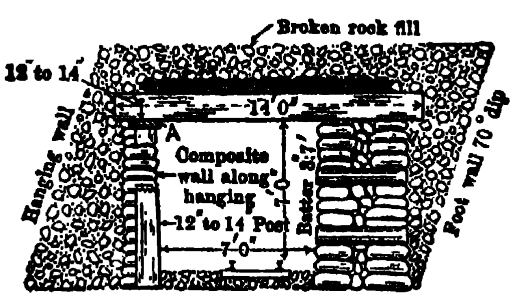

Fig 397. Gangway with One Composite Wall

Stones for facing the walls are 14 to 30 in long; longer pieces when available, or old timbers, are used as ties between the faces. Face stones break joint, to avoid planes of weakness. Faces of walls next to drift are battered 3 to 4 in in height of 7 ft. Rock of Baltic lode tends to break into tabular forms, convenient for facing walls; stones are shaped by hammers where necessary. Top of gangway is covered with lagging on caps (wall-pieces) spaced 3.5-ft centers; pressure from wall-pieces is distributed by a 2 by 12-in plank on top of wall. Fig 397 shows construction where lode is too narrow for two 4-ft walls; a wall of usual width is built along footwall, where heaviest pressure from filling occurs; hanging-wall ends of wall-pieces rest on a horiz timber *A*, 2 in or more in thickness, supported on posts under each wall-piece. Timber *A* is spiked to each post; a narrow stone wall is built between posts, and space behind filled with waste. Such composite walls are adequate along hanging wall of narrow parts of lode and cost less than those in Fig 396. Under wide stopes, a 4.5-ft or thicker wall is required to withstand side thrust of filling; 3.5 ft is the minimum width of a strong dry wall. Fig 398 shows gangway construction where suitable waste is not available for walls like Fig 396; 3-sided cribs (pigsties) are built on each side and filled with waste. Such walls stand well, but fail when timbers rot; in these mines ventilation is good and timbers last 6 to 7 years. Dry walls can be repaired by rebuilding small sections under protection of a false set which supports ends of wall-pieces over section under repair.

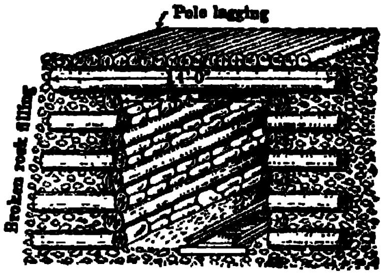

Fig 398. Cribbed Gangway

Dry-wall chutes (mills) are built at intervals of 30 to 70 ft; practice favors longer intervals and the use of cars in stopes for handling ore. Construction of such chutes is shown in Fig 399. The larger stones are used in inner walls to withstand wear of falling ore; outer wall takes most of thrust of filling; central core of loose stones allows outer wall to adjust itself somewhat to pressure, without disturbing inner wall. Walls are started from timbers, which are protected from wear by placing rocks above to overhang

about 4 in. Chutes are built in sections 5 ft high; walls of a new section are started 4.5 ft thick at level of the stope filling and taper to 3 ft thick at top. Mouth of chute is about 4.33 ft wide by 3 ft high in the clear; timber *E*, about 8 ft long, is built into the gangway wall and serves as a lip-piece for fastening chute gate. Vert chutes are easiest to build and maintain; where lode is narrow, some are vert for a few feet above the level and are then carried up parallel to the dip, but inclined chutes are avoided where possible.

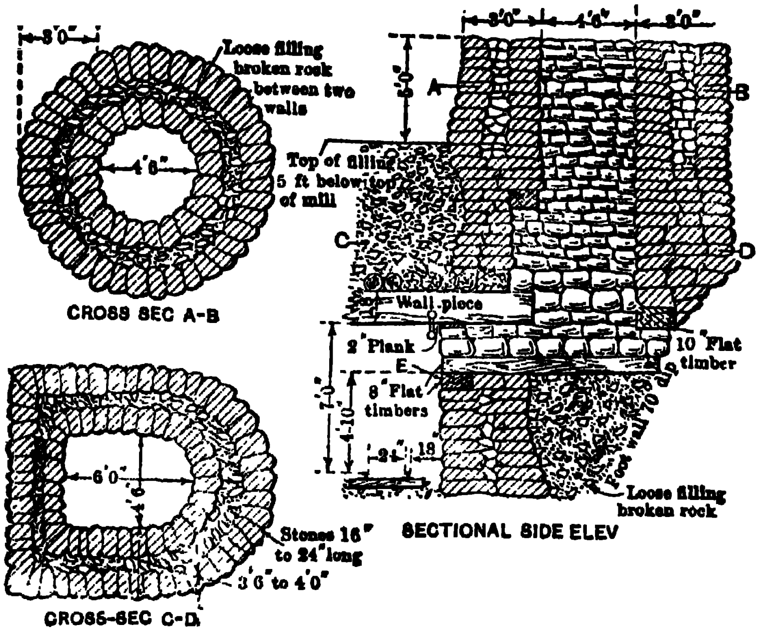

Fig 399. Dry-wall Mill Hole. After C. T. Rice (141)

Cost of dry-walling under suitable conditions compares favorably with that of timber to replace it, largely because of its greater strength and life, and consequent reduction of maintenance costs for gangways and chutes. An incidental advantage of dry-walls is that, since less timber has to be lowered into the mine, more time is available in shafts for hoisting ore.

Stoping and filling methods vary in detail with local conditions. Usually the drift and cutting-out stope furnish enough waste to fill spaces behind dry-walls before wall-pieces are put on; in case of shortage, the space on hanging-wall side of drift is filled; stoping is then started on hanging-wall side, and waste sorted out is used for filling space on footwall side of drift.

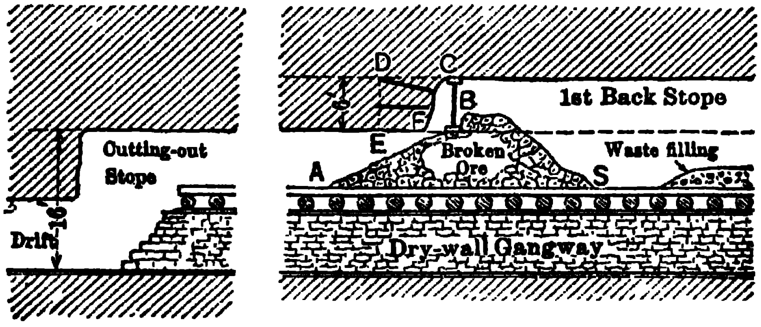

Fig 400. Starting Stopes, Baltic Method; Longit Sec

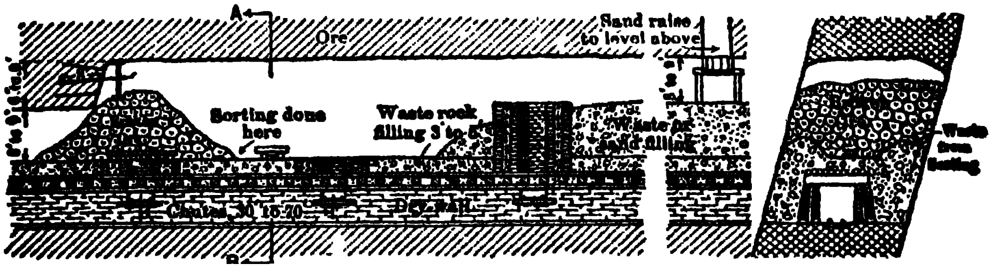
Fig 400 shows one way of starting a stope; first back-stope, 6 ft high, produces a pile of ore about 9 ft deep, the forward face of which, *AB*, protects lagging when the cut *CDEF* is blasted. Sorters at *S* work the ore through lagging into the level; waste is thrown back and to the sides. Where feasible, lagging is covered with waste before stoping begins. Before starting a second back-stope, chutes are built up, and the stope filled to within 8 or 9 ft of the back (Fig 401). Interval between chutes must be adjusted to strength and condition of walls, so that unsafe wall areas are not exposed between the fill and the pile of broken ore. Sorting does not usually furnish enough waste for filling; excess filling is obtained through a raise from above, by shooting out footwall, by driving inclined raises

into walls, or by sand filling (see below). W. H. Schacht states: of total fill used at Champion mine, in 1920–23, 43% came from sorting in stopes, 15% from footwall explorations, 15% from poor backs, none of which required handling. Filling requiring handling comprised: 12% from walls, 9% from development, 6% sand fill. Total fill, including sand, 60% of tons ore broken. Fig 401 shows second back-stope; a 1-ton car conveys ore to chute; waste is thrown back and aside; in higher back-stopes, waste may be trammed to a point like *F* (Fig 404). As stope face advances, mills serve alternately as chutes and ladderways. Successive back-stopes are carried to a height of 60 to 75 ft; questions of safety, cost, and economy of timber led to adoption of method in Fig 404 for mining the remaining level-pillar.



DIAGRAMMATIC SEC IN PLANE OF VEIN

Fig 401. Back Stoping and Filling, Baltic Method

Irregular distribution of copper in lode requires operation of a large number of stopes to maintain regular output; individual stopes advance slowly; removal of level-pillar destroys gangway above. These conditions, combined with practice of mining outward from shafts, often require a level-pillar to stand untouched from 3 to 8 years, during which time ground becomes heavy, and unsuitable for flat-back stoping. It is proposed to apply Baltic method as a retreating system, to shorten time before level-pillars are mined; then a larger level interval might be possible, as well built stone chutes stand wear of falling ore for long periods. Width and dip of lode are also related factors influencing level interval, as chutes should be vert, if possible (Fig 404).

Sorting is done carefully by special men; rock showing even a speck of copper is sent to chutes. Large boulders are broken and the pieces examined; bosses decide whether fine rock, requiring shoveling, shall be classed as waste or ore. Few fines are produced in breaking, hence loss of fines in filling is small; a layer of fine waste, placed on top of the rock fills in stopes, eases work of shoveling; fines may be recovered by skimming off an inch or so of this when the stope is cleaned up. (See Mining level-pillars, below.)

Mechanical loaders, as used in stopes (482), are shown in Fig 402. The shovel (*a*) is a special Thew Electric, with a 20-hp motor and caterpillar tractor, loading into a hopper (*b*), which discharges onto an armored picking belt (*c*). Waste picked from belt is used for fill. Belt outfit weighs 16 tons; length, 24 ft, with 12 ft effective for picking; width, 4 ft; height at discharge end, 8 ft. Picking surface is of treated fir slats, 4 in thick, with cast shoes at ends, covered with 0.25-in steel plate and connected by links. Shoes run or slide without rollers on oiled angle-iron track. A shock platform at loading end cushions the impact of a dipper (5/8 cu yd) of rock. When in use, belt frame is anchored to track by 2 wheel-clamps; it is manned by 2–4 pickers; speed of travel, 6–8 ft per min; about 1/4 of rock broken is rejected. Belt delivers to a 4-ton, hopper-bottom dump car (*d*). This loader delivers lower-grade ore than hand loading; its use appears justified only during labor shortages. For details, see Bib (482), and Sec 27

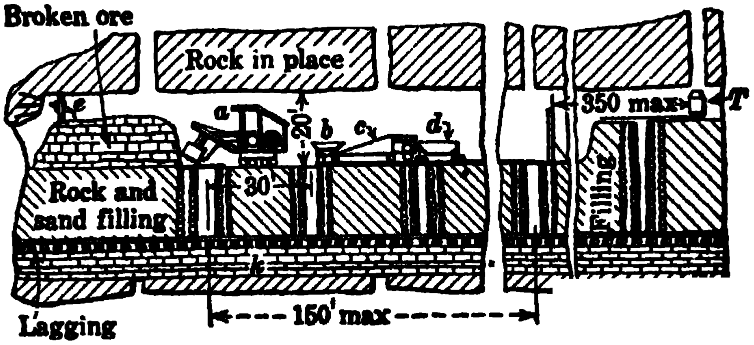


Fig 402. Mechanical Loading, Champion Mine

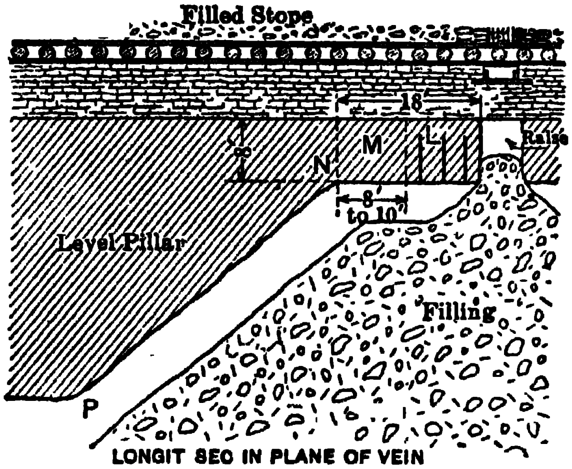
Breaking ground in flat-back stopes is done with breast holes 7 to 10 ft deep (Fig 400, 401). W. H. Schacht in 1923 (555) states that breaking ground is done in horiz slices 4–5 ft high. One row of flat holes is drilled across the back; distance between holes, 5 ft; depth, 7–10 ft. Drifts, of full width of lode (10–30 ft) and 10 ft high, are advanced by first blasting a cut at one side of the drift, then taking successive vert slices across the face. Slices are 18–24 in wide. Depth of holes, to 10 ft; 20–40 holes are required to square a cut, depending on width of drift, character of ground and copper content. Heavy, mounted, wet hammer drills are used in both stopes and drifts; 30% ammonia powder in stopes, 40% in drifts. Distance between back and top of filling affects HEIGHT OF BACK-STOPES taken; enough muck must be made to afford a place to set up drills; for usual relations between these factors see Fig 401; if filling is low, a high pile of broken ore may be obtained by working 2 back-stopes simultaneously, with their faces close together.

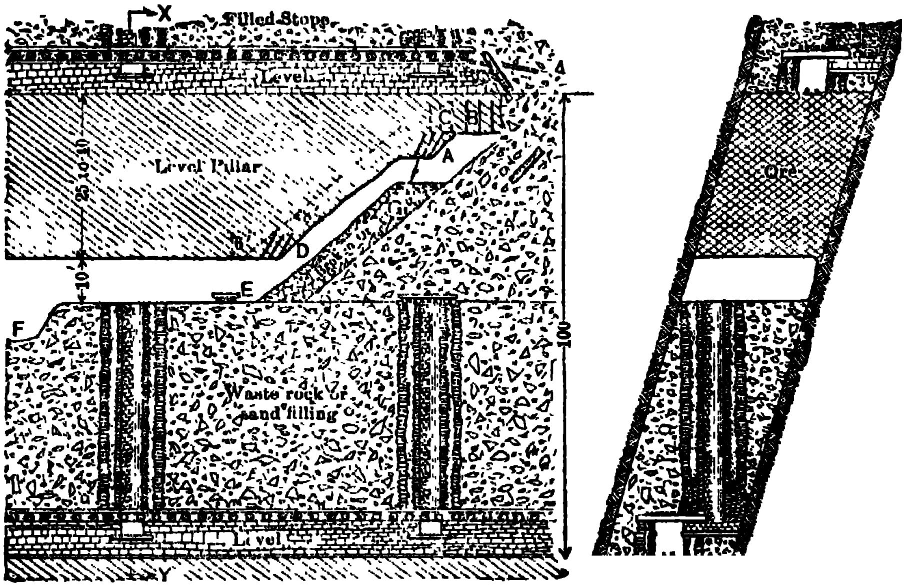


LONGIT SEC IN PLANE OF VEIN

Fig 403. Mining Level-pillars, Baltic Method

Mining level-pillars (locally, "caving pillars"). Work begins at a raise at the boundary, or at a point midway between shafts, and retreats to shaft-pillars.

A rill stope (Art 38, 65) is started from bottom of the raise; cuts are inclined at angle of repose of filling, which is 40°; miners work on waste, which is dumped through raise as fast as ore is sorted and removed. Stope is enlarged to dimensions as in Fig 403; all broken ore is then cleaned up and portion *L* of the 8-ft pillar remaining under the level is shot down from wall to wall. This allows dry-walls and filling in old stope above to drop; projecting stub *M* of the 8-ft pillar keeps open a vert space 6 or 7 ft high along face *PN*. Rock-filled cribs are put in at toe of stope, when needed. Rest of level-pillar is mined as in Fig 404. Stope-drills are used, putting in 5 to 6 half-uppers, 6.5 to 7 ft deep per drill-shift. Usual crew, 2 machine-men and 2 sorters. After round at *A* is blasted, holes *C* are drilled. Then all broken ore in *G* is sorted out and removed; 3 men may take 1 or 2 weeks in cleaning up the stope. Next, round *B* is blasted; waste runs in from above; sloping face of stope is kept open by the stub of pillar left at *C*, and process is repeated. Holes at *D* for starting a new slice may be drilled before broken ore is removed and while the back there is easily accessible. Practice of drilling holes at *C* before they are needed is a safety pre-



LONGIT SEC IN PLANE OF VEIN

CROSS-SEC X Y

Fig 404 Mining Level-pillars, Baltic Method (Diagrammatic Sections)

caution, as the stub must stand for a considerable time and the ground becomes dangerous to work under. In narrow parts of lode or in strong ground, rill stopes for mining level-pillars may be carried with stepped faces (Art 38). Ground is broken with breast holes, which are more effic than uppers in this lode, but barring down takes longer, and this method is not so safe as that in Fig 404.

Sorters work at *E*, and along face of pile of broken ore; waste rock may be piled at sides of stope or dumped at *F*. Two chutes must be kept open, one for ore and one for a ladderway. At the end of a stope, a mill is built close to the shaft-pillar and another about 25 ft away; when toe of fill covers the latter, stoping is stopped and the remaining piece of level-pillar is abandoned. Ore from stub ends of pillars *B* and *C* (Fig 404) mixes with waste, which rushes in from above when they are shot down; about 50% of this ore is lost in the filling. Filling drawn downward in mining level-pillars is replenished by waste from development, dumped into stopes at surface or from an upper level. Filling will readily work down through 5 9 levels; hence, at intervals, levels must be kept open for tramming waste in stopes below. Pillars under these levels are perforated by raises. Best height for level-pillars is about 35 ft; smaller heights do not take full advantage of low cost of ore from pillar-mining; if higher, the back may become bad before top cuts can be taken, and it is difficult to work broken ore down the longer slope of the filling to the sorters. If patches of unmined low-grade ore occur over a level-pillar during stoping, raises are carried up through such areas to tap the filling in stopes above.

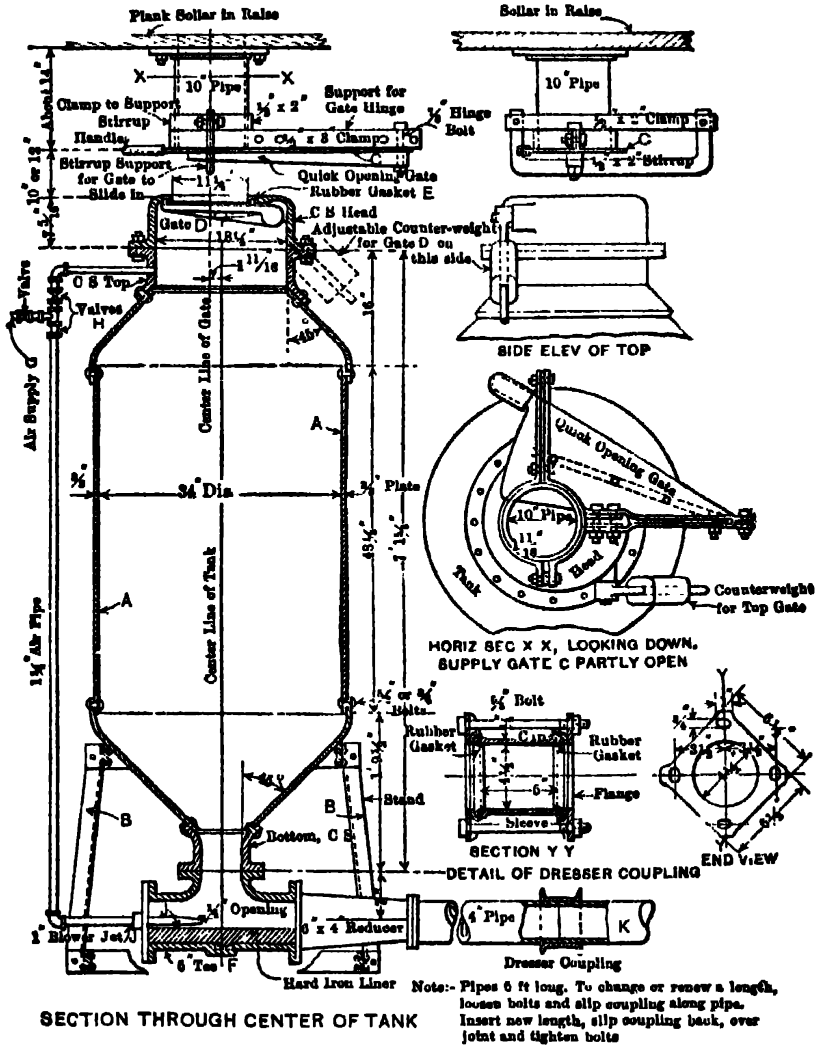


Fig 405. Sand-blowing Tank, Champion Mine, Mich (F. W. Denton)

Sand-filling. Mill tailing, called sand, is hauled back to the mine in 40-ton R R cars, to supply some of the excess filling required in flat-back parts of stopes.

At Champion mine, the sand is dumped at surface into a raise, roughly parallel to No 4 hoisting shaft and extending to 17th level. Sand is drawn at any desired level through chute-gates into 36-cu ft, bottom-dump, hopper cars, moved by electric haulage. Where sand-filling is practiced

levels are connected to stopes below, at intervals of about 300 ft, by 4 by 4 to 4 by 5-ft raises through which the sand is dumped. SAND-BLOWING TANKS, operated by compressed air, have been used to distribute the sand laterally in the stopes (Fig 405, from F. W. Denton). Cylindrical tank *A*, on a light angle-iron frame *B*, is set on top of fill under a raise, as at *T*, Fig 402. Bottom of raise is closed by a sollar, to which gate *C* is attached. Opening at top of tank has a counterweighted gate *D*, which makes an air-tight closure against gasket *E*. Tank terminates at bottom in a tee *F*, connected to a line of 4-in pipe *K*, laid on surface of completed fill and moved or extended as necessary. The Dresser coupling is important, in allowing the pipe line to be deflected slightly at each joint. A connection is made at *G* with air line supplying the drills; valves *H* admit air to top of tank and to blower jet *J*. OPERATION: A tank of sand (1.5 ton) is drawn from raise through gate *C*; compressed air is turned on, forcing gate *D* tight against its gasket and putting the sand in tank under pressure. Under combined effect of this pressure and the blower jet, the sand is forced through pipe line *K*. When tank is empty, air is shut off and a new charge of sand drawn in. By shifting the pipe line, the end of a new layer of filling is built up across full width of stope.

Tank is operated by 1 man; it works successfully with pipe lines 100 ft long; at 70-lb air pressure, some sand is thrown about 20 ft beyond end of a 70-ft pipe line. Observations on 15 runs (with a 28-cu ft tank, air pressure about 70 lb and 65 ft of pipe) gave following time results: for filling tank, 20 to 35 sec; for adjusting valves, 20 to 30 sec; for blowing sand, 1 3 to 1.5 min. 500–1 500 cu ft free air is used per ton of sand. Speed of work varies with percentage of moisture in sand and with length of pipe. Life of pipes is 4 to 6 mo; wear is greatest with dry sand; pipes are turned frequently to distribute wear and obtain max service.

Recent stoping method. Data from A. Mendelsohn (488) in 1931. Method combines principles used in pillar mining (Fig 404) with those of sub-level stoping (Art 43). Raises are 200 ft apart; from them, at points 33 ft and 67 ft above rail, sub-drifts are driven in both directions, at the full width of ore. Power scrapers, with 15-hp engines, deliver ore to raise; loose ground is supported on props, with 6-in headboards. Stoping is shown in Fig 406. Miner drills holes parallel to angle of repose of fill (about 38°) using 4–6 holes across stope, depending on its width; holes are 10–12 ft deep, with 3-ft burden. Round is blasted against the fill. "Copper rock" is sorted out, loaded into a small car and trammed to raise. Breast advances up slope to within 4 ft of waste above; last round is drilled, but blasting delayed until sorting is completed and cut ready to be filled. Most copper rock from final round is found at bottom of fill after blasting. During 1930, on basis of all underground labor, 3.04 man-hr were required per ton of ore; explosive, including that used in development, was 1.3 lb per ton; exclusive of development, 0.8 lb per ton.

64. CROSSCUT METHOD

Crosscut method is used for wide veins or masses, with weak walls and weak ore which will stand unsupported only over small openings. Ore is mined in horiz slices, in ascending or descending order and in small sections, each section being filled before the next is begun.

a. Slices Taken in Ascending Order

Development (see Fig 407) consists of footwall drifts *D*, crosscuts *E*, shaft *F*, and raises *G* to connect drifts at intervals of 40 to 60 ft. A slice is removed as in section *X Y*. From *D*, crosscuts *A* are driven to hanging wall and filled through *G* with waste from level above. Crosscuts *C* are driven and filled; finally portions *B* are mined and filled. By breaking down the back of *D*, another footwall drift is then formed, from which a second slice is taken by driving and filling crosscuts, and so on to top of the lift. *D* is kept open by timbering or dry-walling for handling ore from lift above and filling to lift below; footwall drifts for upper slices are filled as soon as the slice they serve is mined. Broken ore from upper slices is handled to *D* through chutes *H*, built up through the filling as stoping proceeds. Several slices in a lift and several lifts may be worked simultaneously, provided workings in upper slices and lifts are kept in advance of those below.

Ore and filling are handled in crosscuts by shoveling, or in barrows or small cars; much of the filling must be shoveled into place in the crosscuts.

In some cases, successive crosscuts are contiguous instead of being driven in groups of 3 as in Fig 407; then, if ground does not require immediate support, waste may be sorted out in a crosscut and thrown back into the previous one (245).

Crosscuts are 6 to 8 ft high, and 6 to 10 ft wide, or as wide as strength of ore allows. Where necessary, they are timbered with light sets, or stulls and head boards, side-lagging being used to prevent runs of filling into adjacent workings.

Fig 408 shows timbering at the PROPRIETARY MINE, Broken Hill, N S W, where this method has had a limited use. 10 by 10-in struts *S*, running along the sides of crosscut, are supported by corbels on the posts; the back is carried by lagging on cross-pieces *D*; diagonals *E* are put in where required by pressure. Sets are about 6 ft apart; their size depends on character of ground and length of timber available. About 67% of the timber used is recovered on opening a new slice. The tapered shape of posts and the hole *H* (for inserting a piece of drill steel) aid in withdrawing them; or a chain and lever may be used (240).

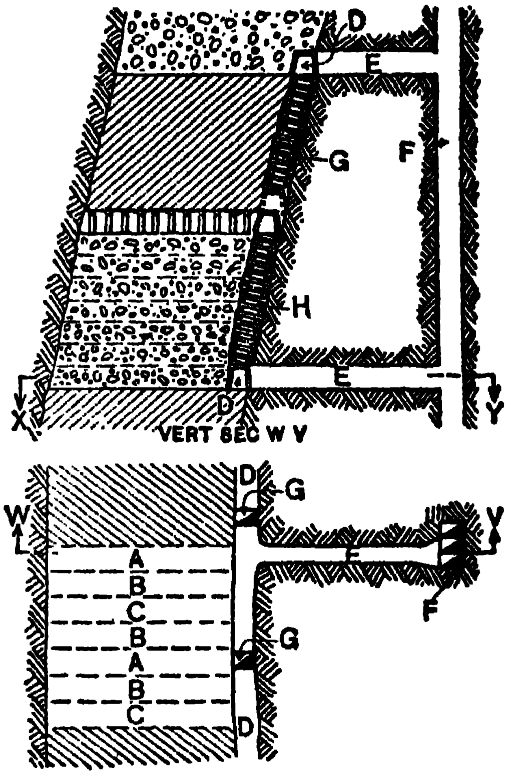

Fig 407

Breaking ground. First openings in lowest slice of a lift are driven like drifts (Art 20); adjacent crosscuts cost less, as ore is free on at least one side. Upper slices are broken cheaply, as the ore is always free on the bottom. At CABEZAS DEL PASTO MINE, Spain (248), contract price for mining the lowest slice averaged 50¢ per ton; for second slice, 25¢.

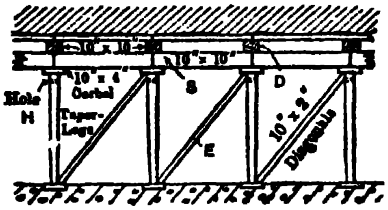

Fig 408. Crosscut Timbering, Broken Hill, N S W

Mining topmost slice under overlying filled stopes requires care. Plank or lagging may be laid on floors of crosscuts in bottom slice, to prevent runs of filling when stope comes up from below; sometimes filling becomes so compact that this is unnecessary. Top crosscuts may be spiled under loose filling.

Level interval. The maximum is usually 65 to 70 ft (246). Filling can not be packed absolutely tight into crosscuts, and each layer settles somewhat under weight of the back. Successive subsidences cause ore above to crush, and increase difficulty and cost of mining upper slices; this effect increases with height of lift and weakness of ore.

At CHAPIN MINE, Mich, where this method was formerly used, settlements of 10 ft in a 100-ft lift are said to have occurred (247). At CABEZAS DEL PASTO MINE, Spain, the filling was coarse quartzite, quarried on surface, and so firm that no subsidence of surface was noticed (248). In some places subsidence occurs because the top slices of lifts are incompletely filled.

Several variations are possible. Haulage drifts *D* (Fig 407) need not be on footwall, but may be in any part of deposit or in wall rock. Crosscuts *A*, *B*, *C*, may run in any desired direction through deposit; large horses of waste may be left in place. Fig 409 shows application to an irregular

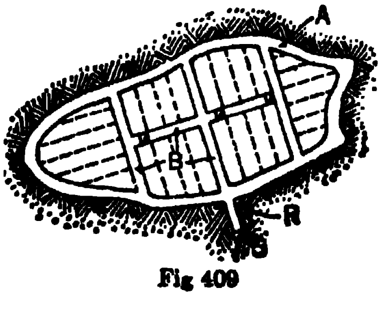

Fig 409

massive deposit, opened by shaft *S*. Usually first work on a level is to outline orebody with a closed drift *A*; then haulage drifts and crosscuts *B* can be placed in best position; one arrangement of crosscuts for slicing is indicated by dotted lines. At least one main waste raise *R* is desirable. For further detail and other variations, see Bib (240, 245–249).

b. Slices Taken in Descending Order

Practice at Tiro General mine, Charcas, Mex, illustrates this variation of crosscut method. Data from H. Willey (241) in 1930. Ores are complex sulphides with varying amounts of sphalerite, argentiferous galena, and chalcopyrite. Principal orebody occurs in fissure vein dipping about 70°. Stoping widths are from a few ft to 90 ft, aver about 30 ft. Both walls generally weak, and ore badly fractured. Top-slicing (Art 72) was not adopted because of necessity of maintaining upper levels. DEVELOPMENT consists of footwall drifts at 100-ft vert intervals, and 10–12 ft outside of vein, connected by 2-compt footwall raises 100 ft apart, and not less than 6 ft outside of vein; footwall drifts and raises are made to conform to vein irregularities by driving pilot drifts in the vein, with crosscuts 100 ft apart. Raises are timbered with 2 independent sets of cribbing of 10-in round timber, with 3-in plank lining, leaving clear openings 3.5 ft square; in damp places, this timber is creosoted. SILL FLOOR is developed by square-setting with 8-in round timber, 5 ft c–c. No sills are placed under the posts, but sills of two 3 by 10-in pine planks, best not less than 10 ft long and overlapping not less than 2 ft at joints, are laid from foot to hanging wall between the rows of posts, resting evenly on broken ore tamped under them. Space between sills is then leveled with broken ore, on which a floor of 2-in plank in 5-ft lengths is laid, their ends resting on the sills; gaps between posts are covered with short pieces. Square-sets are back-filled to within 2 sets of working face. SLICING. To start the first slice, a 6.5 by 5-ft crosscut is driven from the ore pass 12 ft vert below sill floor, penetrating about 6 ft into vein (Fig 410). From its end, narrow footwall drifts run 50 ft in both directions, taking the 12 ft of ore up to the sill floor, vert 10-in posts 5 ft c–c being used to catch up the sills above; these posts are 11 ft long, large end up and squared, with head-blocks 10 by 10 or 8 by 8-in; posts are wedged at bottom, which need not be squared, and set without sills or footboards. If footwall is slippery, the drift may be driven farther out in the vein; or if vein is so wide as to require more than usual time to complete a slice, the drift may be timbered with battered posts and caps, salvaged later. These sub-level footwall drifts are no larger than absolutely necessary, as they have to remain open until slice is finished. From one end of sub-level drift, a crosscut runs towards hanging wall, catching up the overhead sills with 11-ft posts and 10-in headblocks, 5 ft c–c.

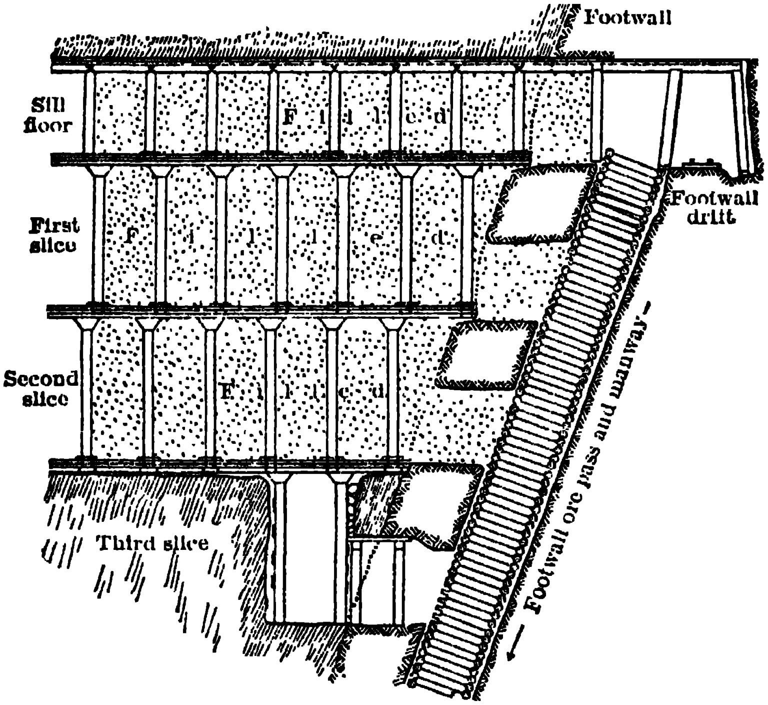

Fig 410. Sec through Ore Pass, Tiro General Mine, Charcas, Mex (241)

As this crosscut nears completion, a second and adjoining crosscut is begun. The 10-ft space thus opened is floored with sills and plank as on the sill floor. Between the last 2 sets in the sub-level drift, 6 ft above the floor, a crosscut is driven into the footwall; from its inner end an inclined raise is put up to the side of footwall drift on main level, cribbed with 8-in round timber and lagged to give 2 independent chutes 3 ft 7 in by 2 ft 8 in clear; one is a manway, other a waste pass. Waste from this work is piled to depth of 6 ft on floor, supported at sides by 2-in bamboo poles (cheapest available material) laid against the posts. Successive 5-ft segments across the orebody then follow similarly. When one segment has been filled to 6 ft, back-filling to full height begins at hanging-wall end; space of one set nearest footwall is left open for handling waste in barrows to remainder of slice, this passageway being filled last when slice is finished. Meantime, similar extraction and filling has begun at other end of 100-ft block; one end of next lower slice can thus be started before upper slice is finished. Fig 411 shows stages of stoping.

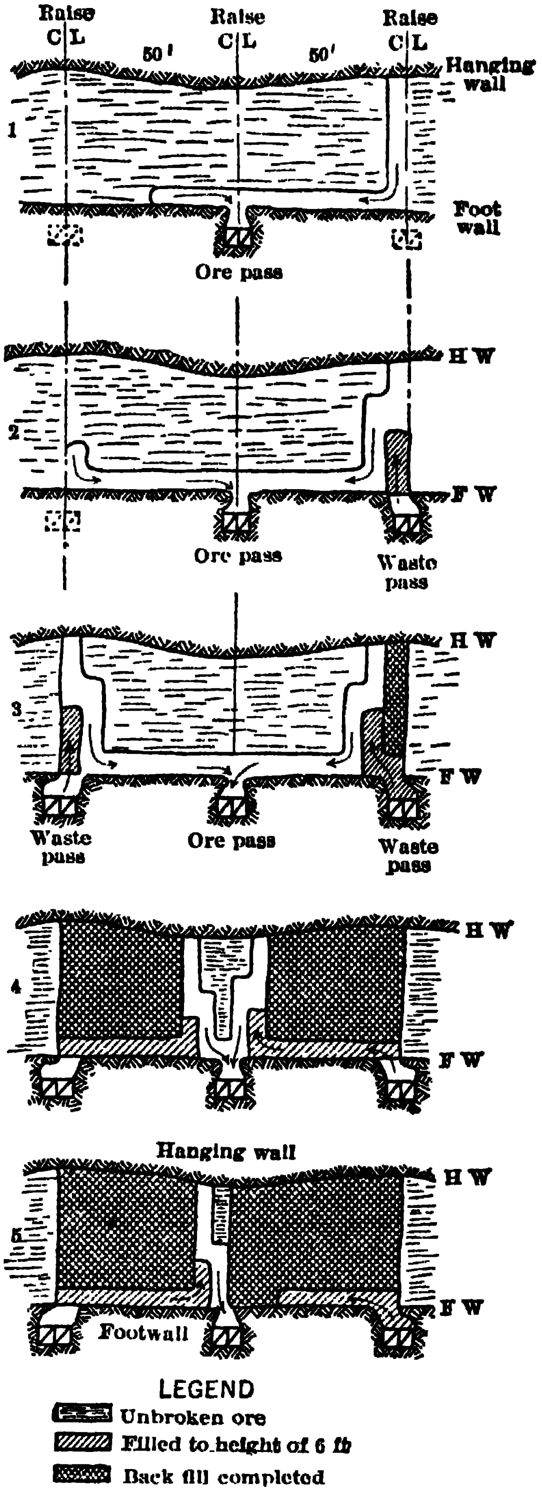

Fig 411. Tiro General Mine, Charcas, Mex (241). Plan of stope floor, showing 5 stages of mining

Success of this method is due largely to avoidance of permanently open passageways through filling; uniform transfer of pressure to filling is also aided by deliberate lack of vert alinement of posts and absence of sills or stringers under them. Simplicity and routine operations are favorable features where labor is unskilled. Nearly all timber is lost, but is less in amount than by square-setting. Compared with former square-setting, saving in cost per ton by slicing method is estimated as follows: In new ore: labor, 10.6¢; explosives, 0.8¢; timber, 41.1¢; total saving, 52.5¢. In old workings: labor, 10.2¢; explosives, 1.1¢; timber, 27¢; total saving, 38.3¢.

Output per man-shift is about the same (1.44 ton in new ore, 1.34 ton in old workings) as with square-setting. Aver output (12 shifts per week) from a 100-ft block is about 1 000 tons per mo. Recovery is practically 100%, compared with 95% from square-setting.

c. Summary, Crosscut Method

Crosscut method allows safe and complete extraction of large, weak orebodies of almost any shape, without serious surface subsidence. Cost of development is high, owing to the small level interval and frequent necessity for driving haulageways and waste raises in country rock. Cost of shoveeling larg amounts of ore and filling is unfavorable to use of this method in the U S. Timber consumption is low, if ore will stand over back of a crosscut until it is filled; even in weaker ore, less timber is used than in top-slicing (Art 70–74) or filled square-sets (Art 46), which are alternative methods affording complete extraction; caving methods are preferable if surface need not be supported.

Crosscut method is sometimes advantageous for mining level-pillars in bad ground over filled flat-back stopes. At Rio Tinto, old pillar and chamber workings (Art 42) were re-mined by this method (549)

65. FILLED RILL STOPES OR INCLINED CUT-AND-FILL STOPES

General data are given in Art 38 (Fig 222, 223). Filling is run into a rill stope through the raise from which it was opened, which enters the stope at its highest point. Filling is distributed largely by gravity. By inclining the stope backs at the angle of repose of filling, the surface of the filling will be parallel to back of stope (Fig 412), and therefore convenient for supporting men and walls; a sloping surface of fill also aids in moving broken ore to chutes.

In narrow stopes, little or no shoveling may be required for handling filling or ore. In wide stopes, filling builds up cone-shaped under the raise and must be moved to sides of stope by shoveling or mechanical scraping; similarly, broken ore must be moved from sides of wide stopes to chutes. See examples below for modes of reducing shoveling in wide stopes. For field of use, see below; also under Comparison with flat-back stopes, Art 66.

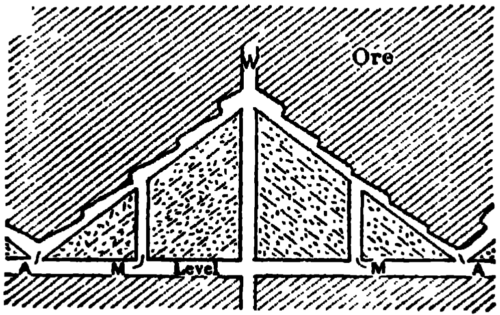

Fig 412. Starting Rill Stopes, Kalgoorlie

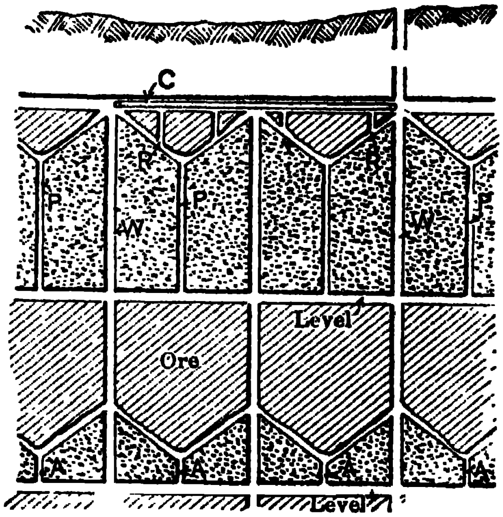

Fig 413. Rill Stopes, Kalgoorlie

Kalgoorlie, Australia (251, 257, 258, 146). This is an old but classic example of this method. Filled rill stopes were used in narrow, vein-like deposits of gold telluride ores, occurring as lenticular shoots of quartz or mineralized country rock, chiefly in amphibolite schist. Method was not applicable on dips flatter than 35°; usual dips were steep. DEVELOPMENT. Ideal plan was to run levels 200 ft apart, connected by winzes *W* (Fig 413) at intervals of 150 to 200 ft; winzes were sunk on hanging wall to minimize handling of filling. A flat cutting-out stope, 7 ft high, was taken. Levels were timbered with stulls for widths to 14 ft; for greater widths, with saddle-back stulls (Art 38). Stulls were 5 ft apart, and lagged with 4-in poles covered with old filter cloth, pieces of cyanide cases, etc, to retain fine filling. Chutes were started about 50 ft apart, at points *A*, midway between winzes *W*, and at quarter points *M* (Fig 412). STOPING AND FILLING (Fig 412, 413). Slope of stope face was about 37°, and rill cut was generally adopted (Fig 223, Art 38). Stopes 10 to 14 ft high were first opened at foot of winzes *W*. Broken ore was loaded into cars in level, through spaces made by taking up 1 or 2 lagging poles, and waste was dumped in through winze from level above. Subsequent inclined slices were 8 to 11 ft thick; operations of stoping, cleaning up broken ore, and filling alternated. Tops of chutes *M* were kept level with filling. When adjacent stopes finally intersected above points *A* (Fig 412), chutes *M* were abandoned and all broken ore was handled through chutes *P* (Fig 413). Chutes were 4 by 4 ft clear, usually cribbed with 7-in round timber; occasional manways were provided by building 2-compartment chutes. Cribbed chutes were also carried up on line of original winzes *W*, if these were used for running filling to lift below. Sand (mill tailing), used for filling, was stacked on surface until moisture content was less than 25%; if wetter it tended to clog winzes. Belt conveyers were often used to distribute filling, as at *C* (Fig 413); then only one winze needed to reach the surface. Even with winzes on the hanging wall, some filling always had to be shoveled in stopes to edge of rill. In rich ore, plank floors were laid on faces of fill to avoid loss of fines and help ore to slide to chutes; old filter cloths were sometimes laid under the floors. Floors were usually omitted, involving the removal of a few inches of filling with the ore from each slice (83). Stopes near top of lift could not be filled through original winzes *W*; auxiliary raises *R* (Fig 413) were put up to handle filling.

Park City Consol Mines Co, Park City, Utah. Data from G. M. Wiles (244) in 1936. Fissure veins in quartzite carry high-grade silver ore, with small amounts of Au, Pb, and Zn. Vein gangue is largely massive and sugar quartz, or uncemented conglomerate-like rock. Walls vary in strength from blocky quartzite to a shattered gravel-like material.

Dips, 50°–75°. Vert shaft was sunk to 400 level; from which 2 inclines follow separate veins to 900- and 1 000-ft levels respectively (1936). Level interval, 100 ft. Original stoping was by shrinkage (Art 68); change to inclined cut-and-fill was made because of serious dilution and loss of ore in shrinkage mining. Open stulled stopes are occasionally used in narrow veins. Drifts under stopes are timbered as in Fig 414; timbers, set in hitches, permit recovery of level pillar below without disturbing the drift. Inclined cut-and-fill stopes are opened by driving, at 100-ft centers, 3-compt raises, middle compt being a manway. Chute-pockets in drift sets are 15 ft c-c. Stoping cuts start from raises and are carried on a slope of 50° (Fig 415). Drilling is with hand-rotated stopers; holes are usually short, but may be 8-ft deep where walls are firm. Explosive, 30% gelatin dynamite. Before starting new cuts, waste is run into stope to within about 2 ft of back; 2-in flooring is laid on the waste before breaking new cut. Height of cut is 6–12 ft, depending on strength of walls. On completing a cut, floors are swept and taken up before another run of waste is added. Stoping labor is about 1.44 man-hr per ton; explosive consumption, 0.55 lb per ton.

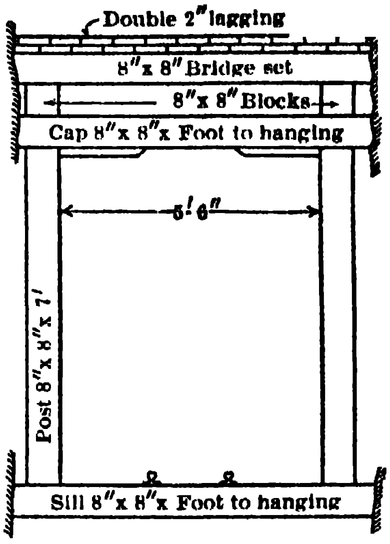

Fig 414. Gangway Timbering, Park City Consol Mine, Park City, Utah

Wright-Hargreaves mine, Kirkland Lake, Ont. Data from L. B. Smith (176) in 1934. For geol features and other data, see Art 39. Inclined cut-and-fill method has been used on both North and South veins. Level interval, 150 ft. Raises *R* (Fig 416) are 300 ft apart. Backs of drifts are first taken down, and sill timbers placed (Art 39). Chute-pockets *P* are 15 ft apart. Stoping starts on each side of raises; face is in steps 8 ft high and 10–12 ft long, giving general slope of about 40°. Waste filling is brought to within 4 or 5 ft of edge of cut. Flooring of half-rounds is laid on the fill. Miner starts on lowest bench, takes 2 rounds ahead and moves up to next bench. When raise is reached, the cut is complete; broken ore is then drawn and roof scaled. Flooring is lifted and stored on stulls

close under the back, until ready to be relaid on new fill. When cuts from adjacent raises meet, manway *M* is maintained, with a chute on each side. When the stope breaks into the level above, stulls are used to support haulage-way timbers; normal haulage continues on level broken into. Method of stoping has been found safe, rapid, and economical.

Victoria mine, Britannia Beach, B C. Data from C. V. Brennan (498) in 1935. Fissure veins carrying chalcopyrite occur in highly fractured volcanics. Ore and walls are generally weak; square-set mining is used chiefly, but many narrow veins are adaptable to inclined cut-and-fill. Distinctive feature is mode of breaking ground; holes are drilled toward chutes, at angle of 20° below horiz (Fig 417). Cribbed chutes and manways are of 10 by 10-in timber. Fig 418 shows sill timbering. For descriptions of this and other methods (chiefly shrinkage) at Britannia Beach, see Bib (562, 592).

Butte district, Mont. Data from H. L. Bicknell, W. B. Daly and others, 1921–1923 (534). For ore characteristics, see Art 46. Normal level interval is 200 ft; when orebody is wide and near shaft, 100 ft. Filled rill stopes used in narrow veins, where ore and walls require no immediate support. Fig 419 shows mode of starting a rill face by taking 3 successive 8-ft slices *X*, *Y* and *Z*, each starting at the raise and advancing toward middle chute (Fig 420). Slices are 6, 4 and 2 sets long respectively. Ore from these is handled through stop boards laid on caps of sill sets. Then sheeting *S* (Fig 419) of 4 by 10-in plank is placed 30 in above sill-set caps and supported by 10 by 10-in posts, caps, and stringers; this protects sill timbers from wt of the fill, and permits repairs without interfering with tramming. Lagging is nailed to stope side of raise, a bulkhead is put in raise near peak of stope, and waste is run into stope to within about 5 ft of the back. Fig 420 shows a stope fully opened, with the middle chute built up; two methods of breaking ground are indicated. Fill is covered with 2-in plank laid on cross pieces of 2-in lagging before blasting. Ore is sorted on grizzlies over the chutes; for details see Art 90. When upper ends of rill stope reach to within 5 sets of level above, the remaining *V* is usually mined as a square-set rill stope (Art 46). Square-sets stand on sills laid across the stope; sills are embedded in the waste, and held from sliding down the sloping face by girtwise braces and blocking to the walls. By similar methods a stope can be changed at any elevation into a square-set rill stope, if weak ore or walls are encountered. The level-pillar, 5 sets high, at top of stope is mined by ordinary square setting.

Fig 418. Typical Sill Timbering, Victoria Mine, Britannia Beach, B C

Parral, Chihuahua, Mex. Data from A. H. Hubbell (194) in 1936. Lead-zinc ore occurs in fissure veins in andesite. Width of ore, 10–125 ft. Shrinkage is used where possible, but inclined cut-and-fill where ore is wide and walls are bad. Fig 421 shows novel application of latter method. Chute raises 15 meters apart are driven from drift in ore near hanging wall, or from crosscuts, as in Fig 421; ore is silled out above level, leaving a pillar 3.5 meters thick. First cut is 8 ft high; second, 6–8 ft; ore is scraped to chutes. Fill raises *R*, 30 ft apart, are driven from back of cut to level above, being located midway across the stope width or near hanging wall. A footwall drift *D* is driven on the level 2–3 meters in footwall and footwall raises *F* from this drift connect the levels at 30-meter intervals, midway between the fill raises. From raises *F*, branch chute-raises *B* are driven to the stope, starting just above back of footwall drift. After fill has been run into the initial stope cut, lines of square-sets are started on the fill opposite each chute raise from the footwall drift. Each line of square-sets forms a trench, the top of which is always at bottom of the rills. Ore broken from faces of inclined slices runs to the trenches, where it is diverted to footwall chutes. Grizzlies at top of the trenches restrict the size of boulders delivered to chutes. As stope advances upward, the initial footwall chutes are replaced by others driven successively at higher points from main footwall raises, as in Fig 421, Sec C–C.

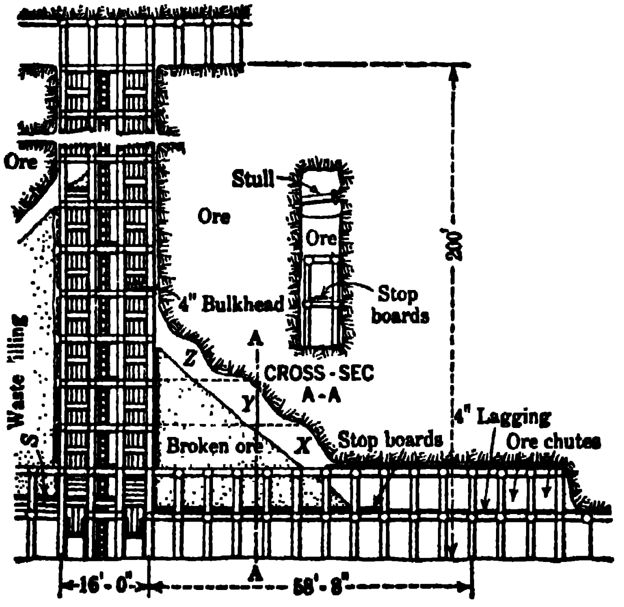

Fig 419. Opening a Rill Stope, Butte Distr, Mont (534)

Campbell orebody, Phelps Dodge Corp, Warren, Ariz. Data from H. M. Lavender (91) in 1930, and from Robert Lenon of Co's Copper Queen Branch in 1938. Orebody is a massive-sulphide replacement deposit in limestone; ore minerals, chiefly chalcopyrite and bornite; gangue, limestone, silica, and pyrite. On 1 600-, 1 700-, and 1 800-levels, orebody is about 500 ft long; width, 50–250 ft; continuous from 1 400- to below 2 300-level. Dip is generally steep, but varies locally from 25° to 90°. Footwall usually well defined; hanging wall, subject to greater irregularity, varies from an economic limit of low-copper content to a sharply defined limit conforming with local bedding planes. Grade of ore is

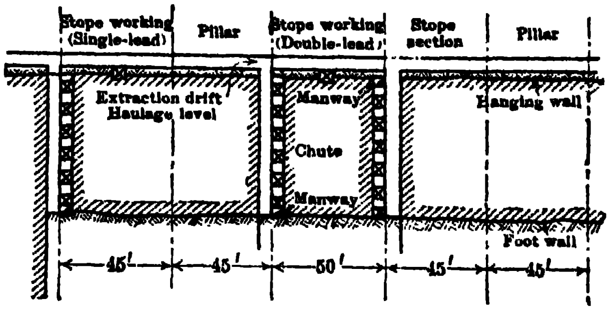
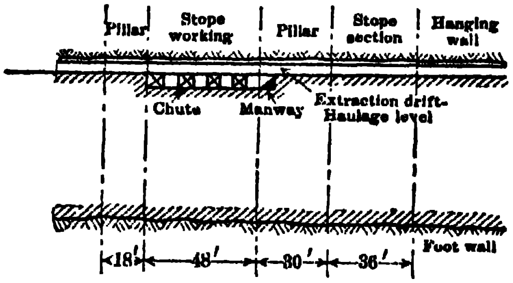
relatively high and calls for mining method giving high extraction. Homogeneous nature of deposit obviates need of sorting. Both ore and walls are strong. The hard ore requires heavy blasting, to avoid making too many boulders. DEVELOPMENT. There are 2 vert hoisting shafts, and 2 ventilation upcasts. Level interval is about 100 ft; alternate levels are equipped for trolley haulage. Haulage-level drifts and crosscuts, 6 by 8 ft to 7 by 9 ft, have 18-in gage track of 25-lb rail, with curves of 22.5 to 30-ft radius. Intermediate-level drifts and crosscuts, formerly 5 by 7 ft, are now 6 by 8 ft, with 16-lb rail. Level development depends on size, shape, and dip of orebody, in accordance with stoping plans. GENERAL PLAN OF STOPING. Orebody is divided along the strike into stoping and pillar sections; the former mined by inclined cut-and-fill; pillars usually recovered by Mitchell slicing (Art 55). Until recently, the orebody was divided into 2 adjoining stope sections, each 45–50 ft wide, separated from the next 2 sections by a 45-ft pillar (Fig 422 A), the Mitchell slices in pillar mining running strikewise. More recently, orebody is divided longit into alternate stope and pillar sections of 36–48 ft (6–8 sets) and 18 or 30 ft, respectively (Fig 422 B); 18-ft pillars are mined by full-width slices as far as practicable; 30-ft pillars are to be split by a row of "single-leads" (square sets), the resulting 12-ft pillars mined by Mitchell slices. Stopes are usually mined in lifts of 200 ft, from one haulage level to next above, with pillars one above another. Stopes are mined as single sections from wall to wall, where width of ore does not exceed about 75 ft. Where, as above the 1 600-level, width of orebody is greater (to 250 ft), stopes are sectionalized crosswise, the sections separated by a vert plane running strikewise.



A-Former system of sectionalizing, with two types of stope development

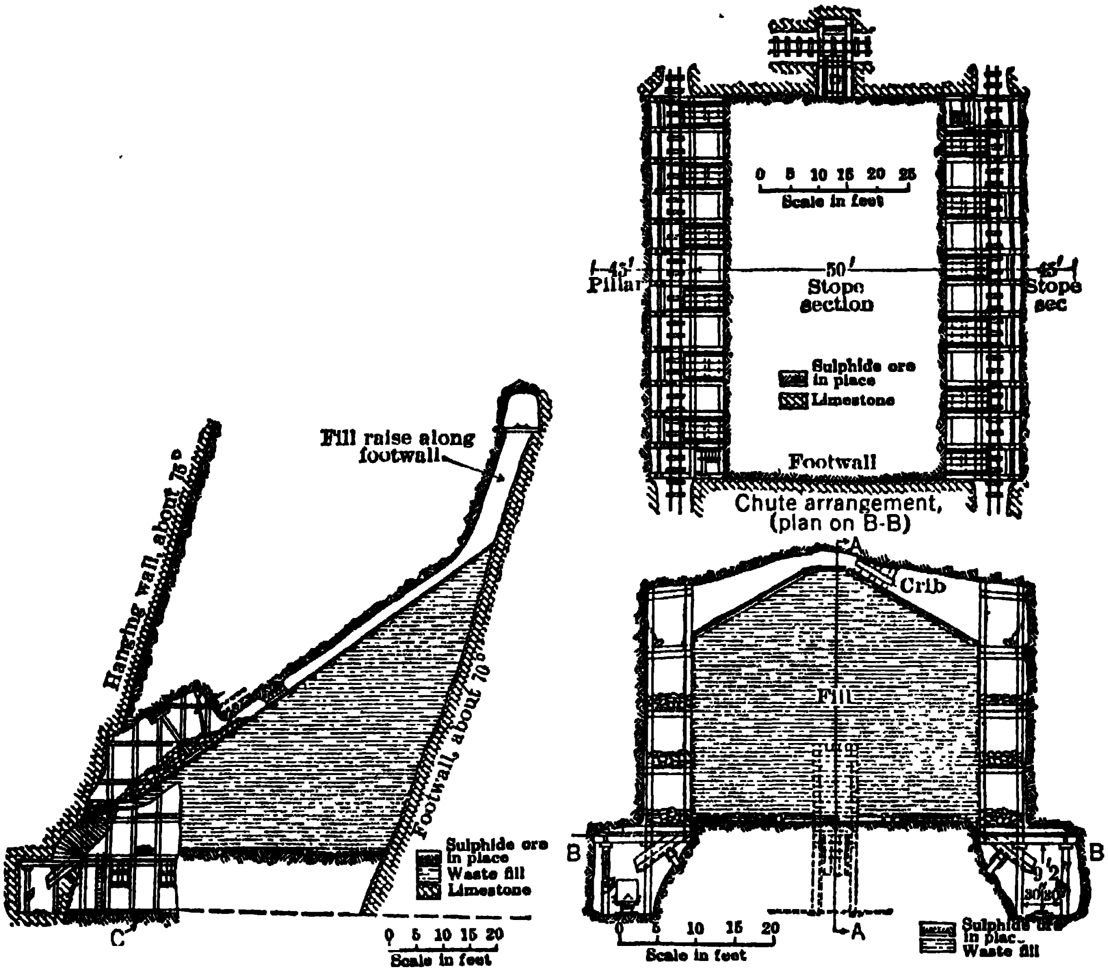


B-Present system of sectionalizing, with development for stoping

Fig 422. Systems of Dividing Orebody into Stope and Pillar Sections, Campbell Orebody, Warren, Ariz

Double-lead stoping. This method, employed prior to the more general use of scrapers, required more timbering than present method to avoid hand shoveling to chutes. From a hanging-wall drift, crosscuts were driven along the outside of the 2 section lines forming the strikewise stope limits (Fig 423). These crosscuts were then enlarged for standard sets ("stringer sets"). Posts were 9 ft 2 in long, their faces being 30 in from center line of track. Bottoms of posts were 6 in below rail. Crush blocks, 6 by 10 in and 20 in long, were placed on top of posts, and over these was laid a 10 by 12-in cap-like stringer, about 13 ft long, with the greater dimension vert. This gave a distance of 9 ft 2 in from rail to stringer. Sets were 5 ft c–c, with chutes in alternate sets. Silling started slightly above tops of stringers. During initial cutting-out between lead sets and shaping the back for initial fill, ore was allowed to pile up to form a natural slide toward each lead. The stope back was arched transversely and inclined upward from hanging to footwall. Initial stoping included driving a fill raise along footwall and on center line of the stope section, the raise holing to the intermediate level above and often extending to next haulage level. Before the first fill, lead sets were started along the stope boundaries. Posts, 10 by 10-in and 7 ft 4 in long, were placed along the outside of each row of sets; posts on the inside row were also 10 by 10 in, but 7 ft 7 in long. The difference of 3 in in length allowed for settlement in the rows next to the fill. Before filling, the stope bottom was covered with a mat of scrap timber, sometimes laid on sills. "Lead sets" were lagged on the fill side with split lagging 3–4 in apart, or 2 by 12-in planks edge to edge. An advantage of the latter was that the gob, in settling, tended to slide along the smooth surface and thus reduce vert pres on the sets. As the stope advanced upward, the lead sets served as chutes. Fig 423 shows a separate chute carried from hanging-wall drift to supplement the chutes formed by the lead sets. Grizzlies of 10 by 10-in timber, spaced 10 in apart, were placed across the lead sets at elevations corresponding approx with the intersection of sloping surface of the fill and the lead sets. With the filling of subsequent cuts and raising the lead sets, these grizzlies, unless badly worn, were moved to the grizzly floor above. Occasional sets within the leads were left covered with worn grizzly timbers, or 4-in flooring, and broken ore was allowed to remain thereon to prevent a direct fall of ore through the sets, thereby reducing wear on the timbers. On completing a given cut, waste was dropped

through the fill raise and assumed its natural angle of repose (about 37°), the stope back approx following this angle. The fill was brought within 2-3 ft of the stope back and covered with 2 by 10-in or 2 by 12-in flooring laid on 2 by 10-in sills placed flush with surface of fill. Flooring usually began 10 ft above lower edge of fill and continued to the top. Spillage of waste from flooring operations rolled to bottom or unfloored section, which was finally floored. Cuts, started at bottom of the incline, were carried up as in Fig 423; they were about 12 ft high and drilled with mounted drifters. Holes 7-8 ft deep were drilled parallel to the floor, with a burden of about 2 ft each. Broken ore was



Sec A-A, with portion of fill and ground cut away at C.

Vert Sec, Parallel with Strike

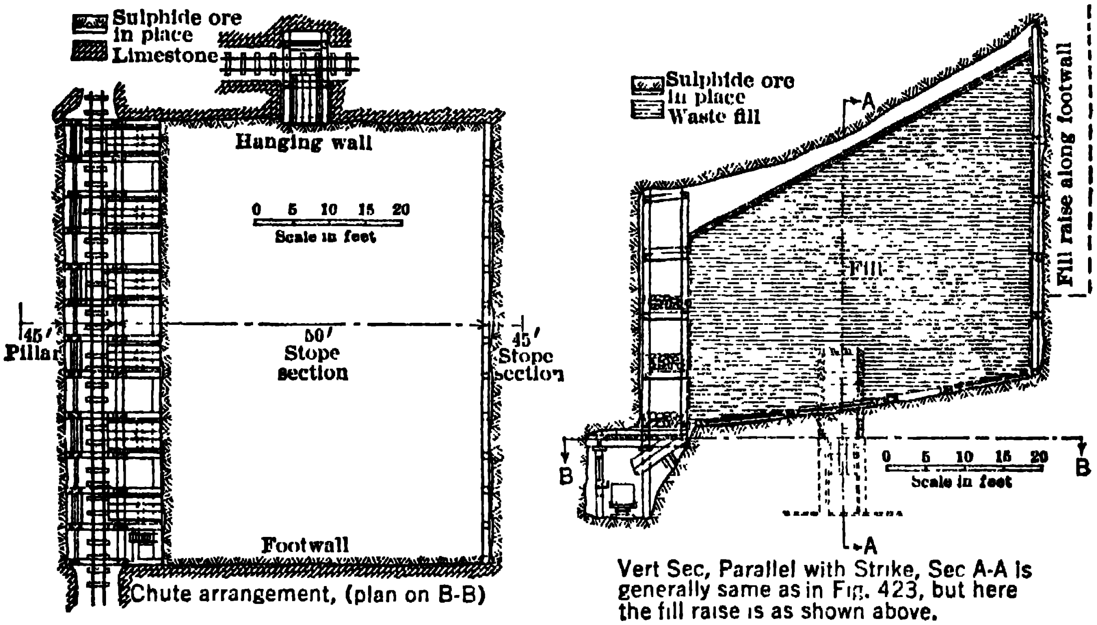
Fig 423. Inclined Cut-and-fill Stope, showing former use of double-leads running parallel with Section Lines, Campbell Orebody, Warren, Ariz (91)

drawn concurrently with mining, but enough from each round was left temporarily to permit back to be reached for barring-down and setting-up for the next round. This undrawn ore protected the flooring during blasting. On completing a cut, the flooring was swept clean of fines, and taken up to be used again in the next cut. Following filling, lead sets were raised and lagged, flooring was re-laid and the new cut started. During mining stages, boulders were "plugged" (block-holed) with jackhammers, usually on the mining floor, although, when necessary, on the grizzlies.

Single-lead stopes. Use of scrapers later permitted modification of the double-lead method. Only one row of lead sets was used (Fig 424). The line of posts and caps was carried up along the opposite section line and lagged to form a gob fence, thus obviating the need of more than one extraction crosscut. In single-lead stopes, the fill raise was driven along the section line opposite the lead sets. As in Fig 424, the raise is outside the section line, for the purpose of serving both stope sections. With this exception, the work in the single-lead stopes was done as in double-lead stopes.

Recent practice. The extraction crosscuts and transverse lead sets have been eliminated. Drifts are run along hanging-wall side of stope section, and from these a longit line of lead sets is carried up (Fig 425). Extraction drift is on hanging-wall side of the leads, so that the drift timbers have a protecting brow of solid ground, thus avoiding direct wt of the waste fill on stringers over the posts. As in Fig 425, inclined cut-and-fill

mining is now used in most of a pillar section between 2 completed stopes, where the lead sets run strikewise. One side of the section is bounded by gob fencing; the other, by solid ground. Drift timbering is virtually the same as for extraction crosscuts in double-lead stoping; but posts are 9 ft 6 in long, instead of 9 ft 2 in, and stringers aver 15 ft long. Chutes are still built in alternate sets. Cutting-out starts by driving a heading, 10 by 15 ft or more in cross-sec, to footwall limit of stope, which may be the footwall itself (Fig 425), or a vert section line previously established. After the heading reaches such limit, a fill raise is driven, unless already made by open sets left for this purpose in a previously mined footwall section. In Fig 425 a raise has been driven along footwall to the level above. Such a raise has no chute at the bottom, the broken ore being scraped away to allow access to the raise. On completing the fill raise and widening the heading to full stope width, the stope back is blasted and sloped upward toward footwall, preparatory to filling and establishment of an inclined floor and back. This preparatory mining is done by shrinkage. Ore broken in the heading, the raise, and making the initial cut, is scraped into one of the chutes by a power scraper set over the drift. When preparatory mining has advanced sufficiently, "single-leads sets" and "gob-fence sets" are started along the stope boundary lines Standard 10 by 10-in square-sets are used for all single-leads; occasionally, 8 by 8-in timber for the gob fence. All sets are cap-butting and framed to make sets 8.5 ft high and 6 ft by 6 ft c–c of posts. A novel feature is the use of 12-ft caps, so that each rests on 3 posts instead of 2. These "double-caps" give added strength and better alinement. A manway set is carried up with the single-leads, sometimes inside the stope-section line, but generally outside, to provide a sound open set from which to begin mining the adjoining section.



Chute arrangement, (plan on B-B)

Vert Sec, Parallel with Strike, Sec A-A is generally same as in Fig. 423, but here the fill raise is as shown above.

Fig 424. Inclined Cut-and-fill Stope, showing former use of Single Lead running parallel with Section Lines, Campbell Orebody, Warren, Ariz (91)

Before beginning filling, the stope bottom is covered with a mat of old timber, or 2-in flooring nailed to sills of doubled 2 by 12-in planks laid on the solid on 5- or 6-ft centers. Flooring is laid parallel to the direction in which the stope below will be mined, and covered with a mat of scrap timber laid parallel with flooring. Other timbering details, and the general procedure of mining and filling, are about the same as for double-lead stoping. Power scrapers are now standard equipment, their hoists being moved from floor to floor as stope advances (Fig 425). In employing strikewise leads, the entire row of leads may reach the hanging wall before the stope has progressed far upward. If so, another row of leads, nearer the footwall, is started on a bench cut into the waste fill, and is connected with original leads by an ore-slide steep enough to eliminate need for a scraper. Fig 426 shows timbering details for this case. A footwall section of a stope 48 ft wide has been previously mined, and mining the hanging-wall section is nearing completion. Two open sets in leads *A* of the old footwall section are being used as a fill hole for the new or hanging-wall section. The full height of section being mined is shown by height of line of sets *B* (about 100 ft). The section above has been mined out, the flooring of upper section being shown at *C*.

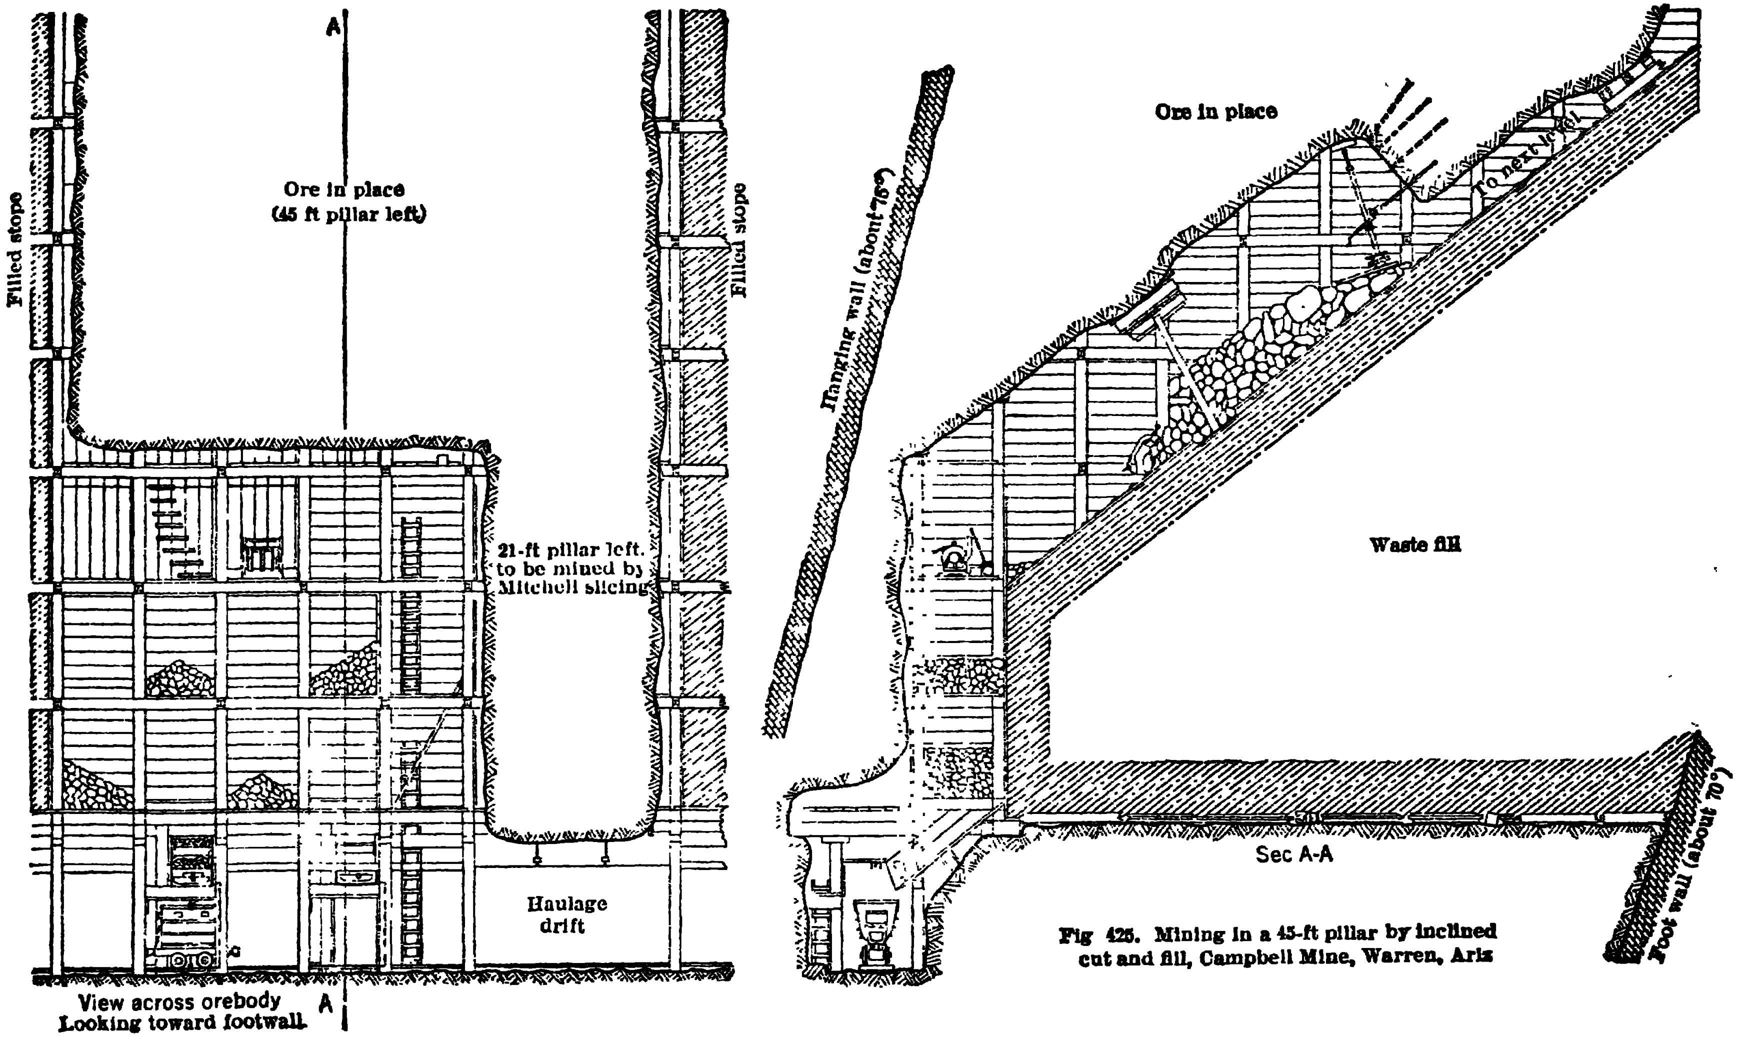


Fig 425. Mining in a 45-ft pillar by inclined cut and fill, Campbell Mine, Warren, Ariz

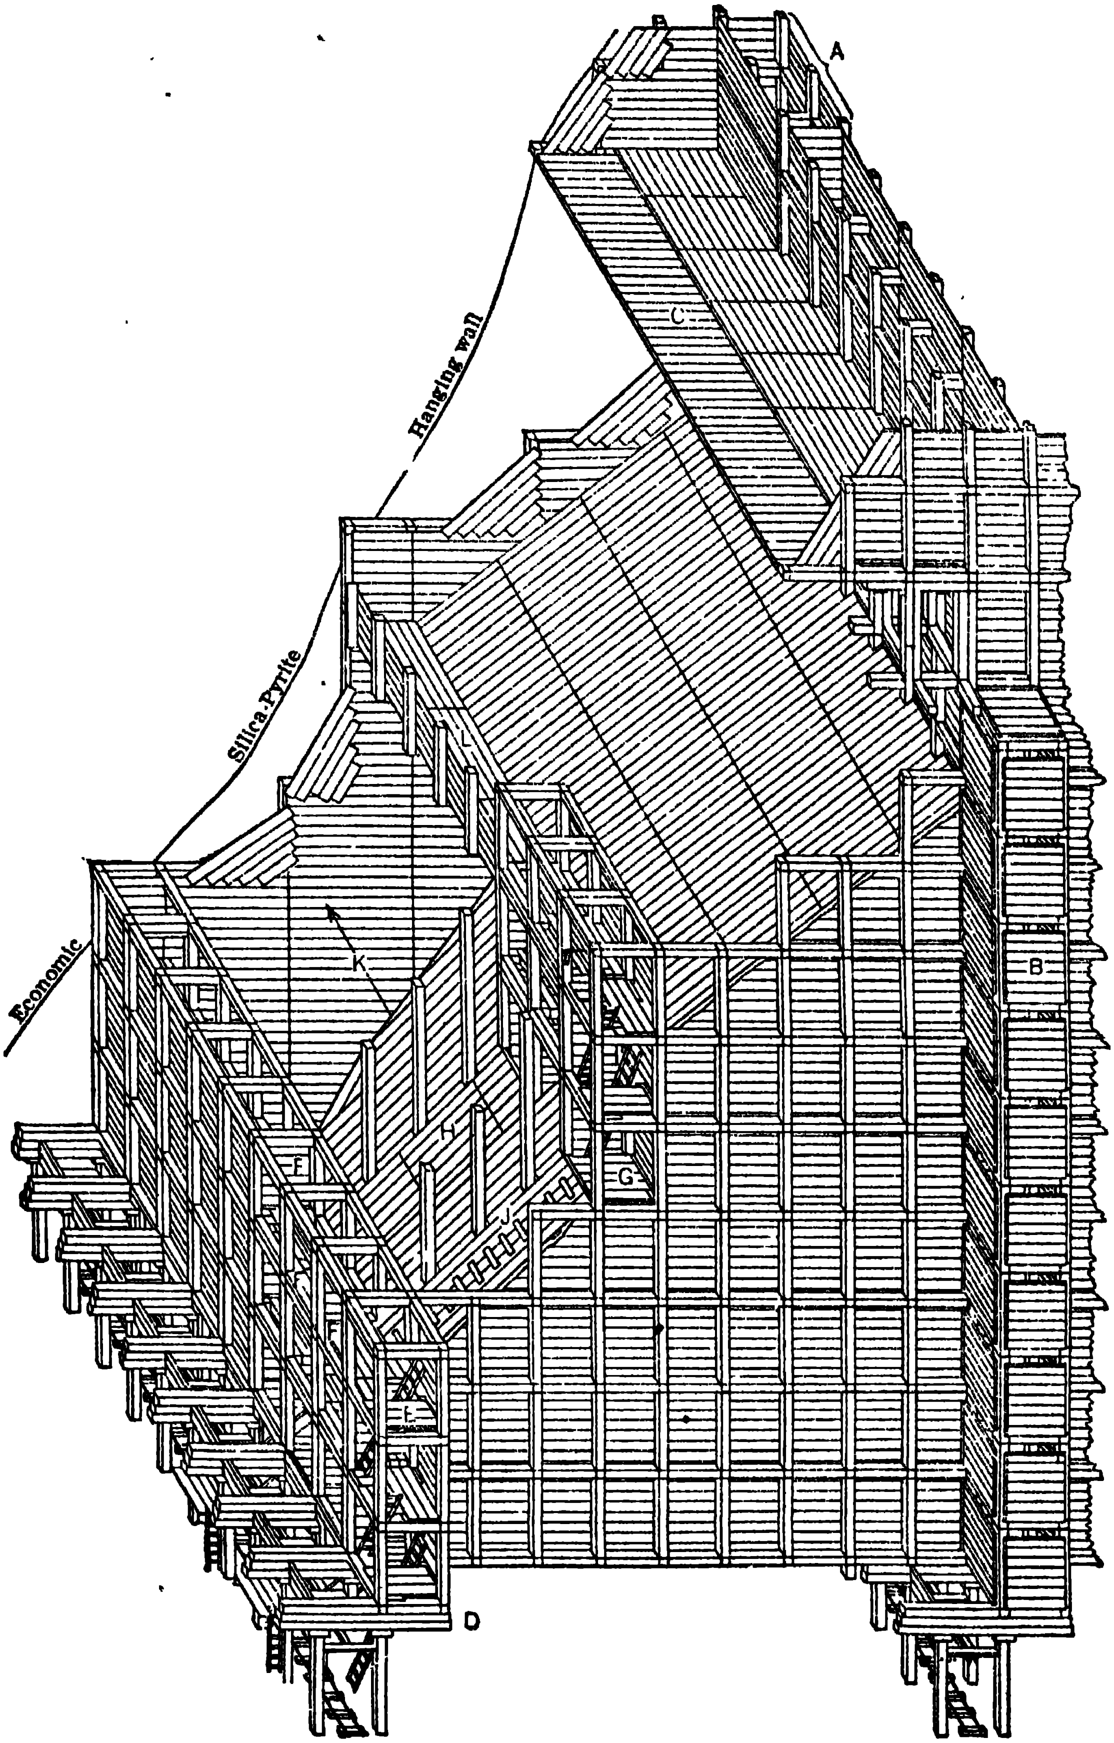

Fig 426. Mining a 48-ft Section under a Filled Stope by Inclined Cut-and-fill, Campbell Mine, Warren, Ariz

In the new section, the ground conditions were heavier than normal, and doubled 10 by 10-in stringers *D* were used over the drift posts. At an elev of about 40 ft, the economic hanging wall was reached. The original single-leads were cleaned down, lagged on inside, and waste-filled, except the manway set *E*, outside the stope section, and 3 sets *F* inside the section, which were left open for an orepass to chutes below. A new row of leads was then started at *G*, these being stood on 3 by 10-in sills laid on a bench cut into the waste fill. Two leads were used as ore-passes; the third, as a manway. The ore slide connecting the new single-leads with the original ones is at *H*; the manway, at *J*. The part of the stope between ore-slide and gob fence *K* was completely waste filled. Top row of sets in the newly placed leads were floored *L*, as a "rakeway." Ore mined above, gravitating to this rakeway, was scraped to the chute-sets. When the stope reaches a height where the crown of ore beneath the mined-out section above becomes thin, the stope is sectionalized into 10–12-ft slices at right-angles to the leads. The first slice is taken on the side nearest the fill hole, and the mat or flooring above is caught up with stulls and headboards as it is undermined. After this slice has been taken from hanging wall to the old section, the resulting hole is timbered off from the pillar by single-cap sets, and from the ore on the stope side by building a gob fence of lagged stulls, which are 8 by 8 or 10 by 10 in and 10–18 ft long. The tops of the stulls may be tied to deadmen in the fill of the completed slice, or to the single-cap sets opposite, by strands of old mine rope. The slice is filled as far as possible by dumping from the level and backfilled under the mat by hand. Successive slices are similarly taken until the entire crown has been removed and the section completely waste filled.

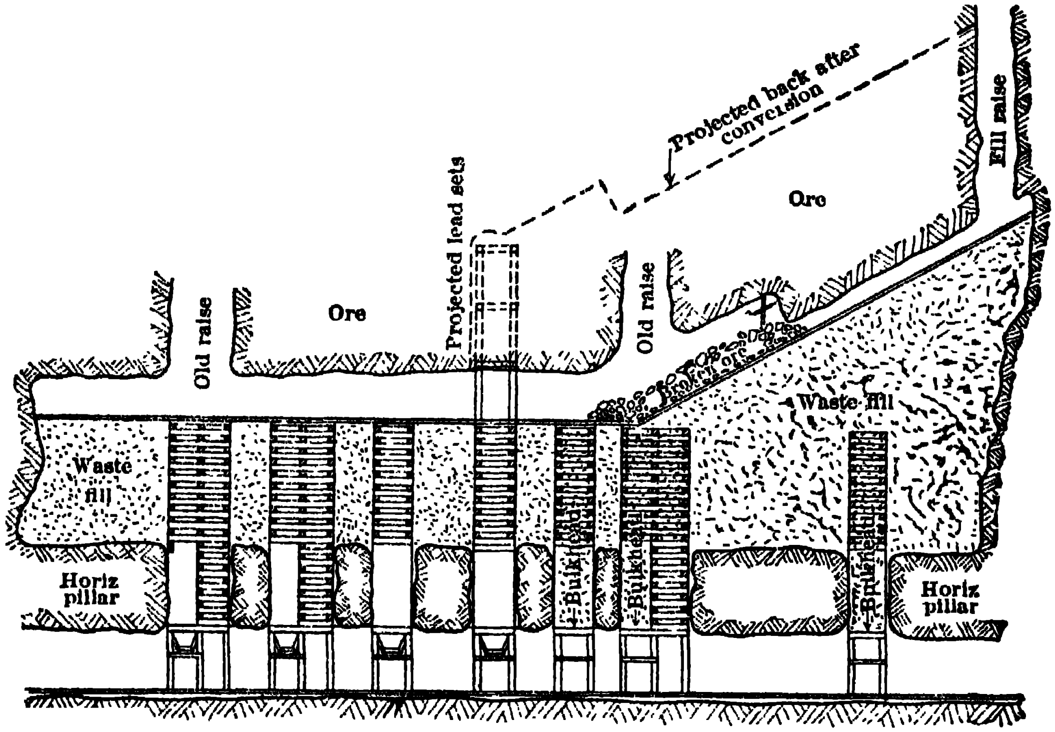

Fig 427. Typical Sec showing Conversion from Horiz to Inclined Cut-and-fill, United Verde Mine, Jerome, Ariz

Costs. Figures in Table 42 include only direct charges of labor, explosives, and timber for inclined cut-and-fill stoping. They do not reflect cost of mining by any other method, nor include any general charges.

Table 42. Direct Costs per Ton, Inclined Cut-and-fill, Campbell Orebody

Period	General Conditions	Labor	Explos	Timber	Total
1934–1937, incl.......	Aver for 2 large stopes in virgin ground..........................	$0.457	$0.120	$0.158	$0.735

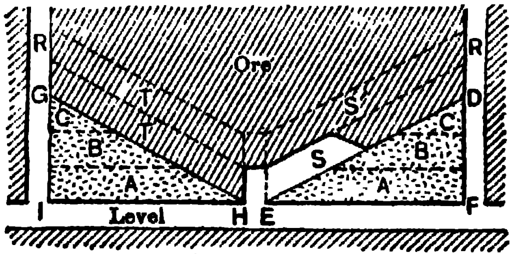
First Quarter, 1937...	All inclined cut-and-fill stopes.......	$0 704	$0.142	$0.226	$1.072

United Verde mine, Jerome, Ariz. Data from J. B. Pullen, of United Verde Branch, Phelps Dodge Corp, in 1938. For description of orebody and of former mining by horiz cut-and-fill, see Art 62. Underground mining was suspended from 1931 to 1937. When resumed, it was decided to adopt inclined cut-and-fill as principal method and to convert the former flat-backed stopes accordingly. The latter were 10–160 ft wide and to 200 ft long, but new stope sections are limited to a max of 60 by 100 ft in sulphide ores and 30 by 50 ft in schist and porphyry ores. Fig 427 shows the longt sec of a typical sulphide stope in process of conversion. As flat-backed stopes had been mined and filled for several floors, old chutes had to be used to deliver ore to haulage level. For each inclined cut-and-fill section, there are at least 2 such chutes. Over them, square-sets are built across the width of stope to serve as extraction chutes, manways, and supply entrances. All other old chutes within the section were bulkheaded, and filled from a raise to the level above. The stope back was then sloped upward from the line of square-sets to the fill raise at an angle of 37° (approx angle of repose of the waste filling). Then 8-ft successive cuts were made, from the square-sets toward the fill raise. Stopes are filled after each cut and floored with 2-in planks; square-sets, 6 ft sq and 8 ft high, of 10 by 10-in timber, follow each cut. Movement of broken ore to chutes and spreading of waste are aided by a scraper, the hoist of which is easily moved along the sets, for reaching the entire stope (see Sec 27). Gob fences along pillar and section lines consist of a single line of square-set posts and caps.

Calamon mine, Posadas, Spain; data from C. P. C. Sullivan (255). A form of filled rill stope is used in a vein of silver-lead-zinc ore in schist; ore and hanging wall are weak and require close support. Aver stoping width, 6.5 ft; dip, about 80°. Levels, 98 ft apart, are connected by 2-compartment raises at intervals of 98 ft. In Fig 428, triangular areas *DEF* and *GHI* are first mined by driving 3 superposed drifts *A*, *B*, and *C*, from raises *R*. The drifts, 8 ft high and the full width of stope, are timbered with close-lagged sets. Each drift is filled before starting the one above; much timber is recovered from fill when exposed by work above. Faces *DE* and *GH* usually slope 28°, which is less than angle of repose of filling. A chute gate is next erected at *HE*, and the ground above broken down to a height of 8 ft; an 8-ft slice *S* is then taken off face *DE*, the work resembling the driving of a flat raise; back and walls of slice are supported by lagged drift-sets. Slice *S* is filled after holing into raise *R*; during filling, the opposite slice *T* is mined. Rest of lift is similarly mined, chute *HE* being built up after each pair of slices *S*, *T*, etc, have been excavated. Broken ore is pulled down the floors of inclined slices with hoes. Filling for horiz slices *A*, *B*, and *C* must be distributed largely by hand. Raises *R* are abandoned as the stopes go up; temporary chute gates are built in them, as required, for distributing filling to inclined slices by a stream of water; filling is waste from old workings or mill tailing.



SEC IN PLANE OF VEIN

Fig 428. Rill Stope in Weak Ore, Calamon Mine, Spain

The deposit was formerly mined by driving and filling horiz superposed drifts between raises (compare with Leaning stope sets, Art 56). The present method reduced timber consumption 50%, more than doubled output per man-day and reduced total costs about 35%. For detail, see Bib (255).

66. SUMMARY, FILLED STOPES

General. Contemporaneous filling methods usually entail higher costs per ton of ore than shrinkage (Art 67–69) or open-stope mining (Art 35–43), but compete with the latter in certain circumstances. Filling is preferable if factors of safety or dilution demand prompt support of walls; it also affords better opportunity for occasional timber support of ore that is not very strong. In general, filling methods afford a higher degree of selectivity than shrinkage or open-stoping, and hence are better suited where ore is spotty or walls are irregular. Horiz cut-and-fill is advantageous where sorting is needed. In recent years a number of mines formerly using open-stopes or shrinkage have turned to filling methods, reflecting a tendency toward safer mining, and higher and cleaner extraction in the richer orebodies.

Filled flat-back *vs* filled rill stopes. SAFETY. Principal danger in both types is from falls of ground. The sloping fill in rill stopes may cause rocks falling from walls or back (or from surface of fill) to roll down the slope and injure men; this risk is increased where fill is covered with plank. As cribbed bulkheads are less easily built in rill than in flat-back stopes, they are avoided when possible; footing for them is less secure when built on inclined surface of waste, and they may be dislodged by moving broken ore or fill. On the other hand, the arching effect of rill stopes may reduce hazard from falling ground. COST. When applicable, rill stoping is usually cheaper per ton than horiz stoping; gravity aids movement of both ore and filling; fewer chutes are required. These advantages in rill stopes are partly offset by better working conditions in horiz stopes; flat floor affords better footing to men than inclined floor, thus facilitating handling drills, steel, and timber. Where weak ground requires close spacing of bulkheads, advantages of rill stopes may be lost. FLEXIBILITY. Opportunity for varying mining procedure is greater in flat-back stopes; area of stope may be extended or reduced at any horizon; prospect openings are easily run into walls, and waste from them used for filling; horses or low-grade ore can be left unmined; in rill stopes, faces must advance uniformly; their output usually ceases while filling; in a flat-back stope, mining may often proceed in one part while filling another. SORTING. Flat-back stopes offer better opportunity than rill stopes for effic sorting.

SHRINKAGE STOPES

67. GENERAL

Definition. Shrinkage stopes are overhand stopes in which the broken ore accumulates until the stope is completed. As rock increases in bulk when broken, from 30% to 50% of the ore in a shrinkage stope must be drawn out as the stope advances, to leave a working space under the back. The remaining ore supports the miners and gives temporary support to walls; it is drawn when the stope is finished. Stopes may be left empty and allowed to cave, or may be filled with waste; latter procedure is called SHRINKAGE STOPING WITH DELAYED FILLING (Art 59). Terms BACK-STOPING and OVERHAND STOPING ON ORE were formerly used in some parts of U S to denote shrinkage stoping; other names are "lay system" (English) and "magazine mining" (Swedish).

Field of use for shrinkage stopes is in steep-dipping deposits of strong ore with strong walls; for limitations of method, see Art 69.

In narrow veins, this method allows practically complete extraction, though level-pillars must sometimes be abandoned to prevent premature caves. Masses or wide veins can rarely be completely mined by shrinkage methods; size of stopes is limited by the area of ore or wall rock which will safely stand unsupported. In large orebodies, permanent pillars may be left for support between adjacent stopes, as at Alaska Treadwell mine (Art 68); this is a form of pillar and chamber work (Art 42). Pillars may sometimes be blasted after completing shrinkage mining, but before final drawing of ore, in which case caving may also be involved (Creighton mine, Art 68). High-grade orebodies usually warrant filling of shrinkage stopes and recovery of pillars by square-setting (Art 46), Mitchell slicing (Art 55), or top-slicing (Art 72, 73). See also Combined methods (Art 83–87).

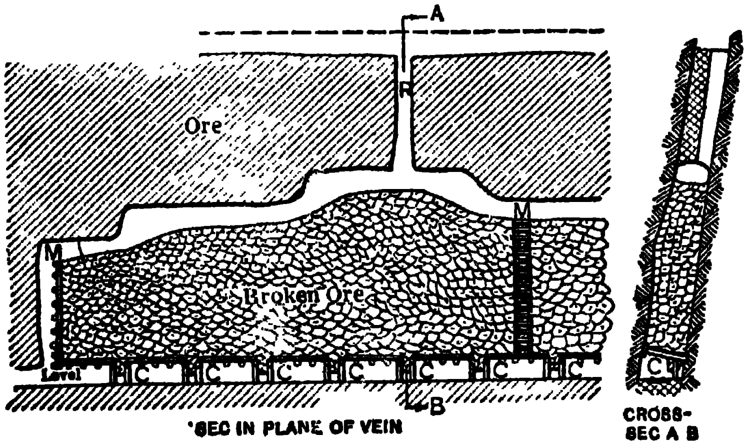


Fig 429. Shrinkage Stope, Narrow Vein

General plan. Fig 429 shows a stope in a narrow vein, opened from raise *R* as an ordinary overhand stope (Art 38). Ore from the cutting-out stope falls to the drift; that from succeeding back-stopes collects on top of level timbers, the excess due to swell being withdrawn through chute-gates *C* (Art 90). Ventilation and access to stope are afforded by raise *R* and manways, *M*. Procedure in wide stopes is similar (see below, and Art 68).

Chutes for shrinkage stopes are sometimes built up at regular intervals like those in waste-filled stopes (Art 60); they are then used for passing excess ore to the level. As the fill of broken ore in such a stope is stable, a weak back may be supported on cribs, but this practice involves much shoveling, which is obviated in typical shrinkage stopes (Fig 429). Chutes may also be justified by the presence of high-grade ore, which can be sorted in stopes and kept separate for special treatment (see Sorting, below). Chutes are sometimes used to handle small patches of waste, which would otherwise mix with the ore. Shrinkage stopes with built-up chutes are relatively unimportant.

Development for shrinkage stopes in narrow veins follows general lines laid down in Art 14. Level interval may be greater than in filled stopes (Art 59), because there are no chutes to maintain. Raises may be far apart, long stopes being opened from a single raise in the middle, or from a raise at each end. Blind oreshoots may even be mined without any raise to level above, ventilation and access being obtained through timbered manways at ends of stope. Development practice in wide orebodies is largely a question of arranging openings for drawing ore economically from the stopes (examples, Art 68).

Shape of stope-face. Both wide and narrow shrinkage stopes commonly have a flat back, under which, in drawing excess broken ore, it is easier to maintain a working space of uniform height than where the back is inclined or irregular. The advantages of a level working floor (Art 66) also apply here. Fig 444 shows a stepped-face shrinkage stope.

The shrinkage principle may also be applied in rill stopes of moderate width; these allow use of down holes, which alone should determine the angle of rill. Steep slopes, on which broken ore will roll, are a pronounced disadvantage in shrinkage stopes. Fig 430, from O. B. Ward (260), shows a rill stope for steep-dipping oreshoots up to 25 ft wide in Lake View Consols mine (for ore occurrence at Kalgoorlie, W Australia, see Art 65). Level interval is 200 ft; inclination of the back is just sufficient (say 18° to 25°) for holes at top of stope to hold water.

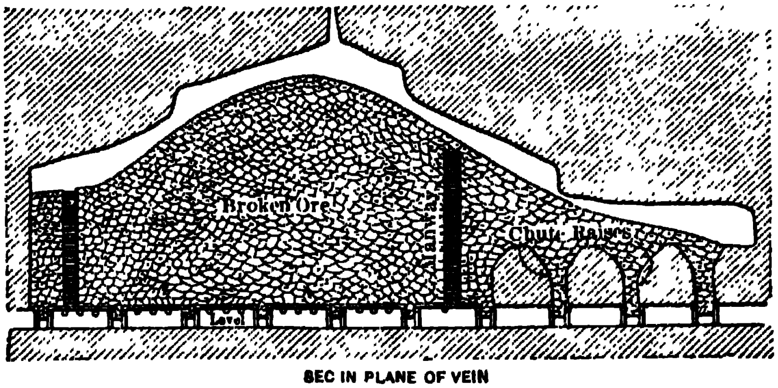

Fig 430. Shrinkage Stope, Lake View Consols Mine, Kalgoorlie, Australia

Breaking ground. Practice is the same as in other overhand stopes (Art 26 to 28; note Fig 172, and accompanying text, also remarks on blockholing, Art 26; see Ariz Copper Co, Art 68).

Arrangements for protecting levels and drawing ore under shrinkage stopes are more or less interdependent; general considerations are:

(*a*) Protection for levels must be strong, to carry weight of broken ore, part of which is supported by footwall in inclined stopes and by friction between ore and walls in narrow vertical stopes; constant drawing of ore destroys any arching effect which might tend to make broken ore self-supporting, and may throw heavy shock loads on timber or other level protection. The walls may also exert heavy lateral pressure when the ore is being drawn (20).

(*b*) Method of protecting levels obviously depends on width of stope. In narrow deposits, simple or saddle-back stulls, stulls and posts, drift-sets, or level-pillars are adequate; choice is based on the same factors as for open stopes (Art 38); square-sets (Art 45) are often used for convenience instead of drift-sets. In wide stopes, 4 arrangements are common: (1) One or more timbered or dry-wall gangways, like those used in filled stopes (Art 64), may be built on stope floor; for example, see Homestake mine (Art 68), also Bib (243). (2) Entire sill-floor may be timbered with square-sets; those sets needed for haulageways and chute-gates are kept open by lagging (see Cresson mine, Art 68). (3) Floor of stope may be opened 10 to 20 ft above the level, leaving a level-pillar, through which CHUTE RAISES are made at frequent intervals to draw off ore; see Nevada-Massachusetts and Rosiclare mines, Art 68. (4) Floor of stope may be opened on the level, with no attempt to maintain haulageways through broken ore; ore is drawn off by shovelers working in numerous crosscuts, which connect edges of stope with haulageways driven nearby in walls of deposit or in pillars between stopes (King mine, Art 68; also Fig 451). CHOICE OF METHOD is based on a comparison beween first cost of opening stopes and subsequent cost of handling broken ore; these costs vary with size and character of orebody, wages and efficiency of labor, and supply costs; no two mines present exactly the same problem. For variations, see Art 68.

(*c*) The way in which ore breaks (or is broken) should be considered in planning for handling broken ore at the levels. Large slabs clog ordinary chute-raises and gates and require blasting to dislodge them; this work is costly and often damages chutes; if slabs are numerous, the delays soon destroy the advantages of chute-gates for cheap loading.

Trouble from last-named source is rarely serious in narrow stopes in small mines; drill holes are shallow, and the few slabs produced may be cheaply blockholed or spalled in the stopes. In such mines ore must be broken fine, for handling in small cars or skips. Under these conditions broken ore may be drawn through simple chute-gates, the installation of which does not materially increase first cost of opening stopes. Such gates are usually for handling pieces of ore not larger than 8 or 10 in.

In wide stopes of large mines, deep holes and heavy blasts are desirable to secure cheap breaking. Ores thus blasted rarely break fine, but contain slabs varying in number and size with structural characteristics of orebody. Cost of blockholing or spalling large slabs to 8 or 10-in size is high; amount of labor and explosive required may equal or exceed that needed for initial breaking. There are special chutes and gates for handling large slabs; bulldozing chambers with grizzlies over levels facilitate breaking up boulders; see Art 90 and Bib (562). But, as such devices increase development costs, the ore tonnage to be handled through them must be commensurate with their first cost to justify their installation. The alternative of abandoning chute-gates and shoveling the ore into cars from stope floor eliminates clogging of chutes, and slabs need to be blockholed only to a size for handling by 2 men; in the U S, these advantages are usually overbalanced by cost of shoveling, and chute gates, etc, are in general use. For detail of various alternatives, see Examples of practice, Art 68. To prevent clogging, the minimum cross-section of chute-gates or of chute-raises should be at least 3 × max dimension of pieces of ore. At large mines, the crushers should be of ample size; crushing in large machines is usually cheaper than blockholing. Underground crushers are sometimes advantageous.

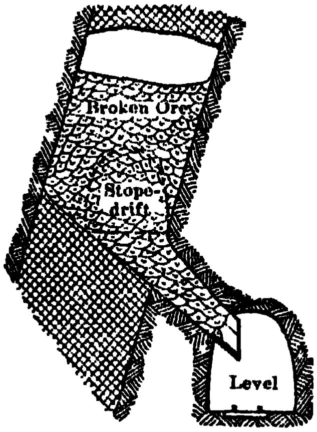

Fig 431. Cross-sec (after Hoover)

(*d*) For convenience in mining level-pillars at top of stopes, haulageways are sometimes placed in the walls of the deposit (Fig 431). Stope is then opened from a stope-drift, as indicated by dotted lines; this device secures strong protection for levels, but is limited to deposits of moderate width; haulageways may be driven in walls on both sides of stope (Ariz Copper Co, Art 68).

(*e*) Haulageways and chute-gates should be located with reference to effect produced on the surface of broken ore at top of stope by drawing off below. In vert stopes, 25 to 30 ft wide, the best location for a single row of chute-gates is in middle of stope; if placed along one wall, the surface of broken ore above tends to pitch toward that wall and shoveling or staging is required to reach the stope-back on that side for drilling. In inclined stopes, ore tends to draw down on hanging-wall side, regardless of position of drawing points; some gates are placed on footwall, for drawing off ore there when stope is to be emptied.

Chute-gates suitable for shrinkage stopes are described in Art 90. DISTANCE BETWEEN GATES should be small, to reduce amount of ore remaining between them when the stope is finally drawn, as empty stopes are often too dangerous for shovelers to enter. Close spacing also allows more even drawing of broken ore. Gates are usually 12 to 25 ft apart; use of A-shaped pillars (Fig 438) between gates allows larger intervals. Where levels are stulled, ore remaining between gates may be recovered by cutting out lagging and dropping the ore on the level (260).

Access to shrinkage stopes is as follows: (*a*) Timbered manways are built up through broken ore; timbered, in narrow stopes, with 2 rows of lagged stulls; cribbed manways are used in wider stopes. For greater security, manways are often at ends of stope; if elsewhere, cribbed manways should be midway between 2 chute gates, and preferably on footwall, where they are least affected by movement of broken ore during drawing. (*b*) **Raises** are driven in walls, or in pillars between stopes, and connected with stopes at vertical intervals of 15 to 30 ft by short drifts. This is common in wide stopes and affords strong protection for traveling and air-ways (see examples, Art 68). (*c*) Raises through back of stope to level above. Access is then usually supplementary to forms (*a*) or (*b*), primary purpose being that of ventilation.

Sorting in shrinkage stopes is not ordinarily feasible. (For exceptions, see Cobalt, Ontario, and Kennecott mine, Art 68.)

Support of back and walls. Shrinkage methods are primarily for use where the back will stand unsupported and walls will stand while stope is being emptied (Art 69). For support of the back in shrinkage stopes with chutes, see Chutes, p. 275. Loose slabs in stopes without chutes (Fig 429) may be supported temporarily by stulls, preferably tapered and set with their big ends up to facilitate recovery from above; this is practically the only form of support feasible during stoping. Occasionally the back and walls of stopes of moderate width are timbered while ore is being drawn, to protect men in the stope or to prevent contamination of ore by slabs from walls (Ariz Copper Co, Art 68).

H. H. Hodgkinson states in this connection (261): Timbering consists of lagging supported by transverse sets or frames spaced 4.5 to 8 ft apart. Fig 432 shows a good set for a highly arched back; a hitch is required at each end of the horiz timber. Fig 433 shows support for a weak wall at *A*. Unsymmetrical sets of this kind are feasible where peak of arch is not in center of stope. Fig 434 shows a rafter set for a stope with a flat back and poor wall at *B*. Timbers should be framed to conform to shape of back, a space of at least 10 in being left above the sets, for placing lagging and blocking; more space adds expense for extra blocking. Arched backs in general throw less weight on timbers and allow more space between sets than flat backs. Fig 435 shows extension of same general plan to the complete timbering of walls; successive stulls, uprights, and lagging are placed as ore is drawn. (Such work is costly and rarely justified in shrinkage stopes. Author.)

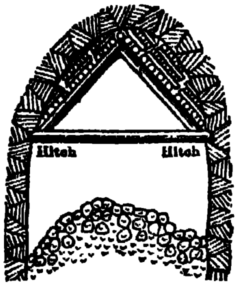

Fig 432

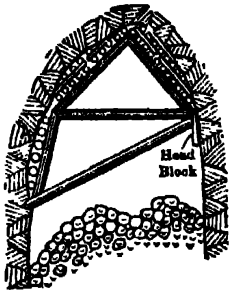

Fig 433

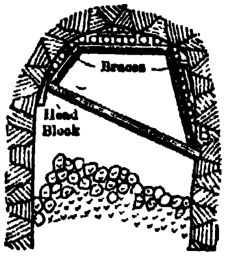

Fig 434

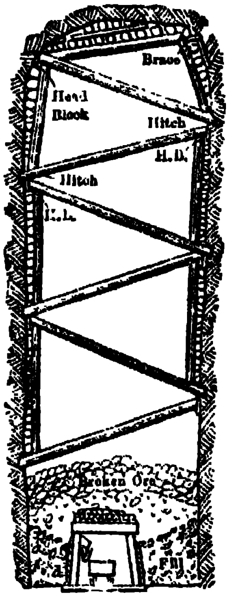

Fig 435

W. W. Lynch states that at United Verde mine, Ariz, shrinkage stoping was employed in 1927 to mine a block about 100 ft long and 50 ft wide. After carrying stope to full height of 100 ft, the back tended to slough on exposure to air. Before final drawing of ore, the entire back was gunited after arching. Result was satisfactory in protecting men working at bottom of stope after drawing of ore and prior to filling. Procedure was one of expediency to meet an unforeseen condition.

Waste filling is the only means of supporting permanently the walls of empty stopes. Filling is dumped in through numerous raises put up to level above through the level-pillar at top of stope. Delayed filling operations of this kind are always cheaper than contemporaneous filling (Art 59), because stopes are open and much of the filling runs into place by gravity; shoveling is required only at top of stope. In long stopes, the length of wall left unsupported during drawing may be reduced by drawing all the ore possible from each chute-gate in succession, starting at one end of stope. As room is obtained, filling is dumped into the empty end of stope from level above; toe of fill advances as the toe of ore pile recedes towards the other end of stope. Attempts made to draw ore uniformly over entire area of stope, and dump waste into the top at the same rate that ore is withdrawn, always result in loss of some ore and serious contamination with waste. See Ariz Copper Co, Art 68; Inspiration mine, Art 80; and Bib (262, 263).

Further details of shrinkage stopes are given in Art 68, 84–87.

68. EXAMPLES OF PRACTICE, SHRINKAGE STOPES

Cobalt, Ontario (264, 265). District was formerly a famous silver producer. Native silver, with arsenides of Co and Ni, occurs in vert fissures in conglomerate, graywacke, and quartzite. Width of veins, rarely over 6 in; assays up to 3 000 oz Ag per ton were sometimes obtained; values often extended into wall rocks, forming 3 to 6 ft of milling ore on each side of vein. Entry was by vert shafts, generally following the vein; level interval, 50 to 75 ft; shrinkage stopes were usual; a few veins were mined in open stulled stopes (Art 39). Practice at Buffalo mine was typical of shrinkage methods with flat-back stopes. The hard, compact ore was broken with 5-ft uppers, placed fairly close together to avoid need for spalling or blockholing. Before stoping began, 6 by 7-ft drifts were driven to the limits of ore; levels were timbered with lagged stulls after the cutting-out and first back stope had enlarged the drift to a height of 13 to 15 ft. Ore from these openings collected in drift and supported miners while drilling holes for a second back stope. Chute-gates were 20 ft apart, and a cribbed manway was built at each end of stope. About 33% of ore broken was drawn during stoping, a 6-ft open space being kept under the back. In stoping, low-grade ore on one side of vein was first blasted. The high-grade streak was then broken with light shots, the ore being sorted, sacked, and sent direct to smelter. The remaining low-grade ore on opposite side was then broken (compare with Resuing, Art 61). At some mines no sorting was done in stopes. Fig 436 is a section through 2 levels of Coniagas mine, showing method of dealing with oreshoots with so flat a pitch that ore would not run along the floor by gravity. Chute-raises *A*, with funneled tops, were put up from the level through barren material; they permitted control of the surface of broken ore during stoping and of the final withdrawal of ore.

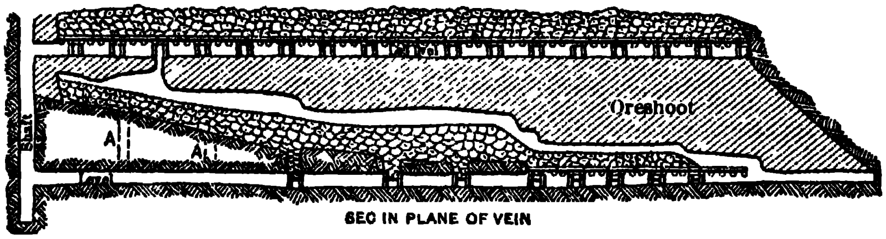

Fig 436. Shrinkage Stope, Coniagas Mine, Cobalt, Ont

Hollinger mine, Porcupine, Canada. Data from A. W. Young (306) in 1935. Gold ore occurs in vert or steeply-dipping quartz-pyrite veins, along fractures in altered and distorted igneous and sedimentary rocks, in which greenstone, porphyry, and "pillow" lava predominate. Wall rock is usually schistose with its planes roughly parallel to strike of veins. Vein widths vary widely; juncture of several veins sometimes makes an orebody 75 ft wide. Chief mining method is cut-and-fill (Art 62); in 1934, shrinkage stoping produced 27.4% of the total. As such, shrinkage is usually limited to veins thinner than 8 ft, and having strong walls, though the first few cuts of cut-and-fill stopes in wider veins are often made by shrinkage. Development is by several vert shafts; level interval was 100 ft in upper part of mine, but lower levels are spaced 150 ft. General plan comprises a main haulage drift on each level, roughly parallel to strike of veins, but not in ore. Crosscuts are 350–400 ft apart. Drifts are turned off in ore at intersections of the crosscuts with the numerous veins. Shrinkage stoping. Preparation consists of silling out vein to full width of ore and to 17 ft above rail. Sill timbering usually consists of 12 by 18-in stulls, 7 ft c-c, set in hitches and at slight angle to horiz; stulls are reinforced by one or more 9-in min-diam round posts. Where vein is too low-grade to be workable at the level, but good ore is known to exist above, raises are driven from the drift to bottom of this ore before stoping starts. Chute pockets are in alternate sets, intermediate sets being lagged with 5-in poles. Stoping is in horiz slices 6–7 ft high. Holes 8 ft deep, burden of 18 in, are drilled at 70°–80° from horiz with wet stopers. Drillers work on contract and aver about 10 holes per shift. Contract rates vary according to width of vein and are graded in a manner that discourages miners from overbreaking. As stope advances upward, a stulled or cribbed manway is carried at one end. After stope reaches a height of about 50 ft, a raise is driven to level above for ventilation and service. Level pillars are left at top of stope, their depth depending on width of ore and nature of ground. Stope is scaled down during final drawing of ore, and weak walls are supported by stulls. On completing drawing ore, stope is filled to within 6–8 ft of back. Costs. Following data apply to year 1934 and are aver for all shrinkage mining of that year: tons ore broken per hole, 2.55; direct stoping labor cost per ton broken: breaking, $0.423; timbering, $0.085; filling, $0.068; scaling, $0.137; stope development, $0.032; total labor, $0.745; explosives, $0.160; total direct labor and explosives, $0.905.

Wright-Hargreaves mine, Kirkland Lake, Ont. Data from L. B. Smith (176) in 1934. Gold ore occurs in fissure veins in porphyry. For geol details see Art 39. Shrinkage stoping is used occasionally where ore is 6 ft wide or more, and walls are strong. Level interval, 150 ft; drifts are in ore. Stoping starts by taking down back of drift to height of 15–16 ft above rails. After broken ore is removed by shoveling, haulageway is established by use of stulls (Fig 429 *C*). Stulls are 5 ft c-c, and set at right-angles to dip except where vein is vert; in latter case stulls are given sufficient pitch to hold firmly. Chutes are built in alternate sets, or 10 ft c-c. Manways are at 90-ft centers. In stopes under

10 ft wide, manways are of 2 lines of lagged stulls. If width exceeds 10 ft, cribbed manways are built against the footwall and fastened to it by eye-bolts and a piece of 16-lb rail (Fig 437). Stopes are flat-back, with breasts 8 ft high; drilling is by mounted hammer drills; holes flat and 6–7 ft deep. Stopes are worked through to level above without leaving sill pillars; stulls used instead. After stope is drawn, it is filled with waste.

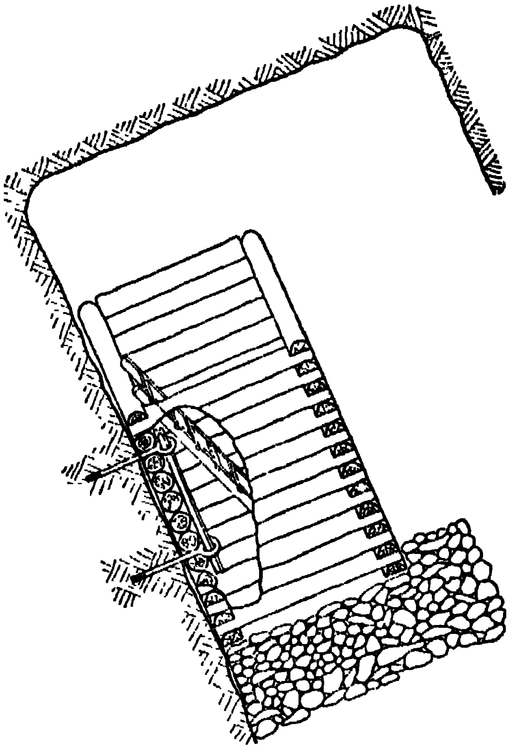

Fig 437. Cribbed Manway pinned to Wall by Eye-bolt and Rail, Wright-Hargreaves Mine, Kirkland Lake, Ont

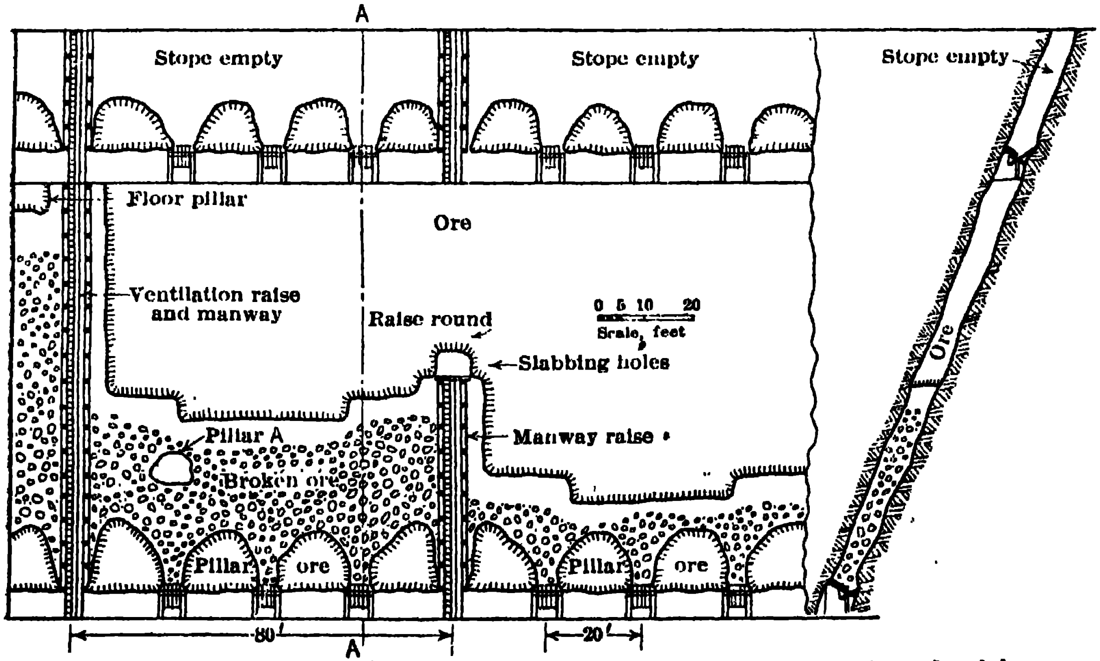
Nevada-Massachusetts Co, Mill City, Nev. Data from O. F. Heizer (196) in 1930. Tungsten ore with about 1% WO_3 occurs chiefly in thin limestone beds dipping 70°–75°. Most productive bed averages 4.5 ft wide; walls stand with moderate amount of support and ore breaks well. DEVELOPMENT. Two main veins are developed by inclined shafts, 730 and 800 ft deep in 1924. Levels are 100 ft apart; drifts untimbered. STOPING. All mining is by shrinkage stoping without filling except that waste from development is dumped into empty stopes. After exposing ore by drifting, a ventilation raise, which is also a manway, is driven to level above. Meantime, chute raises are driven to height of 6 ft above back of drift, and belled out to connect with each other. Chute spacing is 20 ft if ore is dry and draws easily; otherwise the interval is 15 ft. Manways are at 80-ft intervals with 20-ft chute spacing; with 15-ft spacing, manways are 75 ft apart. Stope back is advanced as in Fig 438, one miner starting at ventilation raise and another at the manway. Holes are horiz if ground is hard; otherwise vert, by hand-rotated stopers. As stope advances, excess broken ore is drawn, to leave about 6 ft between top of ore pile and back of stope. Weak spots in hanging wall are supported by stulls or pillars of ore. If grade of ore is low, pillars are left permanently; otherwise they are blasted out after stope is completed. Floor pillars,



Longit Sec Cross-Sec A-A

Fig 438. Shrinkage Stope in Nevada-Massachusetts Mine, Mill City, Nev

6 ft thick, are finally removed by underhand mining. In 1928, average output per man-shift chargeable to underground work was 2.62 tons.

Rosiclare, Ill. Data from E. C. Reeder (197) in 1930. Shrinkage method is used in mining fluorspar. Mineralized fault fissures occur in horiz or flat-dipping beds of limestone, sandstone, and shale. Veins, nearly vert, aver about 12 ft wide; max width is about 34 ft, and 18–20-ft widths are common. In mine described, deposit is 1 900 ft long; developed by vert shaft starting in footwall about 70 ft from vein and near longit center of deposit. Levels are opened at 100-ft vert intervals by crosscuts from shaft and drifts in vein. For the wider veins, chute raises are 25 ft apart and driven high enough for a sub-drift to be driven for connecting tops of raises; sub-drifts are slabbed to full width of vein (Fig 439). In narrow veins, stoping starts just above drift timbers, as in Fig 440. Stopes vary from 100 to several hundred ft long. The stope back is carried in benches, usually drilled with uppers; sometimes, 12 to 15-ft flat holes. Top of ore pile is kept 6–7 ft below back. The thickness of level pillar is computed on basis of 1 ft for each foot in width of stope, up to a depth of 15 ft, which serves for stope widths to 34 ft. These pillars are finally mined and dropped into the empty stope below. Production per man-shift in 1930 averaged 2.93 tons for all men underground.

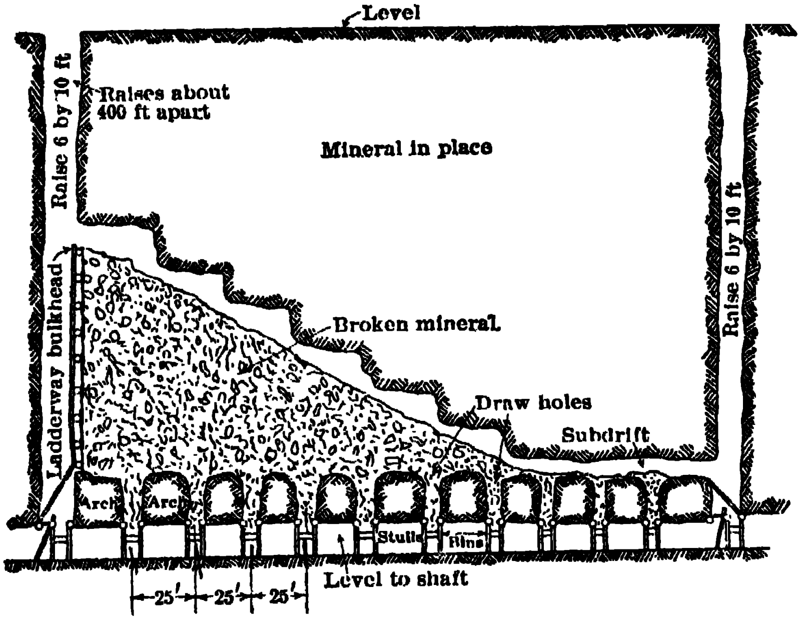


Fig 439. Shrinkage Stope in Wider Veins, Rosiclare, Ill (197)

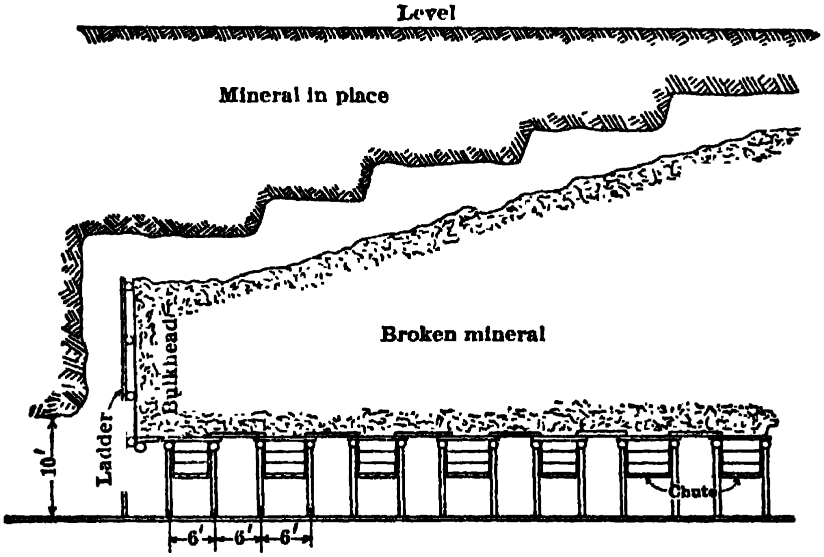

Fig 440 Shrinkage Stope, Narrow Veins, Rosiclare, Ill (197)

Arizona Copper Co, Metcalf, Ariz (152). Methods once used at King and Coronado mines, studied together, illustrate advancement in shrinkage practice. Fig 441 shows method applied at King mine to orebodies 500 to 700 ft long, with max width of 30 ft, occurring in a fault fissure in porphyry; walls were strong and well defined; dip, about 70°. On each level, haulageways were driven in walls, the vein was crosscut at 25-ft intervals, and the entire sill floor of shoot excavated as a breast stope (Art 30), the ore being shoveled into cars. Stope was then carried up as a flat-back shrinkage stope, 33% of broken ore being drawn through crosscuts by shoveling. Access to stope was through raises, at 100-ft intervals, to level above. Back-stopes were 10 to 15 ft high, miners working towards each other from adjacent raises; at some point the belly of ore between 2 parties generally broke off, and the block was blockholed if necessary. Occasionally, parts of vein were too weak to allow safe overhand stoping. Then 2 raises, between which soft ore occurred, were connected by a drift 20 to 30 ft above the back. Ore in the pillar so formed was broken by holes in floor of drift, beginning midway between raises and retreating towards them; similar underhand methods were employed on approaching an upper level.

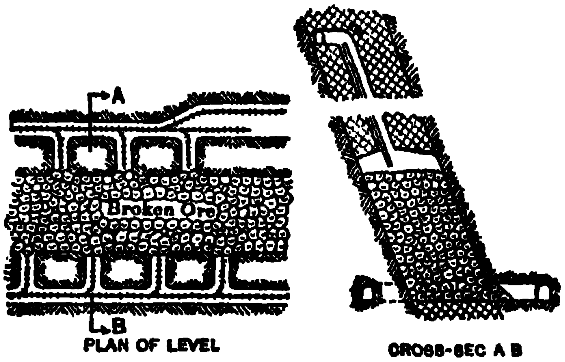

Fig 441. Shrinkage Stope, King Mine, Metcalf, Ariz

Above method was later modified to allow use of CHUTES FOR LOADING CARS. Fig 442 shows its application at CORONADO MINE, for an oreshoot 1 750 ft long, with a vert dip and aver width of 35 ft. Walls and ore were strong, ore broke large and could not be run direct to cars without much blockholing in chutes. Stopes were 150 ft long, separated by 30-ft pillars; raises in centers of pillars, and connected with stopes at vert intervals of 25 ft, furnished ventilation and access. Chute-raises were 25-ft apart, those from hanging-wall drift being half-way between those from footwall drift. Floor of stope was opened 15 to 20 ft above level. Over each chute was a grizzly, on which shovelers broke up large pieces. Fig 443 shows another method permitting gravity loading of cars, and giving opportunity for breaking boulders without blasting in chutes. A level 2 sets high in middle of vein was square-setted. Inclined funnel-shaped raises, alternating to right and left from the sides of upper sets, communicated with the stope floor 20 ft above level. Ore collected on lagging of lower sets, where it was spalled or blockholed, and loaded into cars. Cost of preparatory work was less in this system than in that shown in Fig 442, but final drawing of stope was subject to more delays. "Stopes at the top of orebody can generally be carried to cap rock, and then be drawn quickly without difficulty. Danger of an air blast from sudden caving of an empty stope makes subsequent filling always

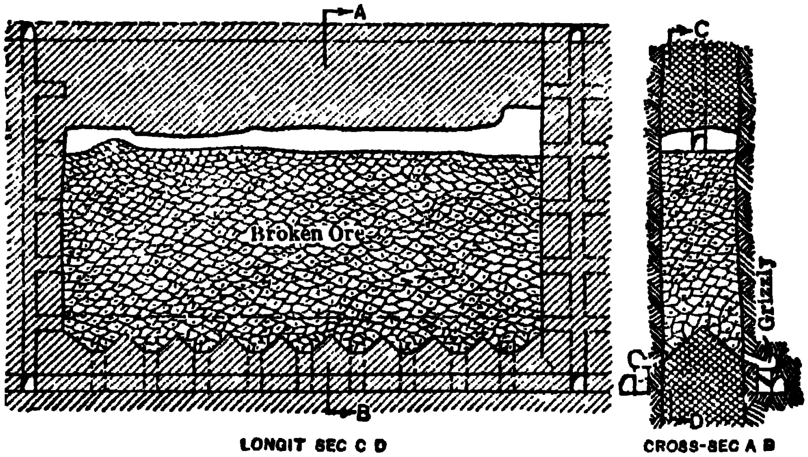

Fig 442. Shrinkage Stope, Coronado Mine, Metcalf, Ariz

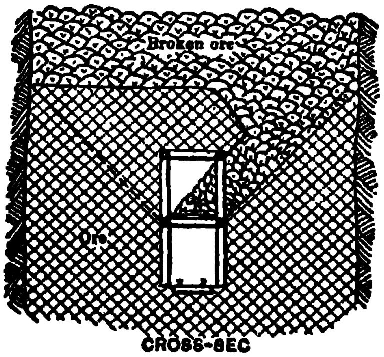

Fig 443

desirable." In one place, an attempt was made to cave overlying waste on a heavy mat of timber laid on the broken ore, and then to draw the ore below, but if the mat descended more than 30 ft, it broke up enough to cause a serious admixture of waste. In deeper parts of oreshoots, shrinkage stopes were stopped 25 to 30 below bottom of the overlying stope; the ore was drawn quickly, and the stope filled with waste. In weak ground, back of stope was arched and timbered before ore was drawn (Art 67). Level-pillars were mined with square-sets started on top of waste fill; then the pillars between stopes were top-sliced (Art 70 *et seq*).

Morris Lloyd mine, Marquette Range, Mich (184). Shrinkage stopes were used for mining a deposit of strong siliceous hematite, 500 ft long by 25 to 75 ft wide; dip, 70° to 85°; hanging wall gave some trouble from falling slabs. Level interval, 150 ft; main haulage drifts were driven near footwall and timbered with 3-piece sets. Deposit was crosscut at 100-ft intervals, to determine width and grade; in wider portions, a second drift was driven later near hanging wall. Max stope width, 40 ft; greater widths were mined in 2 stopes parallel to walls, with a pillar between, or in a series of transverse stopes with pillars. Levels were connected by untimbered raises 100 ft apart, which ventilated and gave access to stopes. Chute-raises, put up at 20-ft intervals to a height of 10 ft above back of level, were timbered with 3-in plank and protected with 40-lb rails from injury by blasting. Tops of raises were connected by a sub-drift 15 ft above the level, stope was then widened to full size, tops of raises were funneled out and stope was carried up as a stepped-face shrinkage stope (Fig 444); 30% of the ore was drawn during mining Ore was broken with 2 stope drills per 50-ft length of face; 1 laborer per 100 ft of stope blockholed and sledged large lumps. On completion of stope, ore was drawn as evenly as possible from chutes, as this seemed to reduce blocking.

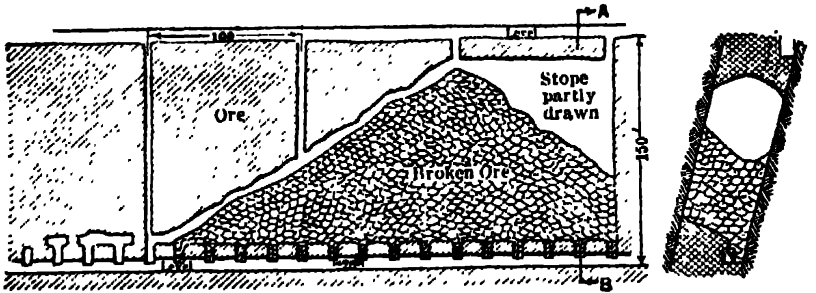

Fig 444. Shrinkage Stoping, Morris Lloyd Mine, Marquette Range, Mich

Replogle mine, Wharton, N J. Lenses of magnetite in gneiss dip 55° and pitch 18°. Shrinkage stopes are made full width of ore (over 100 ft in places) by 400 ft long; transverse vert pillars 50-80 ft thick are left between stopes. A sub-drift is driven close to footwall, leaving a 10-ft pillar over main level. Bulldozing chambers with chute gates below are put in at 40-ft intervals on the sub-level; grizzlies are of 105-lb rails, with 10.75-in openings. Raises are driven from each bulldozing chamber to the hanging wall at an angle of about 40°. Stope floor is opened from the raises in form of a series of transverse V-shaped ridges. Access to stope is through manways in the transverse end pillars. Data from A. H. Hubbell in 1920 (582).

Mt Hope mine, N J. Data from J. R. Sweet (529) in 1932. Magnetite occurs in tabular orebodies dipping 60°-80°, and pitching 14° from horiz. Stoping widths, from a few feet to 40 ft. Height of orebodies along dip is 150-400 ft; length exceeds 7 500 ft. In main body the ore is hard and tough, standing unsupported over at least 40-ft widths. Wall rock is hard, granitoid gneiss. Main 1 000-ft shaft, inclined at 64°, was started in footwall, but cut through orebody below 250 ft. Former plan of development was by levels at intervals up to 260 ft. More recent practice is to drive inclines along pitch of orebody and 25-30 ft beneath it, thus permitting high extraction without undue development cost. Stoping blocks are usually 340 ft long. Stopes are bounded by inclined pillars 30-40 ft wide (Fig 445). Access to stope is by manway raise to top of ore through center of pillar, and connected by short drifts to parallel raises forming a cut-off line between stope and pillars. Inclining of pillars permits low-cost driving of raises. RECENT PRACTICE (1932) is to provide each stope with 4 chutes, 81 ft apart. Chute raises are belled out to make room for grizzly chambers. From ends of grizzlies, undercutting raises are driven along strike at 45°, as in Fig 445, leaving pillars over the grizzlies. Access to grizzlies is through a sub-incline in the hanging wall, parallel to main incline and connected to grizzlies by short crosscuts. Stope face finally becomes flat-backed. Benches are usually advanced from each end toward the middle. Height of benches is 6-15 ft, generally inversely to ore width. They are broken with 14-ft flat holes, drilled by jackhammer fitted with stoper leg and lying horiz on a 12 by 2-in plank, 12-16 ft long, the outer end of which rests on a rung of a ladder leaning against the back. Foot of drill extension leg is held in place by an eye pin inserted in 0.5-in holes bored along center line of plank, the pin being moved forward as required. This novel drilling method is effective. Burden on holes, 3–6 ft. Explosive is 40% dynamite. The 14-ft holes are loaded by first tamping in 12–15 cartridges, and distributing the remainder along full length of hole by alternating sticks of dynamite and wood. Some blockholing is done in the stope; the rest on grizzlies. This mining method does not permit economic recovery of pillars; 90% extraction is expected. Following stoping data are for year 1930: tons broken per machine-shift, 82.53; tons per man-shift chargeable to stoping, 57.59; av tons per man-shift underground, 7.09; av tons per man-shift on property, 4.52; tons broken per ft of hole, 2.58; powder per ton broken, 0.384 lb. For methods at other magnetite mines in same district, see Bib (494, 633).

Walker mine, Walkermine, Plumas Co, Calif (subsidiary of Anaconda Copper Mining Co). Following data, from J. F. Dugan, Gen Supt Mines, Int Smelt and Ref Co, cover practice in 1939. Orebodies are fissure veins of quartz, carrying copper sulphides associated with pyrite, pyrrhotite, and magnetite. Veins are 600–1 400 ft long, 10–60 ft wide, and dip 30°–85°; both walls are metamorphosed sediments and igneous flows.

Fig 445. Shrinkage Stope Development and Mining, Mt Hope Mine, Mt Hope, N J (529). Numbers in circles indicate successive development steps

Mine is opened by a 2-mile adit on 700-ft level, 2 inclined shafts to 1 000-ft level and one to 1 200-ft level. The 700 and 1 000 are haulage levels, from which stopes are started (Fig 446). A sub-level *A* is driven 30 ft above haulage level *B*, and two 6 by 10-ft ore chutes *C* are raised 50 ft apart to bulldozing chambers *D*, connected with the sub-level by crosscuts *E*. Top of each raise is covered by 90-lb grizzly rails with 10-in openings. Above, and with enough brow to keep the grizzly from flooding, short finger raises *F* are milled out into a stope. Pillar raises *G* are driven to level above at 150-ft intervals, and from them are service drifts *H* every 30 ft vert, starting 50 ft above sub-level. Thus, stopes 110 ft long are separated by 40-ft pillars, which are robbed by drilling from the service drifts. Depending on character of ground, pillar-raise center lines may be shortened or lengthened 50 ft, cutting out or adding one chute. This would leave stopes 60 or 160 ft long, separated by 40-ft pillars. Through the level-pillars are mill holes from tops of finished stopes to the level above. These are covered with grizzly rails and then other stopes are opened directly above. Level interval is 100–300 ft vert, depending on the ground, and lifts of as many levels as desired may be opened from one haulage level. Pillar robbing starts at the far end of top level, retreating toward the shaft.

In the Piute orebody, the vein below the 700 adit is flatter than 45° and most broken ore must be scraped to the level (Fig 447). Large chute mouths *O* are 70 ft apart, with a 7 by 18-ft raise *P* driven from every third chute to level above. Service drifts *Q* are driven every 30 ft vert, starting 35 ft above the track, and then the raise is enlarged as a stope. Service, air, and water pipes supply 3 stopes and are brought through the raise from level above. Pillars are robbed from the service drifts. This method is locally called "semi-shrinkage" stoping. Most stope drilling is done with 3.5-in Leyners, mounted on 4-in bars and arms, but heavy rotating stopers are used in raises and narrower stopes. Bits are detachable; hot-milled, and tempered in an elec furnace. Aver break

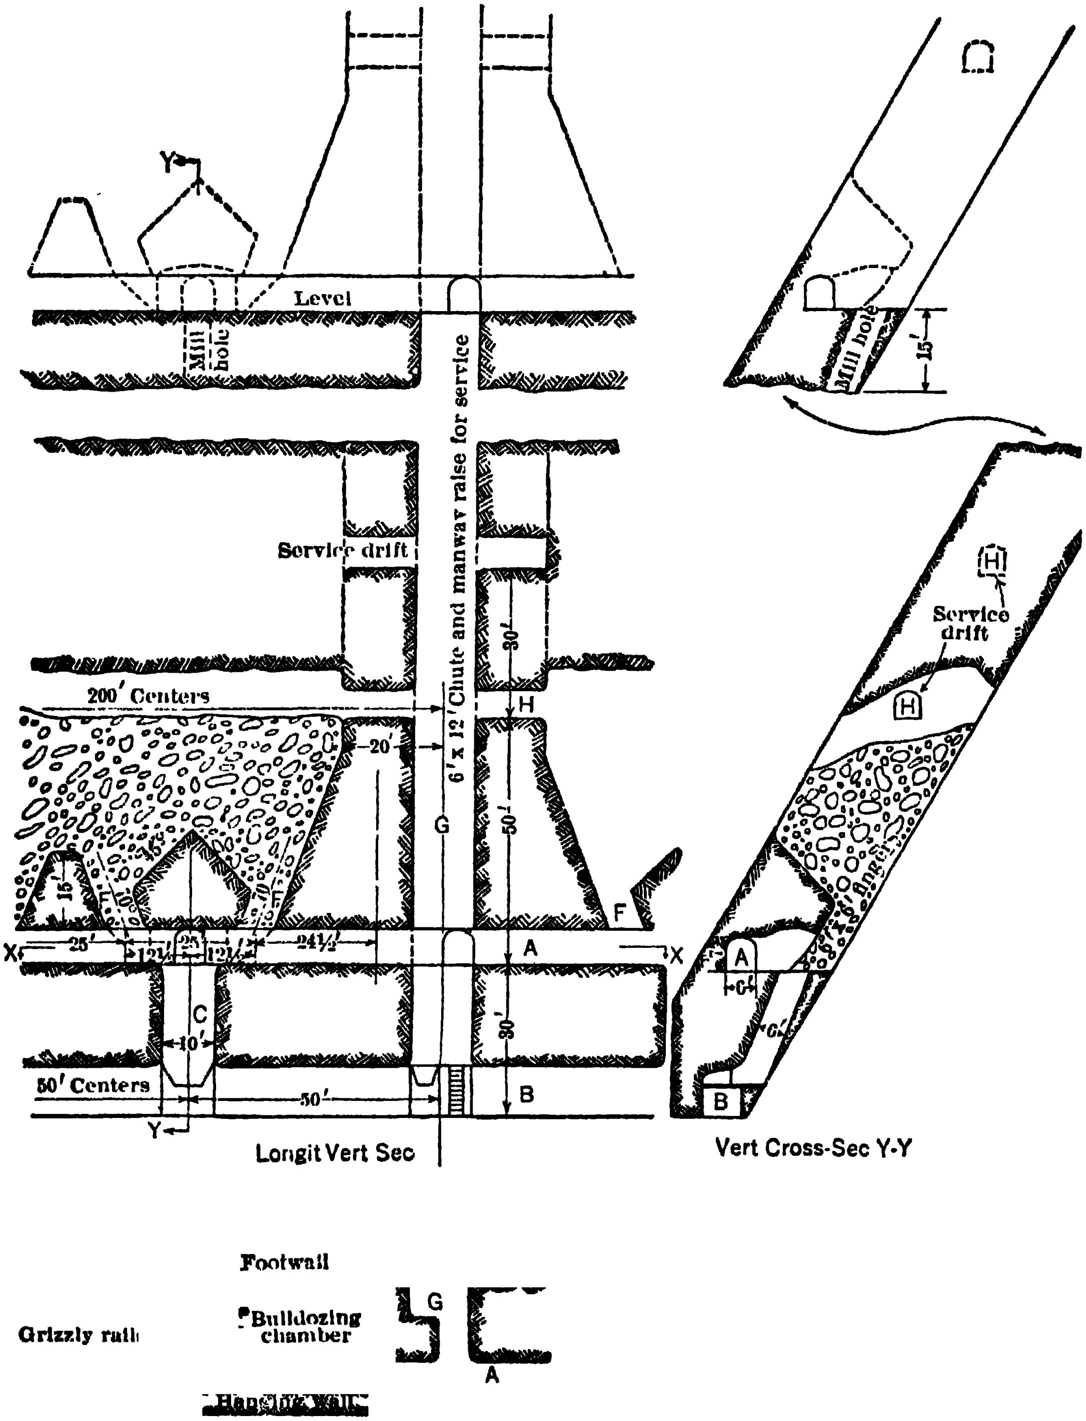

Fig 446. Shrinkage Stoping, Walker Mine (ideal sections)

per machine-shift is 29 tons, with 1.9 sticks of powder per ton; 45% Gelemite is used to blast simultaneously large numbers of 6–12-ft holes.

Application of shrinkage stoping to large deposits is shown by following examples. Excepting Creighton and Homestake, the mines described have low-grade orebodies and methods used are designed to give cheap handling, large output per man stoping, and to require little timber; all essential for cheap mining. The methods are similar, but differ in percentage of orebody extracted, methods and control of ore breaking, and the handling of large slabs that must be broken. Some of these examples might be classed under Combined Methods, Art 83; some have been wrongly classed in Bib (530) as Caving Methods, because the modes of breaking ground may involve caving part of the stope backs.

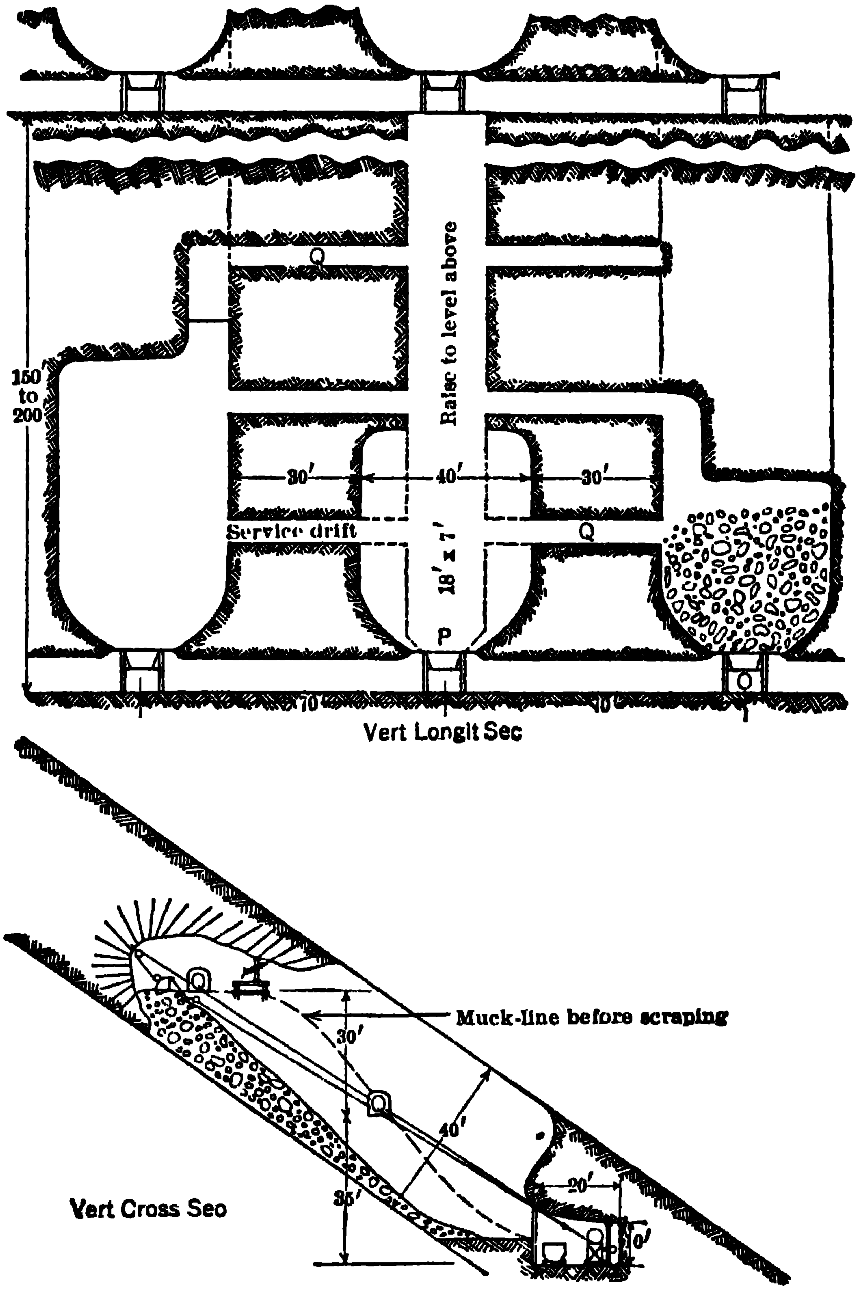

Fig 447. "Semi-shrinkage" Stoping, Walker Mine (ideal sections)

Cresson mine, Cripple Cr, Colo. Data from R. L. Herrick (151) in 1911. Country rock is granite; gold telluride ores occur either in massive shoots in fissured zones, or in replacement veins in well defined sheeted zones alongside of or near basic dikes.

Fig 448 and 449 show method of mining an oreshoot on 600-ft level, which was 280 ft high and 60 by 120 ft in horiz sec. On each level, a breast stope (Art 30), 10 ft high, was carried over whole area of shoot, in which square-sets were erected, as in Fig 448, which also shows track layout and chute-gates. Open square-sets, which were inadequate to support the broken ore after stope had reached some height, were strengthened by lagging the sides of certain sets and then filling them with ore by shooting down the lagging overhead; sets behind chute-gates were left open for access in making repairs. Level timbering and tracks were all recovered after stopes were drawn, starting at one end of stope and retreating toward the other. Flat-back shrinkage stopes were used. As soon as any part of the back reached a point 8 ft below floor of level above, it was caught up on cribs, wedged tight and in places filled with ore. Level-pillars were mined as in Fig 449: work began by drilling holes in back around a crib in middle of stope; the crib was then removed and the holes blasted, making an opening about 12 ft diam into the stope above. Work then stopped for several days to allow loosened rock to work and drop; then the back around the opening was attacked. Cribs were close enough together to allow all holes to be drilled under their protection. After center opening had reached a diam of 30 ft, the remaining pillar sagged and its wt was supported entirely by the cribs; this wt and the resulting incipient fractures materially reduced consumption of explosive for mining rest of pillar. This method is stated to be safe and to effect considerable economy in labor and dynamite, as compared with the drilling of holes from below over the entire pillar and shooting them simultaneously. In one place a continuous shrinkage stope was carried to a height of 320 ft. This saved cost of mining level-pillars which, as the ground was fairly soft and required thick pillars, would have had to be mined by square-setting. Ore was drawn from this stope on several levels through chute raises from workings driven in the walls.

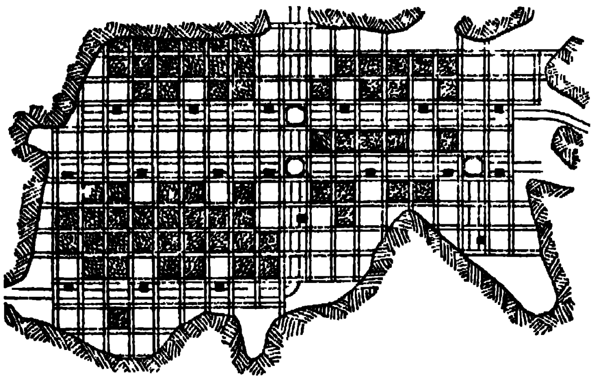

Fig 448. Cresson Mine, Plan of 600-ft Level (Fig 449)

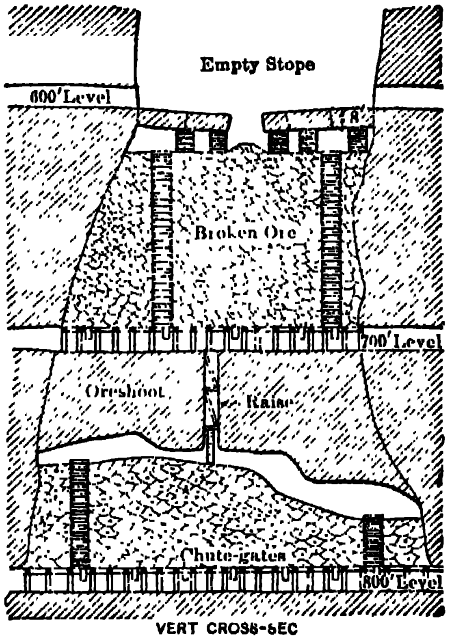

Fig 449. Shrinkage Stopes, Cresson Mine

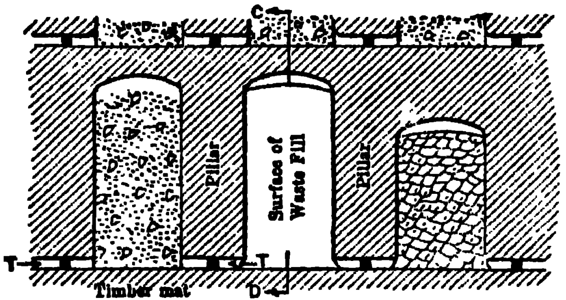
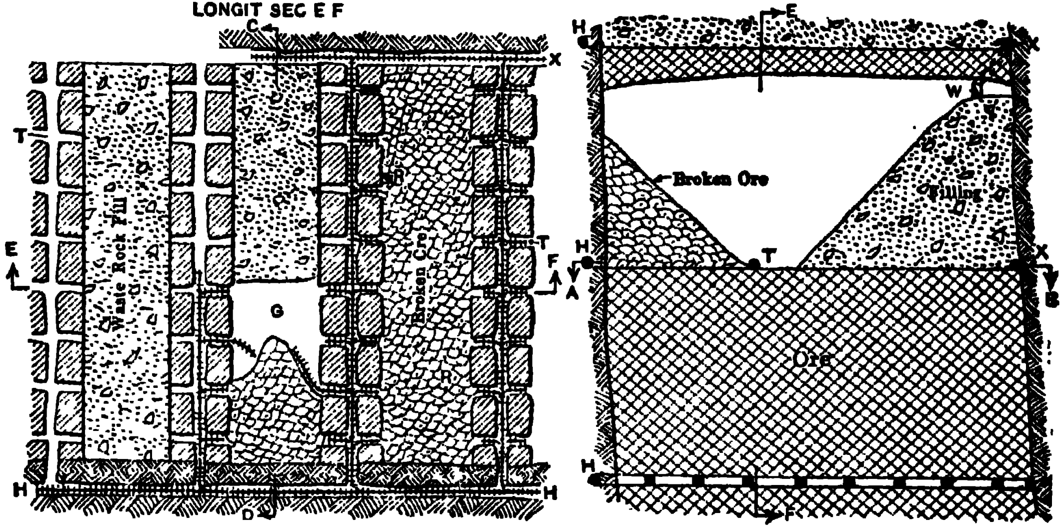
Kennecott mines, Kennecott, Alaska. Data from S. Birch in 1924 (548). Property is now worked out. High-grade copper sulphide replacements are in limestone. Dip is usually steep. Width of orebodies was from a few ft to over 100 ft; length 150 to over 1 000 ft. In some places entire width was high-grade ore, with only a little low-grade. In others high-grade was in streaks 1–10 ft wide, separated by poorer ore. Shrinkage stoping was the usual method; a novel feature was the "double" mining practiced when the high-grade portion of orebody was wide enough. As much as possible of the high-grade was mined first by shrinkage stope and the broken ore was drawn. Surrounding low-grade ore was then mined by ordinary shrinkage stope; if lenses of high-grade occurred in this second stope, they were broken with the mill ore. Care was taken not to overlook ore that made along bedding planes, or on faults or cross fissures away from main body. Generally, as a stope was drawn, it was safe to follow and recover ore in the walls that might have been missed in stoping. Recovery of level-pillars was usually delayed, so that drifts could be maintained for mining oreshoots that often came from below into what was thought to be barren ground. Waste from development was dumped into old stopes. Where possible, development drifts were kept in high-grade ore. Chute raises 25–35 ft apart and 20–25 ft high were put up from the level; they were connected, leaving V-shaped pillars over the level. If ore in a drift became lean, the stope above was carried ahead from the last chute raise to determine the direction in which the drift should be driven. Where ore was wide, 2 or more parallel drifts were driven on the level.

Alaska Treadwell mine, Douglas Island, Alaska, now flooded and abandoned, was formerly an outstanding example of large-scale shrinkage mining in U S, and many details of present practice elsewhere have been developed from work done there. Ore was low-grade, gold quartz, in a mineralized dike of irregular shape, 0–420 ft wide; dip, 50°–65°. Limits of ore were commercial rather than structural; aver assay as mined, $2–$3 per ton. Ore was strong; footwall weak, but supported by leaving on it a strip of unmined ore; hanging wall hard and strong. Profitable mining was done in transverse shrinkage stopes, separated by vert pillars 100 ft apart c–c and 18–25 ft thick, which were continuous through successive lifts and left as permanent support for the walls; horiz pillars were left below alternate levels. Level interval, 200 ft. Stopes were opened 18 ft above levels from tops of inclined chute raises driven 15–30 ft apart along underlying drifts and crosscuts. About 20% of orebody was left in rib pillars. For full detail, see Bib (105, 273).



LONGIT SEC E F



HORIZ SEC A B

CROSS-SEC C D

Fig 450. Shrinkage Stope, Homestake Mine, So Dak (former method)

Homestake mine, Lead, S Dak (104, 271, 272, 199). Production has been practically continuous since 1878. The mine is notable for large-scale shrinkage mining applied to massive orebodies. Orebodies carrying moderate gold values occur as huge lenses in an intensely folded formation of chloritic schist within a series of garnet-mica schists, quartzites, and slates. Individual "ledges" are 50–150 ft thick, but squeezing and folding in places have resulted in orebodies over 300 ft wide; dips, generally steep. Ore is hard, tough, and extremely abrasive, breaking in large pieces unless drill holes are spaced closely. Tendency to break large inspired in early days a method of shrinkage in which all ore gravitated to sill floor and was mucked into cars. A. J. M. Ross states that under this system one "blockholer" was usually required to drill and break large boulders for every 2 muckers. Fig 450 shows general stoping method prior to 1917, as applied to ore wider than 80 ft. Transverse stopes were carried 60 ft wide, separated by 42-ft pillars. Level interval was 100–150 ft. Main haulageways *H* were driven in footwall about 20 ft from ore. Crosscuts were on center lines of pillars. Short drifts *T* ("break-throughs") ran each way at 30-ft intervals from crosscuts to pillar lines. Sill floor was then breasted out 8–10 ft high. Where deposit was very wide, a timbered gangway *X* was erected near hanging wall. At end of break-throughs, shoveling platforms with sheet-steel covering were built, height being that of a mine car. Stope was then carried up as a flat-back shrinkage stope, leaving an arched level-pillar above, about 20 ft thick at crown. Entrance to stopes was through raises to level above or through manways *R*. Final drawing of ore began at one end of stope. As shoveling platforms became useless, they were removed and track was extended into stope (as at *G*). Filling with waste closely followed final drawing. Before filling, floor was covered with a timber mat and sides of pillars were lagged to aid subsequent recovery of level and vert pillars by square-setting. **Recent practice.** Data from A. J. M. Ross (199) in 1931. Distance between levels is 100 ft above 1 100 ft, and 150 ft below that level. Standard plan of development (Fig 451) is to drive a hanging-wall drift *D* far enough from ore to make almost certain that at least 30 ft of barren ground is between the drift and ore. Crosscuts *X* are driven through ore into the footwall at 102-ft intervals, or on center lines of stope pillars, and connected within the footwall to form a footwall drift *E*. Drifts *F*, along both walls, are also driven from these crosscuts. After the crosscuts are connected by the drifts, sill floors are cut out on lines given by surveyors for stopes 60 ft wide and pillars 42 ft thick. Fig 451 is a plan of sill floor development in wide orebody.

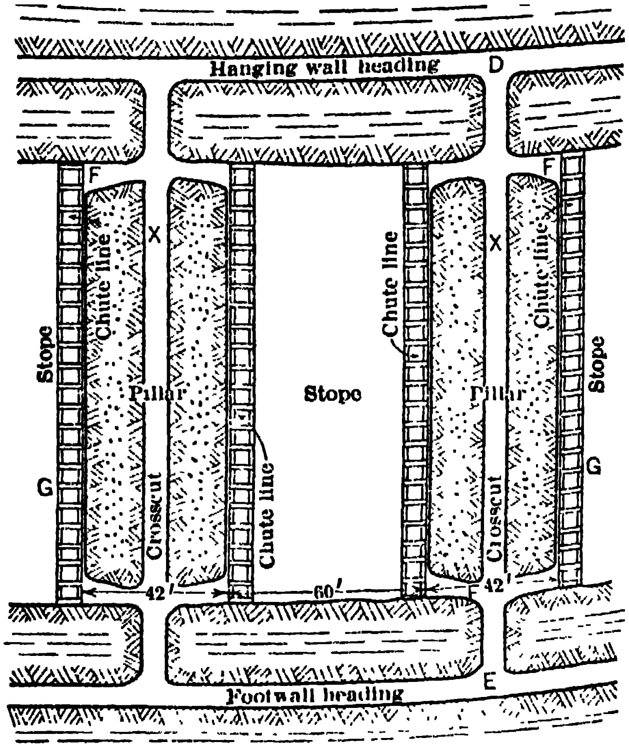


Fig 451. Plan of Sill-floor Operations in Wide Ore, Homestake Mine, Lead, So Dak

After cutting sill floor, stope back is raised and arched in the shape of the ore pile that would be left after the chutes have drawn all that is possible. Broken ore is shoveled out and a timbered gangway *G* ("chute line") is built along each pillar line. Chute pockets are built within the sets for later use in drawing shrinkage ore. The stope floor between chute lines is covered with timber mat, and waste fill is run in through inclined raises *R* (Fig 452). Shrinkage mining now starts and continues to within about 25 ft of level above. Access to stope is gained through drifts from pillar raises. Ground is broken with flat holes, and benches are kept shallow to avoid burying large pieces. All block-holing is done on top of ore pile. After final drawing of ore, stope is filled as soon as possible. Crown (level-pillar) is removed by square-setting. Fig 453 shows cross-sec through stope in narrower ledges. Where width is less than 60 ft, stopes are carried longit, some measuring 100 ft along walls. Dividing pillars are then 25 ft thick and one chute line, along footwall, suffices.

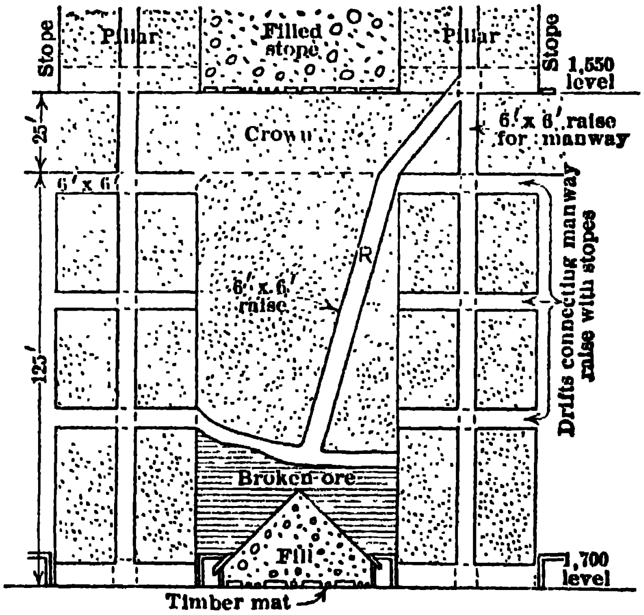

Fig 452. Longit Sec showing Principal Stoping Method, Homestake Mine, Lead, So Dak

Creighton mine, Ont. Data from O. Hall and R. D. Parker (216) in 1930. Large lenticular deposits, chiefly of massive chalcopyrite and nickeliferous pyrrhotite, occur in shear zones in norite and granite at or near contact; norite is on hanging-wall side. Aver dip of main orebody, 45°; of others, 35°–60°. Orebodies reach 1 000 ft in length; width to max of 300 ft. Entry is by inclined shafts in footwall. Level interval 120 ft in upper workings, 180 ft in lower. For many years, mining was principally by shrinkage method; more recently, by cut-and-fill and square-sets. For shrinkage mining, level development consisted of a footwall drift from which crosscuts were turned at 75-ft intervals along center lines of pillars.

In WIDE OREBODIES stopes 50 ft wide extended across orebody from foot to hanging and were separated by 25-ft pillars. Intermediate crosscuts were sometimes run under center lines of stopes to permit closer chute spacing (Fig 454). Footwall raises along contact and on center lines of pillars served for manways and ventilation. Other raises within footwall were ore and waste passes (Fig 455); ore passes delivered from the levels to underground crushers above skip pockets. Inclined chute raises, 15 ft apart on alternate sides of main crosscut, reached cutting-out floor of stope along pillar lines (Fig 454). If intermediate crosscuts were driven, there were also chute raises along center line of stope. Floor cutting, 25 ft above level, started by driving headings along pillar lines to connect chute raises. Headings were then slabbed on sides away from pillars and breast stoping continued until floor was completed. Stope was then carried by flat-back shrinkage stoping to within about 25 ft of level above. Floor pillar (crown) was broken through at hanging wall and mined by retreating toward footwall, using deep vert holes. Recovery of vert pillars consisted of driving raises 30 ft apart along center lines of pillars to within 10 ft of level above. At intervals in each raise, drift rounds were taken toward stopes, and along length of pillar to honeycomb it. Large sections of pillars, or whole pillars, were then drilled and blasted electrically (Fig 456). Breaking vert pillars and final drawing of ore retreated from hanging wall and far ends of a level. Hanging wall caved in large blocks and followed down on broken ore in drawing. Chutes were drawn until waste appeared.

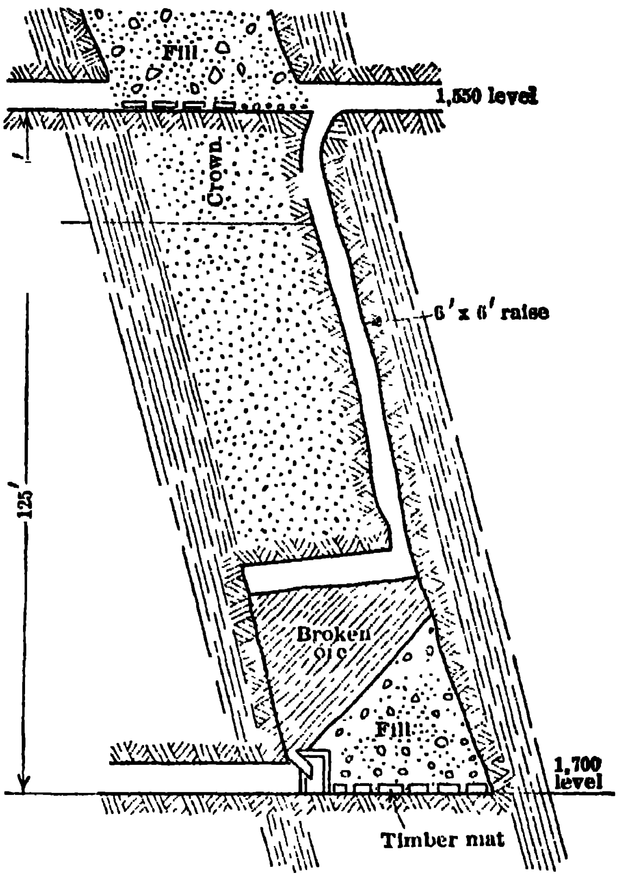

Fig 453. Cross-sec through Stope in Narrow Ledge, Homestake Mine, Lead, So Dak

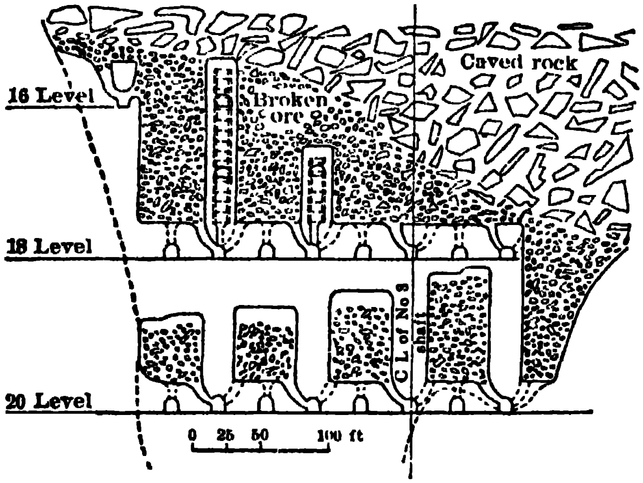

Fig 454. Longit Sec showing Crosscut and Chute-raise Arrangement, Creighton Mine, Ont

In NARROW OREBODIES, shrinkage stopes were carried longit and crosscuts from footwall drift were omitted. Length of stopes was limited by leaving 30-ft rib pillars at intervals, as required. Footwall raises served same purpose as outlined for wide orebodies.

Beatson mine, Kennecott Copper Corp, Latouche, Alaska. (All mining at this property was abandoned in 1930). Data furnished in 1927 by J. L. Fosard, F. M. Radel and J. A. Richards, who

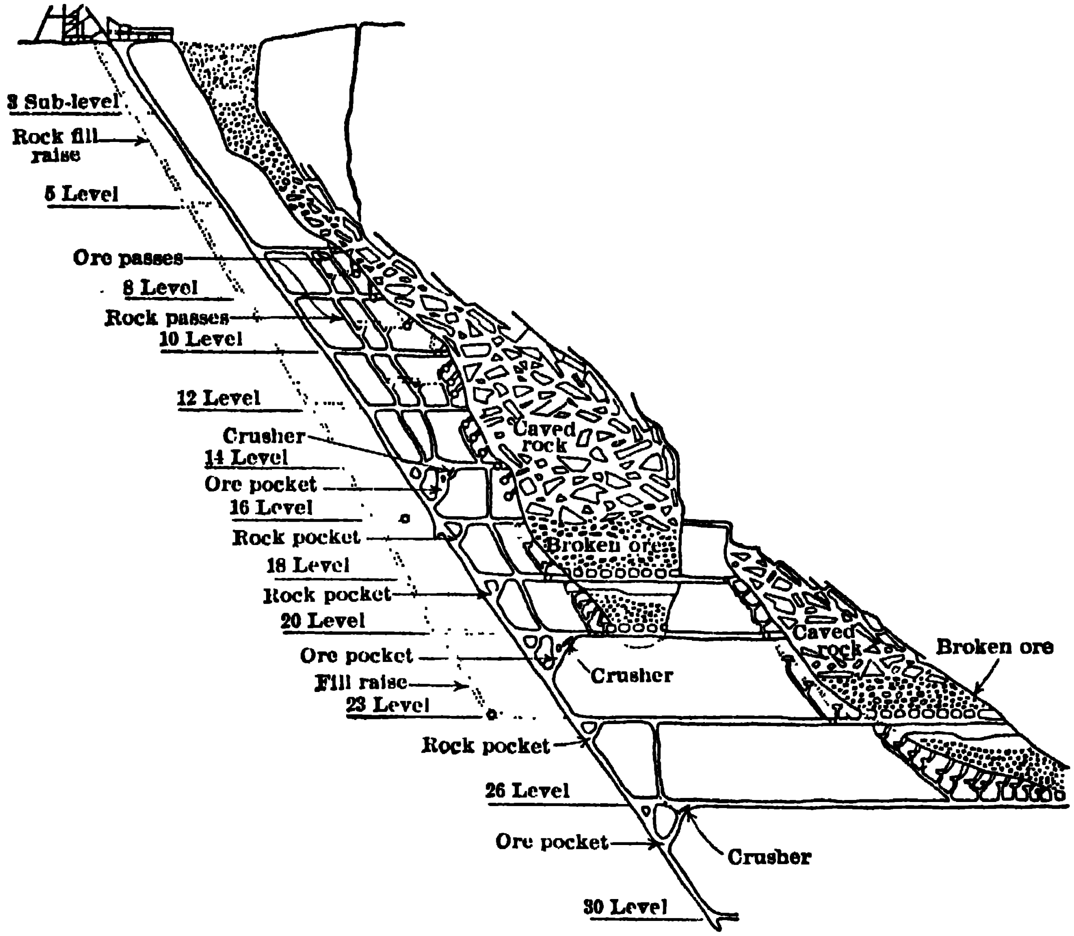

Fig 455. Cross-sec Creighton Mine, Ont

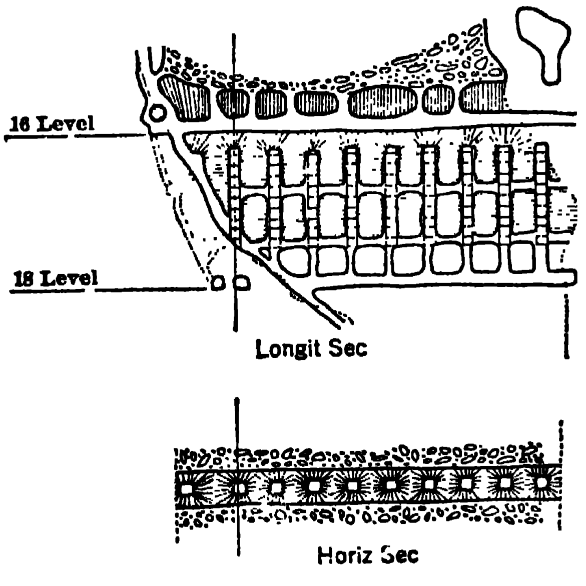

Fig 456. Sec through Pillar, showing Raises and Drill Holes, Creighton Mine, Ont

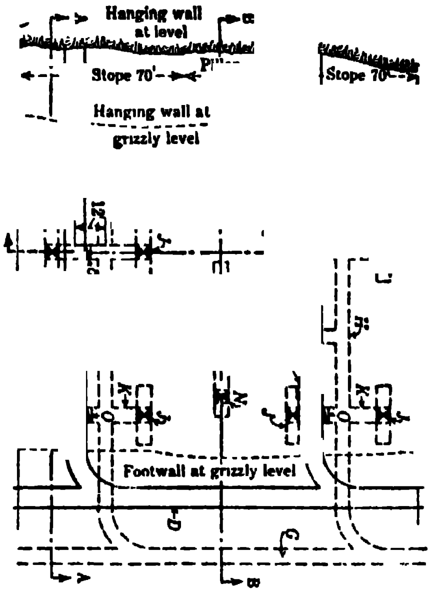

Fig 457. Beatson Mine, Alaska. (Diagram of main and grizzly levels; latter shown by dotted lines)

devised the mining method. Orebody is a low-grade lenticular deposit of disseminated chalcopyrite in graywacke, containing mineralized bands of chert and slate; length of lens, 600 ft; max width, 250 ft; ore aver, 1.6% Cu. Hanging wall is a fault dipping 40°–60°; there is 1–10 ft of gouge, associated with a massive pyrrhotite body, 1–12 ft thick. Footwall is a commercial one; it roughly parallels the hanging. **General plan.** Prior to 1920, mining was mostly opencut. Some underground mining was done in transverse flat-back shrinkage stopes; max safe width of such stopes was found to be 20 ft; production in them averaged 20 tons per machine drill-shift. Chief requirements for profitable mining of lower lifts: large output; safety; cheap breaking (large tonnage per drill-shift); controlled breaking, to minimize dilution by waste; prompt support of walls; cheap handling. The method adopted (locally called the Beatson method) was suggested by results from enlarging raises. It comprised a series of 70-ft transverse shrinkage stopes, separated by 30-ft rib pillars; ore was broken by blasting in deep holes drilled from raises put up through the area to be stoped, so that miners need not work in a stope after it was undercut. Pillars were partly mined and partly caved; broken ore was drawn through bulldozing chambers into chute raises. **Development.** Entry was by a vert shaft in the hanging wall, about 1 200 ft from the orebody; an 8 by 7-ft crosscut was driven through the orebody on each level; level interval, 200 ft. Fig 457–460 show development preparatory to stoping. Haulage drift *D* was parallel to footwall and about 40 ft from it; crosscuts *C* were driven to hanging wall at 100-ft intervals; these constituted the main haulage openings and were equipped for motor haulage. An intermediate level ("grizzly level") was opened 50 ft above main level; this comprised: drift *G*, about 50 ft from footwall, with crosscuts *H*, 100 ft apart on center lines of stopes; drifts *K*, 23 ft long, giving access to grizzlies (bulldozing chambers) *J*; and drift *L*, connecting with crosscut *M*, which was on center line of the pillar and contained 2 grizzlies *N*. Grizzlies *J* were 40 ft apart along the strike and 60 ft apart across the deposit, starting 15–20 ft from footwall; this arrangement proved satisfactory for a 70-ft stope, where the ore was 100–250 ft wide (Fig 458). From the haulage crosscuts *C*, 5 by 5-ft chute raises *R* were put up to the grizzlies (Fig 459); as the raises branched, each chute gate *O* served a pair of grizzlies *J*. Chute gates *P* (Fig 457) were connected by raises *S* (Fig 459) with grizzlies *N* and served to draw the pillar ore. Development was completed by driving the 5 by 5-ft undercutting raises *T* (Fig 458) from ends of grizzly chambers *J*, and connecting them above; 5 by 5-ft mining raises *W* were then put up to level above. In the example shown, mining raises were 45 ft apart, starting 15 ft from footwall; spacing was varied to suit character of ground and width of stope. Fig 460 shows similar openings driven from grizzly chambers *N* (Fig 457) on center lines of pillars. **Stoping.** Stope floor was first cut out 5 ft high; work started from the undercutting raises; drilling with stope drills. After undercutting was finished, miners did not work in the stope again; all drilling and blasting was done in the mining raises,

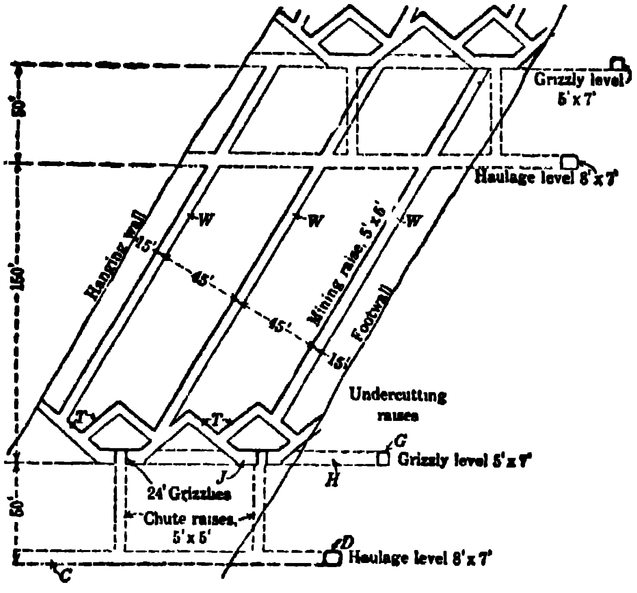

Fig 458. Beatson Mine, Alaska. (Vert sec *AA*, Fig 457, first stage)

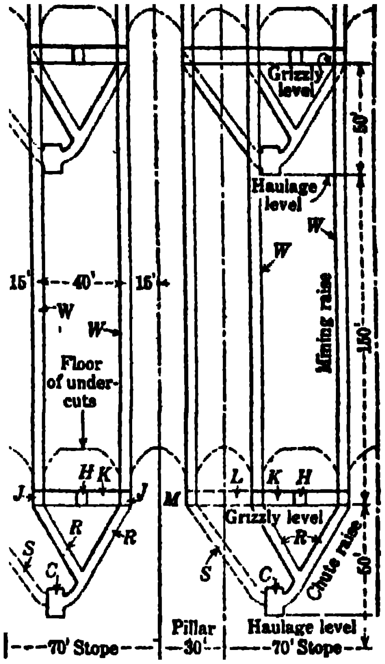

Fig 459. Beatson Mine, Alaska. (Vert sec *XX*, Fig 457)

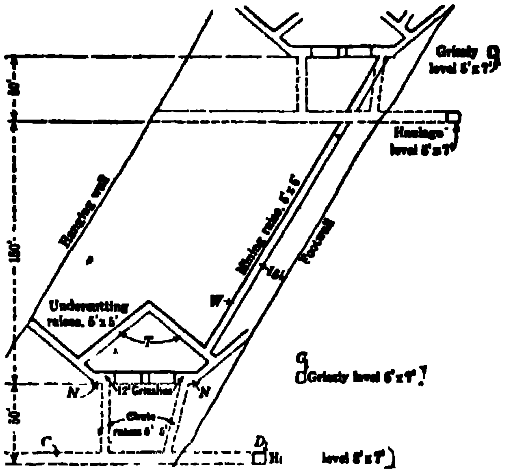

Fig 460. Beatson Mine, Alaska. (Vert sec *BB*, Fig 457)

to which access was gained from level above. Fig 461 shows mode of breaking ground. Drilling was done with heavy jackhammers. Starting 15–23 ft above the stope back, 6–8 holes, about 8 ft deep, were drilled downward from sides and corners of the raise; holes were pointed to bottom on the boundaries of a 15-ft square, with the raise in center. They broke a chamber *A*, which gave room for handling steel up to 20 ft long; the ledges *L* formed supports for a plank platform from which subsequent drilling was done. About 20 holes, 12–20 ft deep, were drilled from each chamber (Fig 461): they were located to break to the pillar lines and cover an area about 30 ft by 35 ft. About 10 ft of ground was left between bottoms of holes drilled from adjacent raises; this ground usually caved, but might be drilled if necessary. Each round drilled from a raise required about 12 man-shifts by 1 man and 2–4 man-shifts for springing and blasting. Stope backs were kept as nearly horiz as possible; broken ore was kept close to stope back to support the walls; drilling did not need to be completed in all the chambers on a given horizon before any were blasted. The mining raises had water and air lines from the level above; also a ladder and chute slide, in which a small skip for steel and supplies was operated by a "tugger" hoist on the level. MINING PILLARS did not begin until adjoining stopes were completed. A pillar was undercut like a stope; then a strip of ore was mined along the footwall by drilling from the raise (Fig 461) as in stopes. Most of upper part of pillar caved; more mining raises might be put up in pillars if necessary. BULLDOZING chambers *J* (Fig 457) were 24 ft long, 5 ft wide and 7 ft high; grizzlies had 11-in openings. DRAWING. Stope and pillar ore were drawn simultaneously and as evenly as possible to prevent waste dilution; drawing retreated from the end stopes on a level. ADVANTAGES OF THIS METHOD of breaking ground compared with ordinary practice in flat-back shrinkage stopes: (*a*) Since danger from falls from stope back is eliminated, it permits wider stopes and a greater ratio between stope and pillar widths. (*b*) Drilling is efficient; all holes are wet. (*c*) Many delays eliminated, as, setting up and tearing down, barring down backs, packing steel, breakage of hose. (*d*) Uninterrupted drilling for 6 out of 7 or 8 shifts increases footage drilled per shift and hence output per man-shift. (*e*) Drawing broken ore does not interfere with drilling. (*f*) Any large movement of ground shows itself in the mining raises. Table 43 gives OPERATING DATA. See also Bib (198).

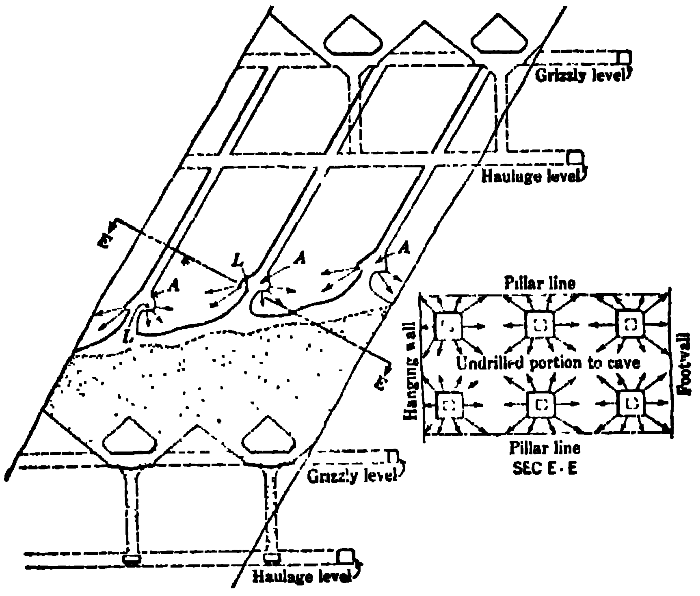

Fig 461. Beatson Mine, Alaska. (Vert sec *AA*, Fig 457, later stage)

(*a*) Based on mining 1 672 888 tons by Beatson method to Jan 1, 1926.

Alaska Juneau mine, Juneau, Alaska. Data from P. R. Bradley (584) in 1929, and L. H. Metzgar (564) in 1932. Mining here might be classified as caving, but shrinkage principles are also involved. It represents efficient underground mining of gold ore averaging only about 90¢ per ton. Values occur in quartz stringers and gash veins in slate containing numerous dikes and sills of metagabbro. Limits of ore are commercial; values are distributed irregularly in 4 ill-defined bands aggregating 755 ft wide, which, with intervening country rock, occupy an area 1 300–1 600 ft wide by 2 400 ft long. A cross fault divides the mine into 2 parts, and a strike fault dipping 55°–60° practically marks the footwall of the ore being mined. Presence of sulphides in the ore indicates values and makes sorting possible. **Development.** Topography is very rough; entry is by main haulage adit (No 4 level) about 2 miles long and 950 ft below surface in the main orebody. Levels above, at 250-ft vert intervals, are connected with haulage adit by ore-transfer raises (Fig 462). Bulldozing chambers may be on main or sub-levels. **Stoping.** Stope preparation consists of driving branch raises from ore transfers, to connect with bulldozing level at 75-ft intervals along strike and 100-ft intervals across strike. Thus, grizzlies are set at corners of a rectangle and serve a stope "cut-out" 130 ft along strike and 180 ft across it. Grizzlies with 25-in openings are of 15-in I-beams or H-beams, with 1-in wearing plates and separated by wooden spacing-blocks; they are set on slope of 1.25 in per ft. After placing grizzly, a 7 by 8-ft raise ("drawhole") is driven from upper end of grizzly at angle of 38° (Fig 463). After extending raise 18 ft, 4 branch raises ("cut-out raises") (Fig 464, A) are driven on a slope of 38°, diverging at 90° from each other. Two branches extend to limits of the area to be undermined. The others connect with corresponding raises from adjoining grizzlies. Thus, the "cut-out" is outlined both across and along strike by a set of raises having form of a large letter W (Fig 464, B). Cutting-out begins just above each drawhole and proceeds at a slope of 38° until the resultant 4 adjacent funnels meet at "peak" and outer limits of "cut-out" are reached. Cut-out miners work on contract basis at 35–38¢ per sq ft (1932), measured on the 38° slope; height of cut, 7 ft. Mounted drifters are used, miner averaging 8 7-ft holes per shift; 45 sq ft per machine-shift is aver break. During cutting-out, stope-raises (Fig 462), about 100 ft apart, are driven to level above. Upper level then serves as supply level and means of access to "powder drifts" below. When stope area is completely undercut, mining proceeds by large-scale blasting. Powder drifts (Fig 462, 464), 4 by 3 ft cross-sec, are driven radially from stope raises and loaded with enough powder to break down into

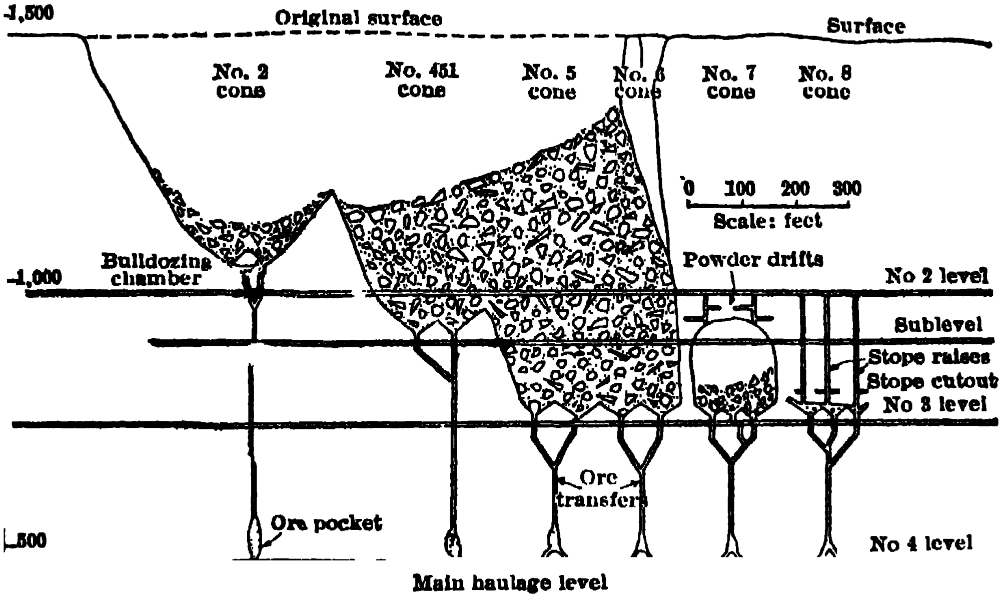

Fig 462. Development, Alaska Juneau Mine

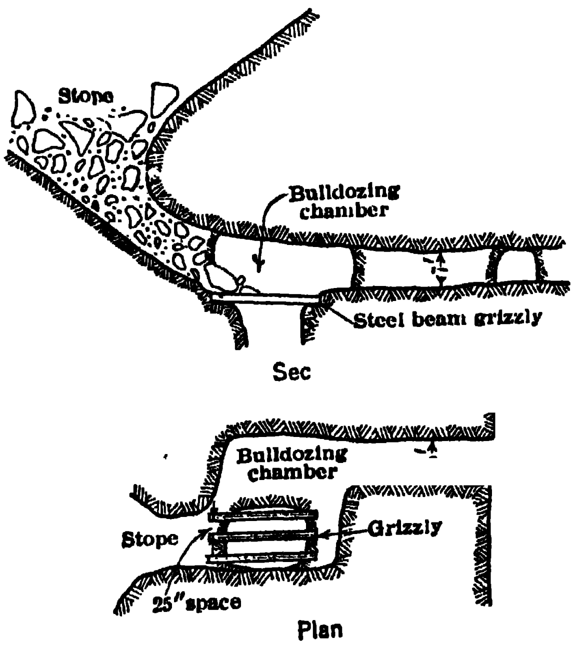

Fig 463. Bulldozing Chamber and Grizzly, Alaska Juneau Mine

the opening below the block of ground beneath the powder drifts, which are carefully planned as to depth, direction and burden, according to local conditions. Length of

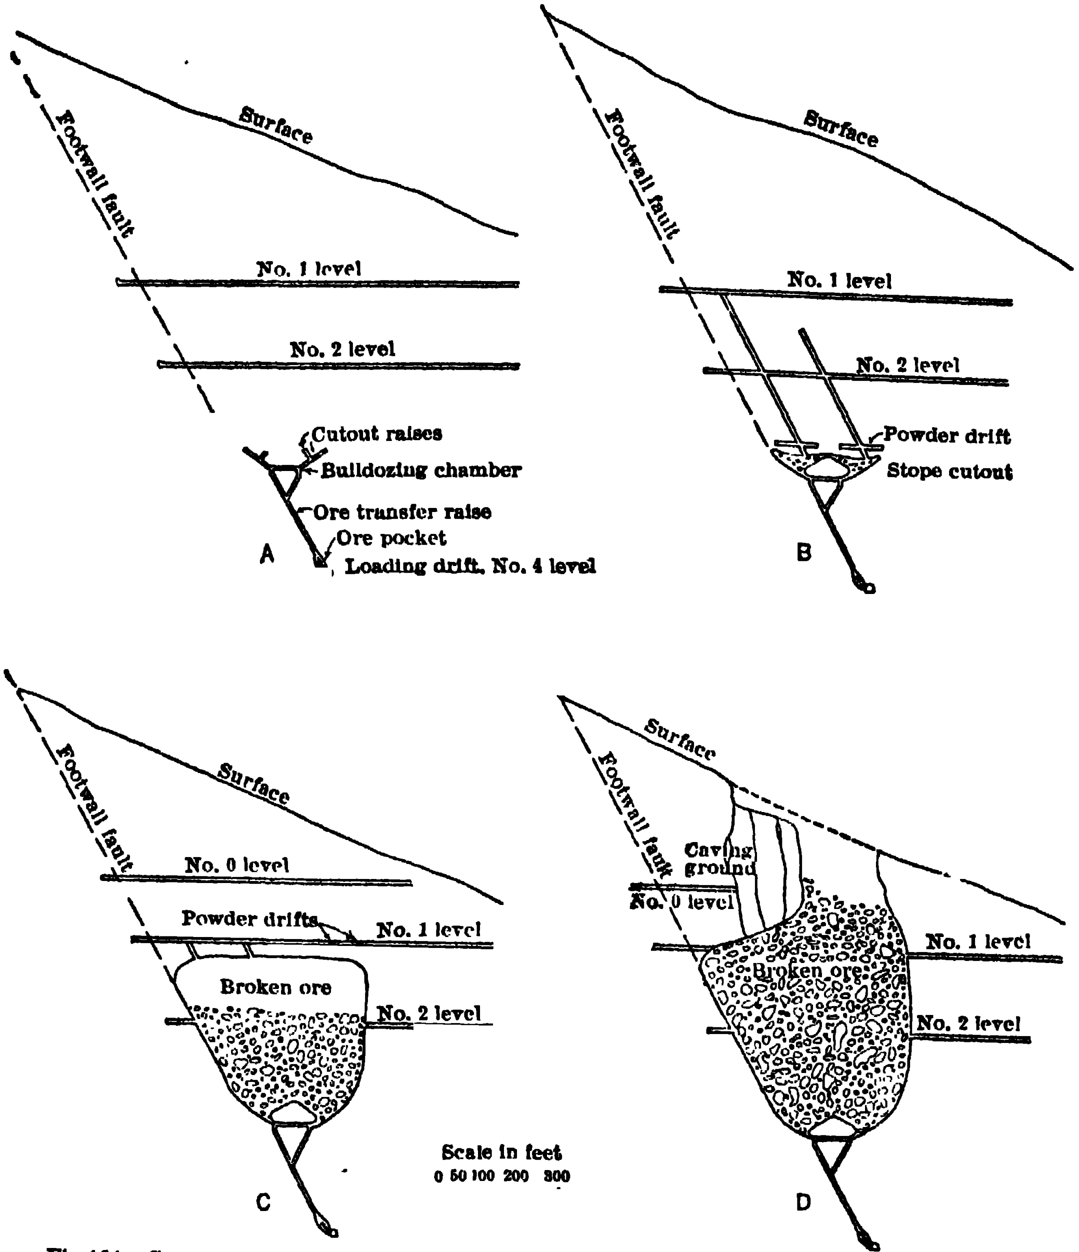

Fig 464. Stages in Development of a Shrinkage Stope, Alaska Juneau Mine, Juneau, Alaska

drift is about 40 ft; burden usually 30–35 ft, not exceeding 50 ft. As much muck as possible from last few rounds is left in the drifts to serve as stemming. Amount and spacing

of powder vary according to experience. Fig 465 shows typical powder-drift layout and distribution of charge. Explosive is 40% ammonia dynamite; it is fired by Cordeau-Bickford fuse, which is detonated by No 8 caps and two 30-ft lengths of safety fuse Through 1928, aver break in powder-drift blasts was 20 tons of ore per lb of explosive; for secondary breaking, powder consumption is 1 lb per 4.2 tons of ore. As stope progresses upward, the area is increased; powder drifts are driven alongside opening to enlarge stope and to induce caving. Grizzlies below are worked actively, so that ore broken by powder-drift blasts will fall considerable distance and break further by impact on ore pile. Mining continues thus until back attains such height and area that caving without blasting begins (Fig 464 D). Table 44 summarizes costs for 1928. Of total cost, development accounted for 20.6%, and mining, 79.4%.

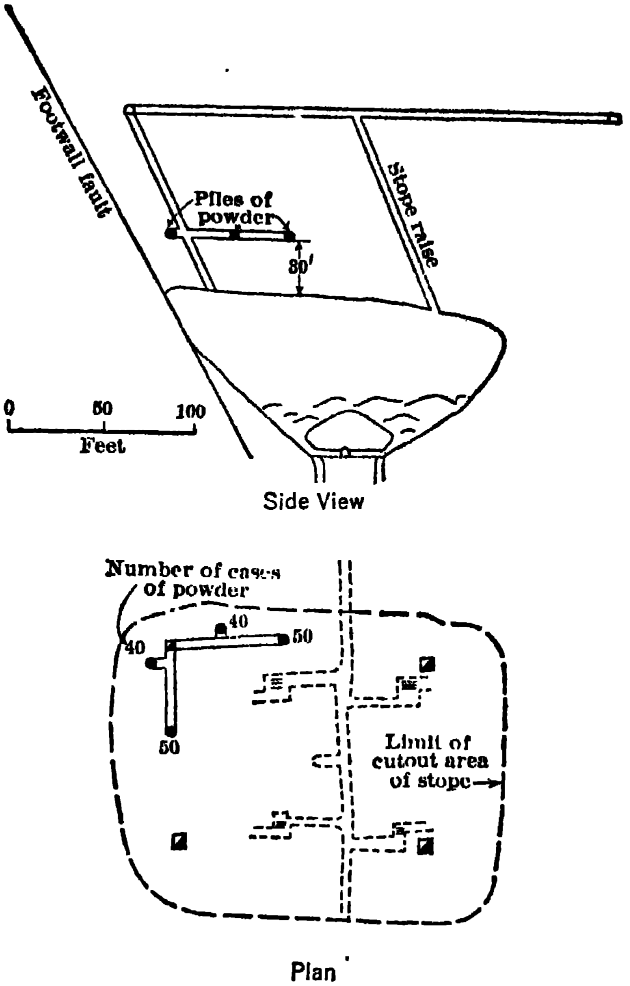

Fig 465. Typical "Powder Drift" Shot, Alaska Juneau Mine

Alaska Gastineau mine, Juneau, Alaska. Operations ceased in 1921. Data, relating to former mining, from G. T. Jackson in 1920 (530). Orebody is an extension of the adjoining Alaska Juneau, described above. The ore bands are in schist as well as in slate and metagabbro, near a contact with greenstone. There is a well marked shear zone along footwall, particularly in slate. Dip, about 60°. GENERAL PLAN. Mining was by large shrinkage stopes separated by permanent rib pillars. Stopes were first undercut. In schist areas, ordinary flat-back shrinkage stopes were carried: all ore broken by drilling and blasting. In slate areas, narrow flat-back stopes were carried up the footwall and across ends of stope; rest of the back caved by its own weight. P. R. Bradley (598) states that the method assumed continuous and uniform ore bands and that caving could be confined to a single band. Neither assumption was correct, and the combined effect of irregularly distributed values and dilution from waste produced ore too low in grade to mill profitably. DEVELOPMENT. From a vert shaft there was an adit haulage tunnel about 2 miles long. Level interval, 200 ft; there were 2 main ore passes in footwall connecting with the adit. Fig 466 shows the development for opening a stope; manway raises *R*, cross-sec 5 by 8 ft, were in the footwall opposite center lines of rib-pillars; short drifts *D*, driven to the pillar lines, gave access later to the stopes. Main levels were in footwall: chute raises, 35 ft apart. Bulldozing chambers were reached through small vert raises and crosscuts indicated by dotted lines at *B*; these openings were half-way between 2 chute raises and connected to bulldozing chambers by short drifts. Tops of chute raises were connected on footwall by small raises run upward at 40°. Some chute raises, continued across the orebody on a 40° angle, were points of attack for cutting out the stopes: they were sampled to determine stope width. A small raise was driven at each end of stope to connect with first breakthrough from manway raise. STOPES in slate were 200–300 ft long; in schist, to 400 ft; rib pillars, 40 ft thick, width of stopes, 40–120 ft. Cutting-out stope was about 7 ft high. IN SLATE, stope floor was cut out about 20 ft narrower than width of ore shown by assays in the raises; machines started at each end of stope and took a cut 7 ft high by 12 ft wide along footwall (Fig 466); then the same size cut was taken across each end of stope. These cuts weakened the ore so that it began to cave over the rest of the back. Men worked in the footwall cut while caving went on, very few accidents from falls of ground occurred. Successive cuts were taken until the back was 40–50 ft below a worked out stope above, then work ceased and the stope caved through to level above. IN SCHIST, ore did not cave readily or caved in blocks too large to handle. Slices about 7 ft high were blasted from the back, starting at footwall and working toward hanging. Backs were safe to work under if care was taken to keep them perpendicular to dip. About 125 tons of ore were broken per machine-shift in slate and 45 tons in schist; costs for labor, explosives, supplies, and general expense in slate stopes were about half those in schist. Aver costs (¢ per ton) for 1915–1918, inclusive, during which period about 6 500 000 tons were delivered to mill

were: ore breaking, 16.17; bulldozing, 7.46; tramming, 6.66; oreways and chutes, 1.01; ore transportation, 3.56; preparing stopes, 8.0; development, 5.0; total, 47.86¢.

69. SUMMARY, SHRINKAGE STOPES

Limitations. Application of shrinkage methods is limited by their rigid requirements as to dip, shape, strength, and character of orebody and its walls. These are desirable methods, because simple, requiring little timber and practically no shoveling in stopes, features which tend towards low costs. Under proper conditions, shrinkage stopes may be used in either narrow or wide veins; as auxiliaries to other methods they are also used in large, massive orebodies (Art 83–88). In some districts in Canada, as Kirkland Lake, Porcupine, and Sudbury, there has been a recent tendency to change from shrinkage to more selective forms of mining, involving higher costs per ton, but possibly lower costs per unit of metal produced. Statements in Art 69 concern only shrinkage stopes without chutes (ore-passes); their application to those with chutes is obvious if read in connection with the limitations of that form of stope (Art 67). Following discussion is based largely on a summary by H. C. Hoover (20).

Requirements for successful application of shrinkage methods: (*a*) Dip of stope walls should generally exceed 60°, for ore to settle freely; tendency of broken ore to draw down first on hanging-wall side decreases as dip steepens. (*b*) Orebody should be regular in shape, otherwise loose ore will lodge on footwall. Empty or partly drawn stopes are often too dangerous for shovelers to enter. Walls of narrow stopes may be timbered during drawing (Art 67), but this is costly and suggests possibility of using open stulled stopes (Art 38, 39). Irregular oreshoots are difficult to mine in shrinkage stopes, even if in steep-dipping veins with regular walls; sudden flattening of a shoot necessitates either a sub-level or else long chute-raises through unpayable ground (see Coniagas mine, Fig 436, Art 68). Regular and fairly continuous orebodies are essential, because shrinkage stoping must be carried on considerably in advance of output requirements. (*c*) In overhand shrinkage stopes, ore should be strong enough to stand over back of stope, occasional slabs being stulled. Possible width of stope in a given orebody may be increased by working underhand, as in Beatson method or at Alaska Juneau (Art 68), where miners do not work in stopes after finishing undercutting. Conversely, weaker ores may be mined in stopes of given width by underhand than by overhand. But consistently weak ore cannot be mined in shrinkage stopes. (*d*) Ideally, the ore should be of uniform value; at least payable throughout. Except in narrow stopes, patches of waste can not be left unbroken, and sorting in stopes is rarely feasible (note exceptional conditions at Cobalt, and at Kennecott mines, Art 68). (*e*) Walls should stand without crushing or spalling off into the broken ore when stopes are drawn. Friction between ore and walls during drawing increases any natural tendency of walls to slab off; the hanging wall especially should be strong. (*f*) Prospecting openings can not be run in the walls of shrinkage stopes, hence limits of orebody should be well defined. (*g*) Physical or mineralogical peculiarities of ore may prohibit shrinkage stoping, for example: Some broken ores tend to "pack" in stopes, and must be blasted out; ordinarily this occurs only when stopes are left undrawn for a considerable time; frequent drawing prevents packing. Packing may be due to pressure or to cementing action of mine waters on pyritic ores; it may be controlled if size of stopes and plan of work can be regulated for drawing stopes promptly. Pyritic ores may oxidize so rapidly that heating occurs in shrinkage stopes; danger of fire may preclude use of shrinkage in such cases. More often, oxidation is less rapid, but may affect recovery in flotation process.

Advantages of shrinkage stopes: (*a*) Cost of development is usually low. (*b*) No shoveling or tramming is required in working space at top of stope; if ore can be drawn through chute-gates, there is no shoveling (see Art 67 for conditions justifying shoveling in drawing off ore). (*c*) Little timber is used; staging for miners and shoveling plats are unnecessary; timber for manways is recovered when stope is drawn. (*d*) Ventilation can usually be maintained at little expense. (*e*) Compared with filled stopes, shrinkage stopes sometimes wholly save cost of filling; filling an empty stope in one operation is always cheaper than contemporaneous filling. Shrinkage stopes avoid loss of fines in filling, and cost of ore-passes, and of shoveling ore to them. (*f*) In narrow veins, shrinkage stopes compete with stulled stopes (Art 38, 39), and are preferable for wide veins and heavy walls. They furnish firm working floor for miners; timber staging may reduce effic by causing feeling of insecurity. (See Art 43 for comparison with sub-level stoping.) (*g*) Shrinkage stopes afford large reserve of broken ore, but see disadvantage (*d*) below.

Disadvantages of shrinkage stopes: (*a*) If chute-gates are used, fine breaking is required; some large pieces may be buried in broken ore, and make trouble in chute-raises and gates. For alternative mode of dealing with this problem see Arrangements for protecting levels, Art 67. (*b*) Some spalling of waste from walls into ore always occurs; a given amount reduces aver value of broken ore more in narrow than in wide stopes. Much ore is lost if walls crush. (*c*) Ore can not be selected from different stope faces, for maintaining a uniform grade. (*d*) Ore left in stopes until they are finished ties up a considerable investment for labor, explosives, etc, to break it, and added working capital is necessary. At a given mine, tonnage of broken ore eventually reaches a fairly constant max. Interest on money required to break this tonnage is an operating charge against shrinkage methods; it represents cost of utilizing broken ore for support. H. C. Hoover cites an example where, on 250 000 tons annual production, the interest (5%) on capital represented by broken ore amounts to 7¢ per ton treated (20). A large reserve of broken ore is advantageous in insuring a regular output; but, only the ore in completed stopes is available for this purpose. In the few Lake Superior iron mines using shrinkage stopes, this storage feature may be availed of to save cost of stock-piling and reloading 60%–70% of the ore mined while navigation is closed. (*e*) Shrinkage systems are not flexible. When once started, they are difficult to alter, owing to lack of frequent raises; especially true if filling is the only alternative. Change of method may be required by change in dip, or in character of ore or walls in depth. (*f*) Walls of shrinkage stopes, unless very strong, can be re-stoped for lower-grade ore only when stopes are filled promptly and filling is left undisturbed; walls often crush when filling is drawn for use in lower stopes.

CAVING METHODS

Caving methods, strictly, are those in which ore is first undercut and then broken down by its own weight, or by weight of overlying rock, or by a combination of both. But, as a result of custom, operations involving caving of the material overlying an orebody, as a systematic and essential part of the work, are also classed as caving methods, though practically all the ore is broken by drilling and blasting. Three distinct methods, SUB-LEVEL CAVING, BLOCK-CAVING, and TOP-SLICING, result from this classification, each having many modifications. For comparison, see Art 82 and 83.

70. TOP-SLICING

General. Top-slicing practice in the U S was developed from the "North of England Caving Method," used in certain English iron mines. Term top-slicing is sometimes erroneously applied (270) to sub-level caving (Art 75). Descriptive terms "Top-slicing and Cover-caving" and "Top-slicing and Partial Ore-caving" (286) have been proposed to describe the two methods accurately, but have not been generally used. Top-slicing method is also called simply "Slicing."

Field of use is in wide veins, masses, or thick beds of weak ore, where clean mining and high extraction are desired and where the overlying surface need not be supported; for its limitations and conditions, see Art 74.

General plan. Ore is mined in horiz floors or slices, taken in descending order from top of the deposit. Each floor is mined in small sections, the roof of each being allowed or forced to cave before an adjacent one is attacked. Work on each floor retreats from limits of ore toward points of entry; all ore is broken by blasting. The principle is illustrated by

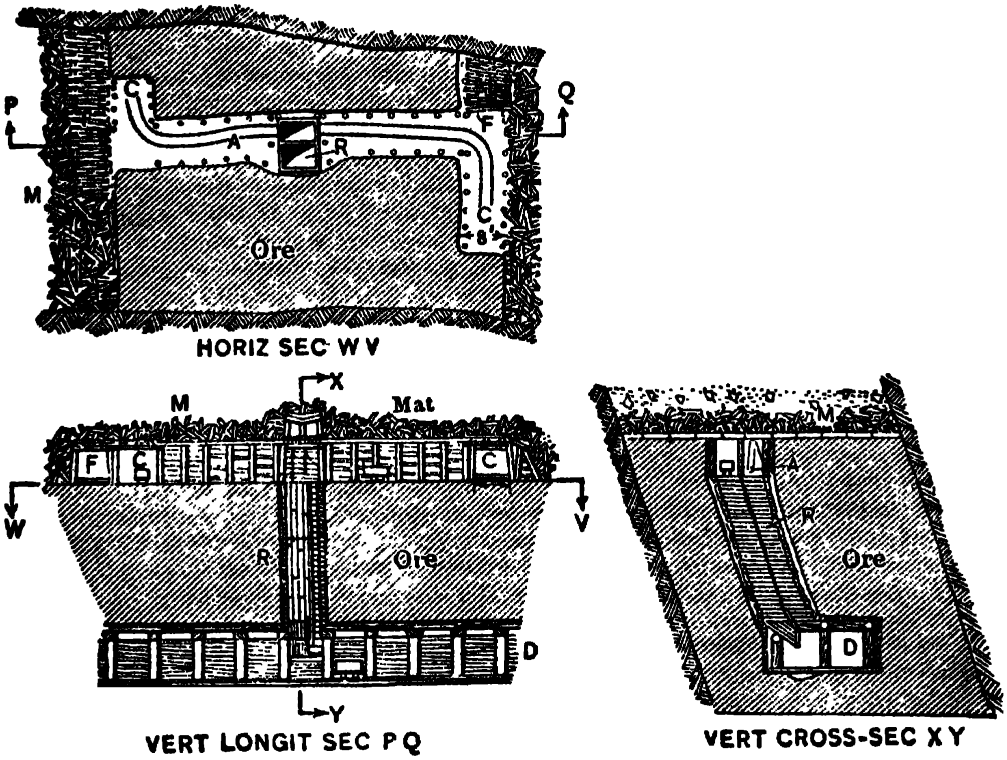

Fig 467. Top-slicing, Lake Angeline Mine, Mich

Fig 467, showing top-slicing at Lake Angeline mine, Mich, 1894; J. P. Channing describes it as follows (287).

Ore was soft hematite, averaging about 75 ft wide and overlain by glacial drift. First level was opened 75 ft below top of orebody by driving a drift *D* about midway between walls; 2-compartment, cribbed raises *R* were put up to the overburden at 100-ft intervals. From top of each raise a 7 by 8-ft drift *A* was driven 50 ft each way, meeting caved ground, as shown, or a drift from the next raise. Drifts were timbered with 3-piece sets and were advanced by spiling, where necessary, as under loose overburden at top of deposit. Slicing began by driving 7 by 8-ft crosscuts *C* to the walls, at points half-way between raises or at ends of drifts alongside caved ground, as shown. Crosscuts were timbered with 3-piece sets of 6 to 10-in round timber, spaced 2 to 4 ft apart. Ore was shoveled into cars holding 1 500 lb and trammed to chute compartment of raise. When a crosscut was finished, its floor was covered with split lagging *F*, laid close together on 3 8-in round stringers. The crosscut sets were then blasted down, allowing overburden to drop. Contiguous crosscuts were driven and caved in succession, working back toward each raise until a slice 8 or 9 ft high had been removed from top of orebody. Other slices of same height were successively mined below the first. After taking several slices, the work assumed the form shown by Fig 467. A mass of twisted timber *M*, the MAT, collects at the top, its thickness increasing as work descends. The mat forms an artificial roof between ore and overburden; its subsidence may be controlled and it is easily picked up on timbers of the slice below it. Slicing usually begins on a new floor as soon as it will not interfere with work on floor above, and before the latter is finished; this maintains steady output. Simultaneous work on several floors is shown in Fig 489 and 491, Art 72. Openings like drifts (*A*, Fig 467), driven on each floor as a preliminary to actual slicing, are called SUB-LEVELS. They are designated by number, No 1 being highest on each lift. Term SLICE means a horiz layer of the orebody; also an opening driven for removing blocks of ore outlined by sub-level development. Thus, crosscuts *C*, Fig 467, are slices; exact meaning of the word depends upon the context.

Modifications. All top-slicing resembles in general Fig 467, but details vary widely in different orebodies. Variations in timbering of slices give rise to terms DRIFT-SLICING, PROP-SLICING, and SQUARE-SET SLICING, denoting work in which slices are timbered with drift-sets, stulls, and square-sets respectively. Drift-slices may be driven 2 or 3 sets wide, or square-set slices may be 2 sets wide and 2-4 sets high, if conditions allow. Such excavations are called ROOMS, this work being sometimes termed "top-slicing by rooms" to distinguish it from "top-slicing by drifts" (or crosscuts), as in Fig 467 (286). Other modifications are to secure cheaper loading; thus, effic use of mechanical loaders (usually scrapers) in slices modifies the layout of raises and slices. In some cases, slices are made with sloping floors, for loading by gravity; called INCLINED TOP-SLICING (Art 73). Art 71-73 show details of modifications of top-slicing.

Development. ENTRY. Shafts must be located where they will not be affected by caving. If the position of property lines compels sinking in ground overlying the orebody, pillars of ore must be left for shaft protection, and these are not minable unless they can be reached from adjoining property. On Mesabi Range, Minn, auxiliary shafts for handling timber are sunk at points over the orebody, the shaft pillars being mined last; even then, much ore may be lost through wearing away of the outside of pillars as the mat descends around them. LEVEL INTERVAL. Table 45 summarizes practice at mines described in Art 71-73; levels are usually 50 to 100 ft apart. The intervals must be smaller in wide deposits and in heavy soft ore than in narrow orebodies or stronger ore. In most ores soft enough for top-slicing the maintenance cost for levels and raises is an appreciable expense tending toward a small level interval; cost of hoisting slice timbers in raises also increases with height of lift. In some districts, a balance is struck between these costs and that of driving and equipping haulage levels, as follows: Levels for mechanical haulage are spaced 100 to 300 ft apart vertically, or, where conditions allow, only one such level is driven at bottom of deposit. Intermediate hand-tramming levels are then opened as required, 35 to 50 ft apart vertically; they are often connected with a shaft in the country rock, through which timbers are lowered. LATERAL DEVELOPMENT. Levels may consist of a single drift (Fig 467), but in orebodies of large horiz section a rectangular system of drifts and crosscuts is often driven, arranged to allow proper spacing of raises for handling ore from slices. Layout of intermediate levels, where used, follows the latter plan, tramming distances being then determined by location of raises connecting with main level; even in wide orebodies short trams can be secured with relatively few raises put up from a haulage level consisting of 1 or 2 drifts (Fig 491); similar factors determine the most effic layout where loading in slices is done with scrapers (Fig 486). RAISES should be so located as to strike an economic balance between cost of handling ore in slices and cost of development; close spacing cheapens the former but increases the latter. Table 45 indicates that the commonest raise interval is 50 ft, but this does not indicate the distance that ore is trammed or "slushed," or scraped and trammed in slices, unless taken in connection with area of orebody and design of raises. Raises often provide the only means of entrance and of handling timber to slices, and then must have 2 compartments. SUB-LEVELS. Where slices are 11-12 ft high or more and ore is strong enough, sub-levels may be driven as untimbered drifts, say 6 ft high, instead of full height of slice, as in Fig 467. This increases speed of sub-level development; the sub-level is then enlarged at entrance of each slice, just before starting the latter. Usually sub-levels opened long before they are needed are costly to maintain, as caving of the mat on the overlying slice throws great pressure upon them. See Fig 489 for one method allowing simultaneous work on several floors, without opening sub-levels until caved ground above has come to rest. Development plans should be as simple as possible.

Breaking ground in drift-slicing is a form of breast-stoping (Art 30). In high square-set slices, some ore is broken overhand. For examples, see Fig 475, 477, 478, 490.

Timbering in slices supports comparatively small areas of mat for only a short time, hence light timbers of poor grade are adequate; to cheapen costs, round timber is used wherever possible.

Three-piece DRIFT-SETS with vert posts and simple framing are most used for slices, because: (*a*) they are generally strong enough; (*b*) floors laid without sills are easily picked up on the caps in the underlying slice; (*c*) in working alongside of caved ground, posts of sets are lagged along the solid side before the slice is caved, to keep back the gob. SQUARE-SETS have the same advantages, but require more timber. They are used in ground too heavy for drift-sets, or in high slices where single drift-sets would require posts of unmanageable length and superposed drift-sets would not support the side pressure of caved ground. PROPS (vert stulls) are employed where floors are laid on sills, the latter taking the place of the cap of a drift-set. Props are also used in slicing under rock capping at top of an orebody, and under peculiar conditions in Minnesota iron mines (Art 71). For light pressures and under a thick mat, "tee-pieces" (*i e*, stulls with head boards of two 2 by 12-in plank, 4-5 ft long) form cheap and satisfactory supports for plank floors laid without sills (66). See Art 71-73 for details of timbering.

Table 45. Top-slicing Details

(*a*) See Art 71. (*b*) For parallel slicing; may be greater for radial slicing. (*c*) Not required until thickness of orebody approaches 100 ft, when 1 intermediate may be driven; for greater thicknesses, spacing of intermediates averages 60 ft. (*d*) See Art 72. (*e*) Economic height 11 ft. (*f*) Aver 10 ft. (*g*) Max. (*h*) Sills are laid under floors and caught up on props in slice below. (*i*) Approx. (*k*) Sub-gangway method. (*l*) Or other multiple of 11 ft. (*n*) Not used. *ds* = drift sets, 3-piece. *sq* = square-sets. *bh* = bulkheads. *str* = stringer sets. *pr* = props or stulls.

Note.—Before using this table consult details of work in Art 71–73.

Floors may be of lagging or plank. Plank is best, because it may be laid with tight joints to keep out fine waste; it is also easier to lay and to block up from below than round lagging. Usually, one layer of 2 by 10 or 2 by 12 plank, in 10 to 16-ft lengths, makes a good floor; double layers may be needed in a few slices at top of orebody; on Mesabi Range, single layers of $^5/_8$-in resawed or 1-in hardwood boards have been found adequate; wire fencing laid on poles is now in common use (see Art 71).

Sills under plank floors are generally omitted in horiz slices, but are used in inclined slicing, Art 73. On the Mesabi, 3-in poles 8–16 ft long are sometimes laid 1–2 ft apart to help support the boards when they become the back of the slice below. To avoid breakage, the plank should lie directly on ore, hence sills must either be sunk in the floor or embedded in a layer of broken ore supporting the plank. Cutting grooves for sills is slow and costly, and, as it is practically impossible to have slices on successive sub-levels directly under one another, there may be trouble in picking up sills from below. Sills allow use of props instead of drift-sets in slices, but this is not a compensating advantage, as it saves little timber. Occasional omission of floors on certain sub-levels is possible only under a thick mat, and is not feasible in high-grade ore. It was successful at Miami; at Cananea it increased costs in spite of saving timber.

Handling timber. In top-slicing, as in Fig 467, all timber for slices must be hoisted up the ladderways of raises; column-mounted, air-operated hoists (tuggers) may be used; where scrapers are used for moving ore, scraper hoists often serve also for hoisting timber. See Mesabi practice and that of Iron River Distr, Menominee Range (Art 71) for modes of arranging work so that timbers may be dropped to sub-levels.

Blasting down timbers in slices to force mat to cave is done by simultaneous firing of small charges of dynamite in holes bored in the posts. Holes are usually near the middle of posts, and are 4 to 6 in deep; in large-scale work, much time can be saved by having 1 or 2 men bore all holes with air-driven augers. Half a stick of dynamite or less is used per post; it is often unnecessary to blast all the posts in a slice.

Some engineers hold that mat settles in better shape if the supporting timbers are allowed to fail by pressure than if they are blasted down; some blasting is almost always required. Top-slicing is possible only when the mat caves promptly and rests solidly on top of slice; this condition is apt to be met when posts in slices are shot down. For handling small areas of mat which "hang up," see Morenci-Metcalf district, Art 72.

Recovery of timber is rarely attempted in top-slicing, largely because cheap timber is used, which will not stand removal and reuse. But, possibilities of salvage are indicated by following statement from P. B. Scotland, Gen Supt Ariz Copper Co, Morenci, in 1914.

"In mining coal by longwall method (Art 108), 25 to 50% of the stulls supporting the roof are recovered. When mat becomes thicker in our top-slice stopes, a similar saving might be made. At present, the mat is often penetrated and broken by vertical stulls, which would not occur if they were removed. In longwall working, it is . . . more economical to timber closely and make large recovery of stulls than to reduce the number of supports and lose all of them."

Height of slices. (*a*) Height of drift-slices and of those where sills of the floor above are picked up on stulls is limited by max length of post that can be handled; this is determined partly by size of openings through which timbers must pass and partly by comparative costs of handling and erecting timbers of different lengths. Usual height of drift-slices is 10 to 12 ft (Table 45), which represents an economic mean of all the factors. Art 71 gives examples of high drift- and prop-slices, and reasons for their use. (*b*) In very heavy ground, height of slice is generally reduced to avoid need for heavier posts, which cost more to handle and often more per bd ft than the 6 to 10-in diam commonly used. Long posts also tend to fail by "swinging" under heavy pressure. (*c*) Mode of timbering influences possible height of slices. Square-set slices may be several floors high; slices 17 to 20 ft high are sometimes timbered with 2 superposed tiers of drift-sets. Lateral pressure from caved ground limits use and height of such slices (278). (*d*) Higher slices are possible under a thick strong mat than under a poor one. Low slices are often taken at top of orebody until mat is well formed, then the height is increased to its economic maximum. (*e*) Character of ore may limit height of slice. At Miami (Art 72), ore sloughed off the top of faces higher than 10 ft faster than it could be mucked out and the bottom shot; this caused mat to cave prematurely (285). (*f*) Height of slices should be the economic max, to reduce the number of sub-levels and amount of flooring timber.

Hand loading. In horiz top-slicing, all ore broken in slices is shoveled. This is a disadvantage of the method and shoveling plats should be used. Ore is shoveled direct to raises or into barrows or small cars. Direct shoveling is cheapest, but requires raises spaced 25–30 ft apart throughout the orebody. Factors involved in choice between barrows and cars, for transport to raises, are illustrated by the following extreme examples:

At Bingham, Utah, ground was very heavy, slices were narrow and timbers required much reinforcement. Barrows holding 350 lb were used on sub-levels. 1 000-lb cars were found unsatisfactory; they could not make the short turns required, nor reach far corners of stopes, nor pass distorted timbers in narrow runways. It was found that leads for barrow work should not exceed 75 ft (66). Before the general use of radial slicing and scrapers on Mesabi Range, Minn (Art 71), ore was handled in cars at much lower cost than in barrows; sub-levels were straight and usually stood without timbering; slices were wide and laid out systematically; tramming distances on sub-levels reached 300 ft.

Mechanical loading (Sec 27). Scrapers or other mechanical loaders usually reduce cost of handling ore broken in slices. Scraping is usually called SLUSHING in Lake Superior district when done with a single-drum hoist. Ore may be scraped directly into raises (Fig 481), or up a slide into cars for tramming to raises (Fig 469), or there may be 2 scraping operations: (*a*) to get the ore out of the slice; (*b*) to scrape it to a raise (see Copper Queen mine, Art 72; Utica Extension mine, Art 71). In Lake Superior iron districts, ore in slices is now handled almost entirely by scrapers with double-drum hoists.

Gravity loading. In high square-set slices, ore from upper floors is handled through chute-gates (Fig 479). In inclined top-slicing methods (Art 73) the floors of slices are driven on an upward slope of 30°–33°; causing broken ore to slide out of the slice into funneled chute raises, or into a narrow square-set or shrinkage stope opened as part of the development preparatory to slicing.

Ore-storage. Chute-compartments of raises provide for this, which aids in maintaining steady output. Storage capac decreases as slicing approaches a level. Close cooperation between miners and trammers on levels is then necessary to avoid delays. "Hanging chutes" sometimes provide storage, while slicing on lowest sub-level of a lift (Art 90).

Sorting. Waste unavoidably broken is thrown back and becomes a part of the mat; top-slicing is not adapted to ores requiring systematic underground sorting.

Formation of mat. Slicing may begin directly at the top of orebodies overlain by SOFT GROUND, using spiling, where necessary, to advance sub-levels or slices. In heavy ground, this work is slow and costly, and causes unavoidable mixture of ore and waste. An alternative, which may be cheaper in spite of the ore sacrificed, is to start slicing 5 or 10 ft below top of orebody. Pillars thus left cave on the floors in highest sub-level, and aid in holding back fine waste during first stages of work.

Top-slicing is used also for mining orebodies overlain by a ROCK CAPPING; contacts between ore and capping are often irregular. It is then essential that the capping shall cave and not hang up over large areas, which may give way suddenly with disastrous results; a flat surface under which to begin slicing is also necessary. Hence, irregular tops of orebodies are usually mined as open square-set stopes (Art 45). Following are examples of practice (see also Mesabi square-set slicing, Art 71).

At Detroit Copper Co's mines, Morenci, Ariz (Art 72), tops of highest raises were connected by drifts and crosscuts, from which an open square-set stope, usually 10 to 20 ft high, was carried to capping. Stringers of ore extending into capping were followed by raises, which also weakened the back. Stope floor was covered with 2 layers of 2-in plank, at right-angles to each other. Deep uppers were drilled at short intervals in back of stope; holes were also drilled in posts of square-sets; all holes blasted simultaneously (279).

At Ariz Copper Co's mines, tops of orebodies were mined by open stopes, square-set stopes, or sub-level caving (Art 75). A double floor of 2-in plank was laid; overburden was caved either to surface or sufficiently high to make it safe to work under the mat (178).

At Cananea, Mex, tops of orebodies were mined with square-sets. Flooring was of 2-in plank laid on 5 by 10-in sills, 10 ft long. Capping sometimes stood long enough to allow salvage of some timber. When capping hung up, sets were not blasted down, but filled with waste to form a cushion above the mat on which large slabs might fall without endangering work in slices below (282).

In this work a continuous square-set stope over whole area of orebody is unnecessary. As 1 or 2 floors of caved sets sufficiently protect the slices, stopes of this height are opened at different elevations in different parts of the deposit, as required by irregularities in lower surface of capping. This avoids high square-set stopes of large area, and does not interfere with slicing. Where contact between ore and capping is regular, simpler methods of starting a mat are feasible. If capping is very soft, slicing begins at top of orebody, usually with double floors in first few sub-levels to build up mat quickly. In harder ground, a breast stope 8 or 10 ft high is carried across top of deposit, with stulls and headboards to support the back. After laying a floor, the timbers are shot down. Foregoing operations are also preliminary to other caving methods in which weight of caved ground above the workings is an essential.

Ventilation is generally poor in top-slicing unless fans are used. Slices often form "dead ends"; decaying timbers in mat give off heat and some CO. For example of artificial ventilation, see Miami, Art 72, where the installation of blowers caused marked increase in effic of labor (285).

Percentage extraction by top-slicing is high; usually only 5–10% of total ore is lost. Further details are given in Art 71–73.

71. TOP-SLICING IN IRON MINES

Mesabi Range, Minn, thicker deposits. In essentials, the following data on top-slicing (contributed anonymously in 1938 by one of the Mesabi mining companies) apply to, and are typical of, any underground mine on the Mesabi Range, when the orebody is thicker than can be mined by one slice. Drilling and blasting are done in timbered slice-drifts, extending to the predetermined limit of the orebody, and retreating toward main haulage drifts.

Conditions affecting choice of method. Orebodies of the Mesabi Range are flat-lying deposits in shallow troughs, of great lateral extent as compared to depth; usually overlain by slate, taconite (ferruginous chert) and glacial drift, in places, by glacial drift alone. The orebodies are generally less than 200 ft thick, max 400 ft. Overburden varies from a few ft to over 300 ft. Underground mining is adopted when open-pit methods are not physically or economically applicable. Such factors as form and dip of orebodies, variations in strength of ore and wall rock with depth, and structural irregularities, as faults, slips, fissures and fracture zones, have little influence in the choice of mining methods, as they are of minor importance on the Mesabi Range.

Main development. SHAFT LOCATION. When the size, shape, and depth of an orebody to be mined underground has been determined, the shaft is located in rock near deepest part of orebody, so that as much ore as possible will be tributary to it, and the deposit will be completely drained by it. Shaft pillars in ore are avoided; possible disturbance by subsidence receives careful attention. On surface, consideration must be given to topography, adequate space for plant, timber storage, stockpile ground, railway connections; also to adjoining operations, present or future. MAIN HAULAGE LEVEL. In many Mesabi Range mines, it is possible to develop the mine with only 1 main haulage level, which is located in ore, on or near the bottom rock. If the tonnage is large and a long life assured, economy of upkeep and repairs favors the driving of main drifts in the bottom rock. If the orebody is 100 ft or more thick, 1 or more tramming levels are driven to avoid choking of ore in long chutes, and facilitate movement of timber and supplies. The plan of the main level conforms with the shape of orebody and contour of bottom rock. A system of parallel drifts in direction of the long axis of the orebody, connected at intervals by cross drifts, is desirable because it promotes ventilation, more rapid drainage, permits a greater number of chutes, and the routing of traffic in one direction. The main haulage drifts are usually 8 by 8 ft (inside) if timbered, or 9 ft wide and 8 ft high in rock. In timbered drifts, sets are 5 ft c-c, the back lagged with round 3–6-in timber; sides are lagged when necessary. These drifts are generally on a 0.5% grade, in favor of load.

Sub-level development. The top sub-level is located to provide a height of ore of 12–14 ft above its floor. Vert cribbed raises, 5 by 5 ft if to serve as chutes, are driven on one side of main haulage drifts, are usually 50 ft apart, and are carried to top of the ore. From these raises, 8 by 8-ft crosscuts, usually timbered, are driven at right-angles to main-level drifts, at the elev of the sub-level, until the extreme edge of the orebody or property line is reached. If the bottom rock is encountered, the drifts are continued at a higher elev, involving a transfer of ore from beyond the rise. At intervals, the sub-level drifts are connected by crosscuts, for ventilation.

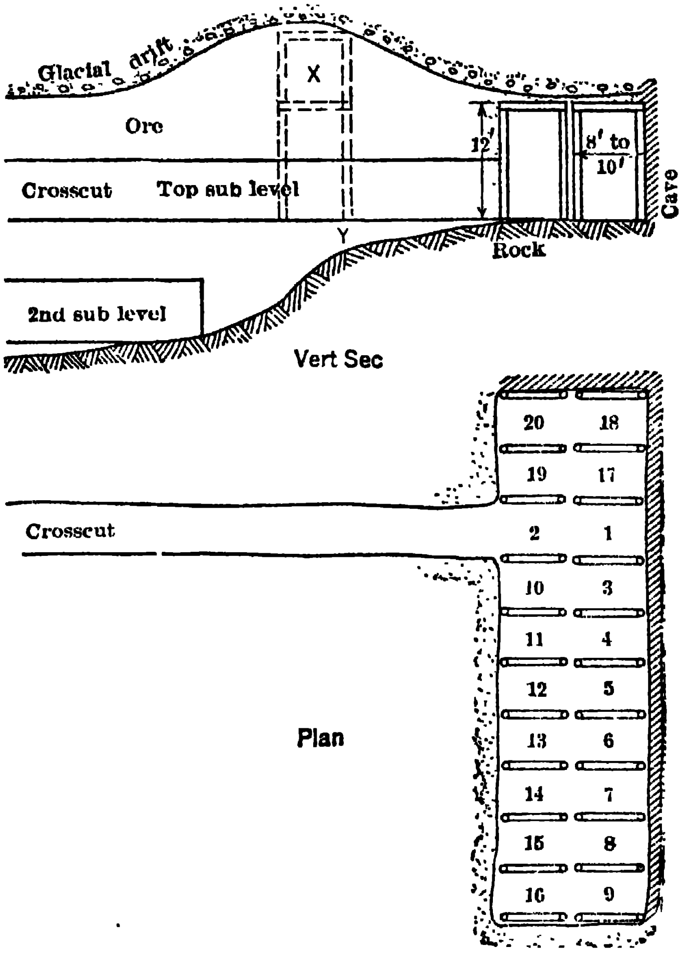

Fig 468. Details of Top-slicing, Mesabi Range, Minn

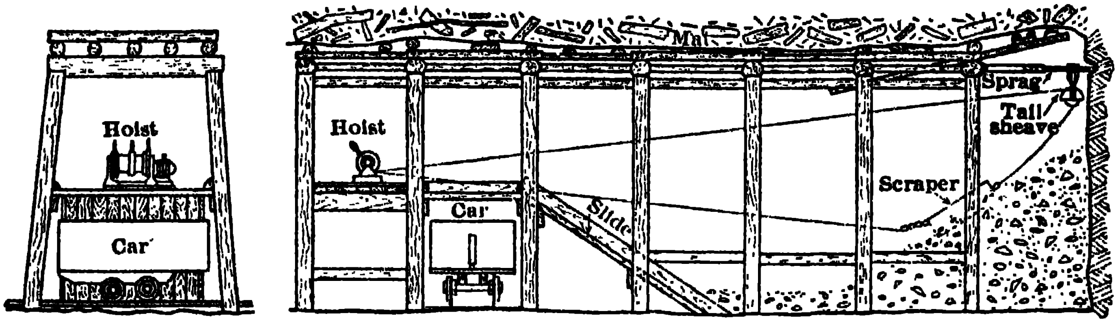
Mining by parallel slicing. Slice-drifts are started at the far end of each crosscut from the chutes, by blasting out the full height of ore and erecting an "opening" 3-piece set of timber (No 1, Fig 468). Caps are lengthwise of the crosscut, and the slice-drifts are driven at right-angles. Set No 2 is next placed, as opening set for the second slice. Sets 3–9, on approx 6-ft centers, are then mined, the breast of the slice-drift now being within 2 sets of the corresponding sub-level drift to be driven from the adjoining crosscut. Sets 10–16, and 17–20 are then removed, in order. The room thus opened is now 2 sets wide and, if under a loose back, it carries considerable weight. If so, poles are laid on the floor in longit rows at 24-in centers, and covered with 42-in diamond-mesh wire fencing. Sides of the rooms next to solid ore are also covered with fencing, stapled to the posts. The inside posts and caps are then blasted out, allowing the room to fill with waste from above. The fencing prevents intermingling of waste and ore, and protects the miner when working underneath or alongside the caved room. If the back is of sand and gravel, as wire fencing will not prevent contamination, $^3/_8$- to $^7/_8$-in hardwood boards are used; sometimes with wire mesh to reinforce the boards. This operation is repeated until entire sub-level is mined. Meantime, the second sub-level, 12–14 ft below, is developed so that mining can begin there under the cave when the work above has retreated far enough to mine safely. The order of removing the slices, as described, may be varied to meet local conditions. If the ground above is heavy, the order in the second slice-drift might be No 15, 16, 14–11, leaving No 10 to support the entrance until 19 and 20 are removed. In very heavy ground, a slice-drift is dropped as soon as completed. The upper surface of the orebody is often very uneven. Should the ore extend higher above the sub-level than can be mined by 1 slice, a second slice-drift superimposed upon the first is driven, dropping the ore down to the floor of the first (*X*, Fig 468). Near the boundaries, some ore usually remains between the sub-level floor and the bottom rock; as its thickness is not great enough for slicing from the sub below, this ore is recovered by stoping up the bottom before caving (*Y*, Fig 468).



Rear Elev of Slice Drift

Side Elev of Slice Drift

Fig 469. Slice-drift, Scraper-loading to Car

Loading and transport. Formerly the ore was loaded by hand shoveling into barrows or cars. Now, scrapers are generally used. If distance to chute is great, sub-level cars are loaded as in Fig 469; otherwise, the ore is mechanically scraped to chute (Art 91). Elec haulage is general on main levels.

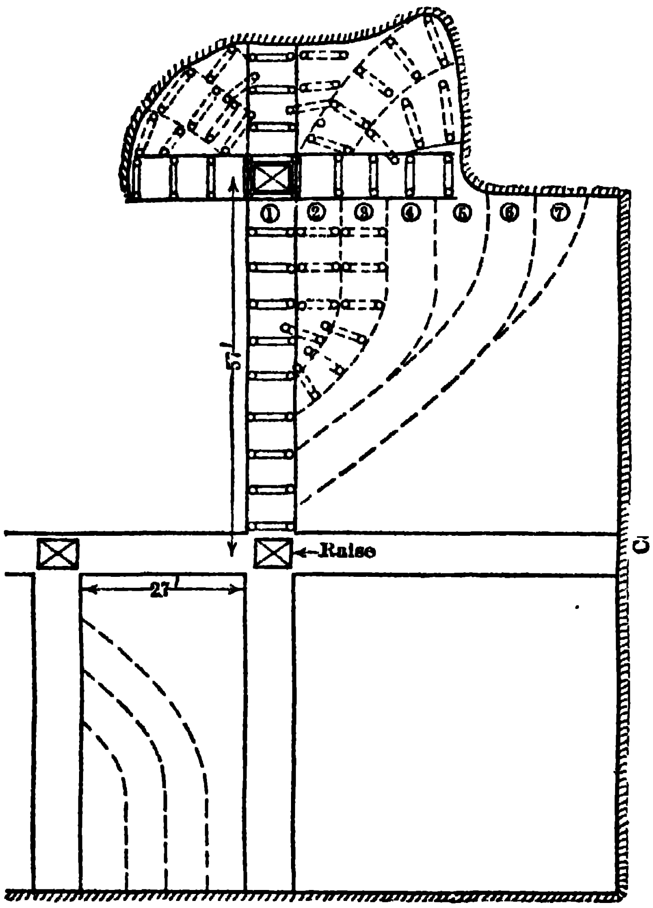


Fig 470. Radial Slicing, Mesabi Range, showing Successive Stages of Removal

Mining by radial slicing. The adoption of power loaders has caused a change, under certain conditions, from the usual methods of top slicing to "radial" slicing. Scraping to cars or chutes with single-drum air hoists, as early practiced in parallel slicing, required snatch blocks to turn corners, or else the movement of ore in 2 or more operations. The first step towards radial slicing was the use of more chutes, 20–33 ft apart (Fig 481). This permitted a direct pull from the slice-drift at right-angles to the chute and from drifts radiating from either side; and also the blasting of ore in the first 2 sets directly into the chute. With the adoption of double-drum elec hoists, returning the scraper to the working face mechanically, the length of slice-drifts was increased to as much as 100 ft, 60–70 ft being common, and close spacing of chutes became unnecessary. By starting a new slice-drift from the side of a completed slice, and lengthening the caps as the distance from the chute increases, a fan-shaped area is mined with the chute at its apex. Advantages of radial over parallel slicing are: (*a*) high production per miner; (*b*) unnecessary to maintain a cross-cut for a considerable time; (*c*) reduced wear on ropes and snatch-blocks; (*d*) hoist operator has full view of scraper most of the time. Fig 470 shows successive stages in mining by radial slices; Fig 471, 472 show variations in method. There is no standard plan, because after preliminary development the mode of attack depends largely upon character of the ground, and weight and movement of the cave above.

Timber. Top-slicing requires relatively cheap timber and lagging, such as round green timber with the bark left on. Caps are 8–10 ft long and 10 in min diam; posts up to 18 ft, 7-in top diam. Lagging in main drifts is 6–8 ft long, with 3-in top, live tamarack being best; in the slices, split cedar with 3.5-in min diam. Timber consumption per ton of ore depends on: the sub-level interval, whether bottom and sides of slices are covered by boards or wire fencing, and height, width, and spacing of sets in slice-drifts. Aver consumption in the mines of one large Mesabi company is approx 3.50 bd ft of round timber and 0.0046 cord of 6-ft lagging per ton of ore. Explosive is a semi-gelatin 45%–60% dynamite; consumption is about 0.5 lb per ton of ore. Output per man-shift underground is from 8.25 tons in multi-sub-level operations to 13 tons in thin one-slice mines.

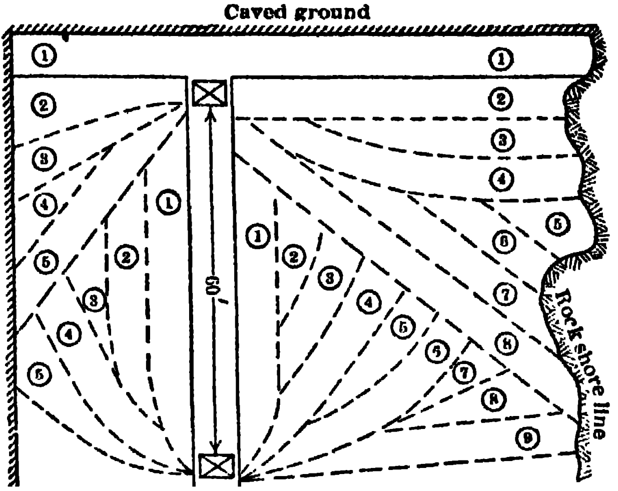

Fig 471. Radial Slicing, Mesabi Range, showing Variations in Plan

Mesabi Range, Minn, thin deposits. Data from J. V. Claypool in 1937 (267) and 1938 refer to slicing of deposits averaging about 16 ft thick in the Hibbing-Chisholm district. Capping is usually a bedded, ferruginous, slaty paint rock. Total overburden is 70–240 ft deep, of which glacial drift may compose 70–100 ft. Nature of capping is such that mining becomes dangerous unless done under skilled supervision and in accord with practice based on experience. Orebody is divided into slicing panels ("pillars") 100 ft wide, through the center of each of which an 8 by 10- or 10 by 10-ft timbered drift *A* (Fig 473), preferably at right-angles to haulage drift, extends to the ore limit, a distance of 400–700 ft. Slicing starts at the outer end and runs 50 ft each way from the entry drift. Slices are 10 ft wide and from 3 ft high on boundaries ("shorelines") to 18 ft in the main orebody. Drift sets are 6 ft 4 in c-c, with round tamarack sprags of 3 to 6-in

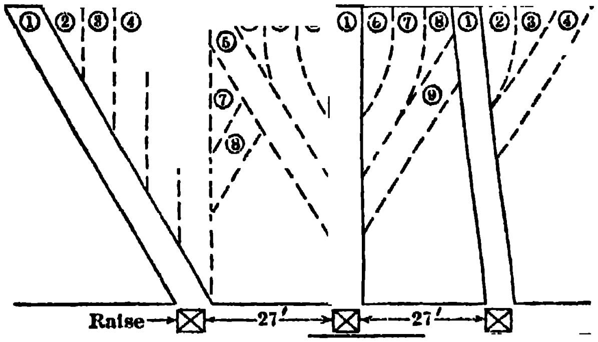

Fig 472. Radial Slicing, Mesabi Range, showing Variations in Plan

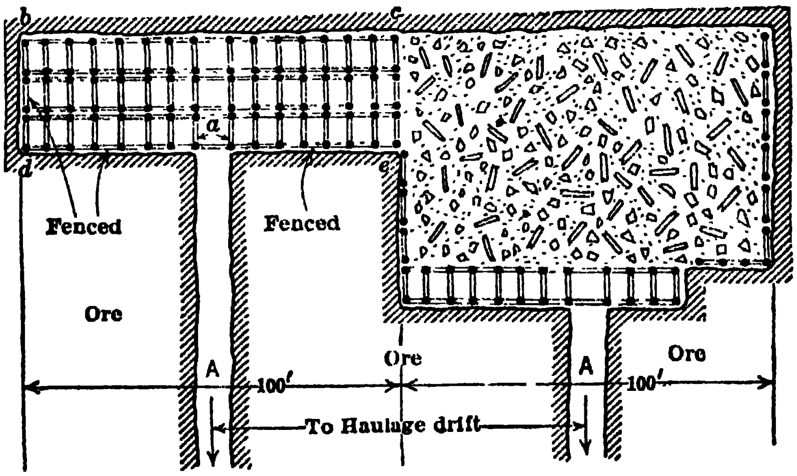

Fig 473. Parallel Slicing, Hibbing-Chisholm Distr, Minn. If *b-c* is a shore line, the 2 caps and all posts except those along *b-d* and *d-e* are blasted; if *b-c* is a face of minable ore, this side also is wire-fenced and its posts are not blasted

diam. For safety, TIMBER used is of good quality. Posts are of green Norway, jack, or white pine, with 7–12-in top diam; caps, of same material, are 10–14-in. Caps were formerly 8 ft long, but experience showed that 10-ft caps afford better control of caving. Back poles are of live tamarack, 8 and 10 ft long and 3–5 in at small diam. Split lagging, of live white-cedar, is 7 ft long, with min diam of 3.5 in. For lagging above the back poles, $^5/_8$-in hardwood boards are used. When starting SLICING in a new "pillar" of solid ground, a room 3 slices wide and 100 ft long can usually be opened before the wt warrants blasting down. A room should show considerable press before attempting to cave it. When a room is ready for caving, its sides and ends next to unmined ore are covered from top to bottom with 42-in diamond-mesh fencing. Strips of fencing overlap a little, so that openings do not occur when press is exerted by debris following blasting of the timber. After a room has been fenced, the inside posts (all except those against solid ore) and the caps *a* of the 2 opening sets in the outermost slice are bored and blasted. Best results are when posts and caps of the 2 opening sets, next to the room entrance, are fired first. After caving the initial 3-slice room in a given "pillar," the following rooms are only 1 slice in width. Wt and diagonal press are usually troublesome in the second and third slice of a group, as the capping is strong enough to hold together until the third slice is blasted down; it then shears off and comes down completely. Retreat in one pillar usually precedes that in the adjoining pillar by 3 or 4 slices, or more if the back is hard to control. Slicing stops at 50 ft from haulage drift, after which the pillars of that drift are similarly sliced, retreating towards the shaft. Transfer of ore from the breast into chutes (as required when irregular bottom makes a footwall haulage drift desirable), or into cars for transport to shaft, is done with power scrapers. Slices are well lighted with 100-w flood lamps, so that miners can see the back at all times from a safe distance. Output per man-shift underground averages 13 long tons. Explosive, 60% semi-gelatin, 0.5 lb per ton. Timber, 2.5 bd ft per ton.

Miscellaneous data on Mesabi practice. Following notes are based on data published in 1912, 1913, and 1924, by C. E. van Barneveld (35, 482); W. Bayliss, E. D. McNeil, and J. S. Lutes (275); L. D. Davenport (276); A. L. Gerry (277). The descriptions apply chiefly to hand loading, now largely displaced by power scrapers, but are suggestive in showing variations in slicing details used to meet special conditions. DRIFT-SLICING AT EDGE OR "SHORE LINE" OF DEPOSIT. Fig 474 shows method. 3 by 3-ft test raises *R* were first put up 50 ft apart, to determine height of ore over the sub-level. At *C*, where ore was about 7 ft high, crosscut *DE* was driven, 7 ft wide and full height of ore; first slice *EF* was then taken. Crosscut and slices were timbered with 3-piece sets, with 7-ft caps and vert posts of a length to suit height of ore. Slice *EF* was advanced until ore became too thin to work; posts of last sets were usually 24 to 30 in. Other slices were driven alongside (see dotted lines). Ore was shoveled or wheeled to a car in crosscut *DE*. As the rock at shore line usually rose at a steep angle, it did not pay to turn the track into the slice. For this kind of work, sets are best placed with their caps along the sides of *DE*, instead of across it (Fig 475). Though slicing could have been started directly from the sub-level drift, a distinct gain resulted from driving a preliminary crosscut, and slicing up the slope of the bottom rock, ore came down grade, posts of slice-sets were of about equal length, and the whole layout was more flexible. When ground in slices became heavy, the timbers were shot down and new slices started alongside; all ground to right of *DE* was thus mined and caved

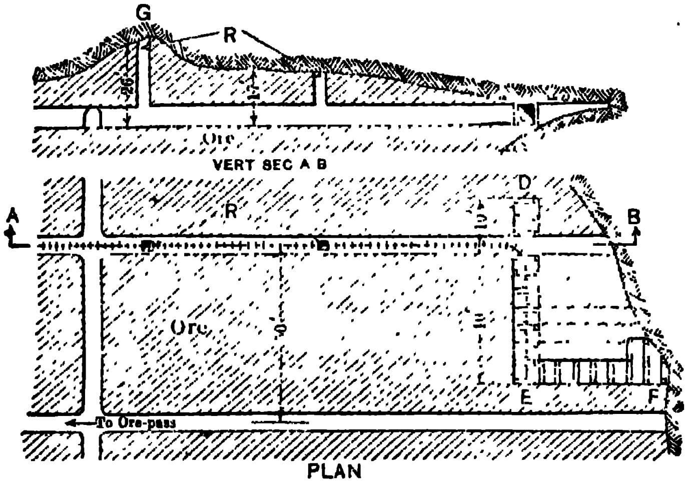

Fig 474. Starting Slices at Edge of Deposit, Mesabi

Square-set slicing. Top of orebody is usually rolling, height of crests frequently reaching 30 or 40 ft. Square-set slicing has been used in such cases, especially when the area was small. Raises could be put up, and another sub-level opened for mining in 2 drift-slices, but this involves costly development, difficult ventilation, and delay in ore production Square-set slicing was done in rooms 2 or 3 sets wide and 2 to 4 sets high; completed rooms were boarded up and caved as in drift-slicing. The method was elastic. Fig 474 shows typical conditions; the roll at *G* was 26 ft high, and would be sliced from existing sub-level. The change from drift-slicing would begin where ore was about 17 ft high. The first square-set slice was taken in the solid, leaving 1 set of ore standing between it and last caved drift-slice, to insure that the square-sets were in line and at right-angles to sub-level drift. This slice, 2 sets high, was timbered as it advanced; the pillar between it and the drift-slice was then mined, the order of removing sets depending on weight of ground. In succeeding square-set rooms, the first slice was taken alongside the cave, the caps connecting with the timbers on wall of previous room. Chisholm set (Fig 334, Art 49) illustrates size and type of square-set used. Fig 476 shows a room next to the cave; ground was first excavated for set *A*, which was firmly blocked; top was lagged, except a space 18 in wide across the set, which was covered with cross-boards, and served as a chute-gate for loading ore broken above. Ground over *A* was then broken into with a hole as in Fig 477, and excavation was squared up to take set *B*; set *C* was then raised, broken ore falling to lagging on set *A*. Other sets were placed over *C* until top of ore was reached; back of highest set was blocked and lagged; side lagging was rarely necessary. Set *D* was mined next (Fig 478); its top was covered with lagging and short boards, but the lagging ran at right-angles to that on set *A*, so that the long dimension of chute opening would be parallel to the track turning from *A* into *D*. Sets *E* and *F* were then mined, from sets *B* and *C*. Work was resumed on sill-floor in set *G*, and continued until a slice 1 set wide had been mined along the cave side of room; set *H* and those over it were taken last. Second slice was taken in same way, starting with set *A′* (Fig 476); ground in sets over *A′*, *D′*, *G′*, etc, was attacked from open sets over *A*, *D*, *G*, etc. Track was run into the first slice only; ore from upper sets of second slice was handled to cars through rough chute-gates (Fig 479). Usual length of rooms was 51.67 ft, which took 7 sets, including set in sub-level drift; caps of odd length were used at ends of connecting rooms. Square-set slices rarely exceeded 4 sets high; if higher, the side pressure from caved ground made it difficult to prevent timbers from swinging. On finishing a room, all lagging was dropped to sill-floor, and used for boarding up posts along the solid side and end (Fig 480). In upper sets, posts next to ore were boarded with horiz 1-in boards, and the room floor covered with the same. Holes were then drilled in some of the timbers and charged; entrance to room was boarded up and timbers were shot down. Rooms might be blasted with or without system; Fig 480 shows a systematic method; timbers marked by arrows were blasted; caps and posts at *A*, *B*, and *C* were expected to act as props and allow room to cave without disturbing timbers against solid ore. Some foremen shot down posts next to cave, 1 or 2 center posts and a few caps, claiming it caused better settling and left timber in better shape for working adjacent slice. Some timbers on the ore side of room often fell when the cave occurred; they were replaced as ground was timbered in taking the slice alongside.

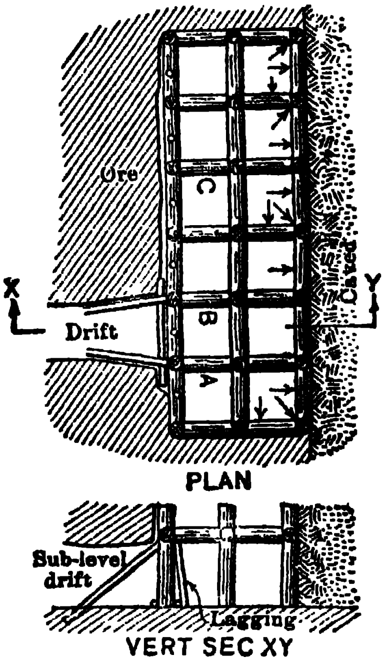

Fig 480. Boarding-up Rooms and Blasting Timbers, Mesabi Square-set Slicing

Prop-slicing. In extensive areas where ore was overlain by considerable thickness of firm taconite, slice at top of deposit has been taken out with props spaced as required; max length of prop, 20 ft. Some orebodies 5–18 ft thick lay between 2 layers of taconite, the roof layer being 40–50 ft thick, very hard and tough and caving only when a large area was mined out Such ground was developed by a main haulage road, from which drifts were run 50 ft apart to the "shore line"; pillars were then mined in 10-ft slices. Drifts were timbered with

3-piece sets; slices, with 10 to 18-in props, placed 3–6 ft apart on cave side of slice. Where height of ore exceeded 12 ft, 1 floor of square-sets was erected and 2 props were set on each cap. This form of prop-slice is an open, stulled stope; it gave cheap ore and left large rooms which were not caved unless roof required it; the roof came in large blocks when it caved.

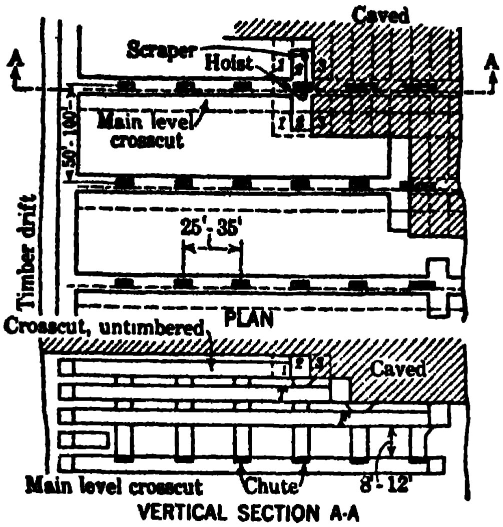

Fig 481. Drift Slicing, Scraper Loading (diagrammatic)

Scraping into raises. Early development plans, for hand loading into cars, required long trams on sub-levels. Better adjustment between these and haulage by elec loco or mule on main level was secured by type of development in Fig 481. At intervals of 50–100 ft along main drifts, crosscuts are driven to reach all ore above by vert raises. Raises from crosscuts are 25–35 ft apart, and connected by crosscuts on each sub-level. In parallel slicing, slices extend both ways from raises to lines midway to adjacent sub-level crosscuts. Scraper handling has replaced hand loading. Each raise serves slices 1, 2, 3. Top of raise is funneled toward slice 3 (*T*, Sec *A A*, Fig 481), and the corners of slice 2 are removed near crosscut to allow ore from slice 3 to be scraped into the raise. After slice 2 is mined, the raise is funneled towards slice 1, as at *F*. Single-drum hoists were formerly used, with 25- to 35-ft hauls to raise. With double-drum hoists, slices 50 ft long on each side of raise are common; these hoists, with radial slicing, made close spacing of raises unnecessary. Adaptation of power scrapers (Sec 27) to development plans, originally laid out for hand loading, has been done in 2 ways: (*a*) ore is scraped up slides at entrances of slices and into cars (Fig 469) trammed by hand to raises; (*b*) ore is scraped out of slices to the entry or "transfer" drift, and thence to the raises by another scraper. Fig 482 shows general plan of such an installation, where aver length of transfer drifts is 340 ft (268). For further details of this installation, see Art 91.

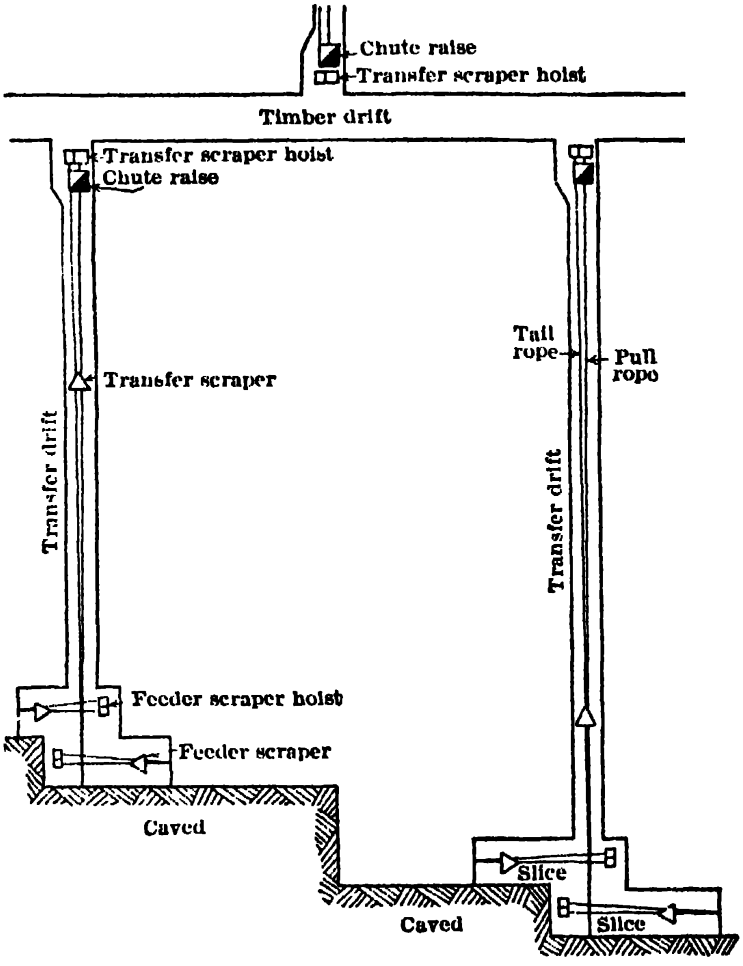

Fig 482. Use of Scrapers in Top-slicing, Utica Ext Mine, Mesabi Range, Minn

Utica mine, Eastern Mesabi Range. Data from C. E. van Barneveld in 1924 (482). Orebody was a bed of hematite, 10–45 ft thick; dip, slight; capping, paint rock and taconite. Fig 483 shows development and illustrates difficulty of applying top-slicing in thin orebodies with flat dip; see "Requirement (*f*)," Art 74.

Mine was opened by a vert shaft *V*, placed to cut the deepest ore near property line. Main level comprised 2 haulage drifts *F*, *H*, connected at intervals by loops *L*. Drift *F* followed or cut into foot-wall; drift *H* was kept as near hanging wall as depth of ore permitted. Raises *R* were 50 ft apart along main drifts. Sub-level interval, 13 ft; sub-level development comprised a series of parallel crosscuts from the raises, connected by timber drifts *T* (Sec *A A*, Fig 483). To meet problem of handling ore to the shaft from top sub-level (52 ft), the 26-ft sub-level

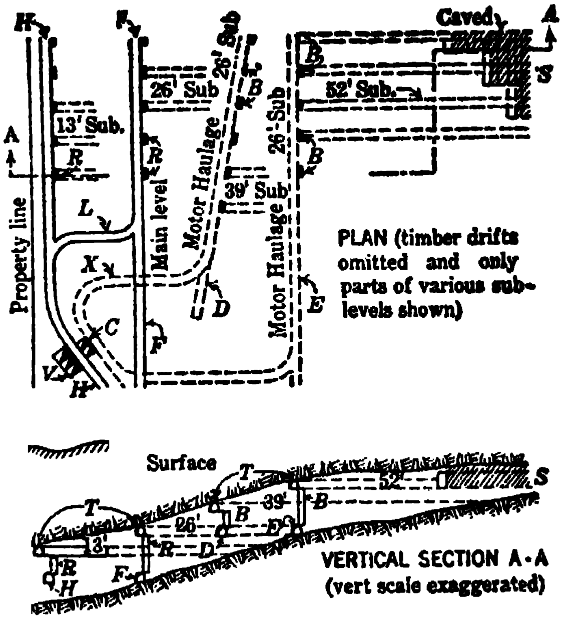

Fig 483. Top-slicing, Utica Mine, Minn (diagrammatic)

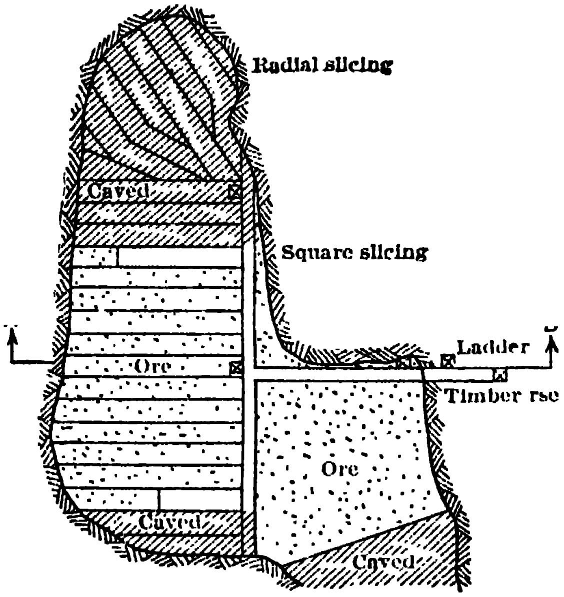
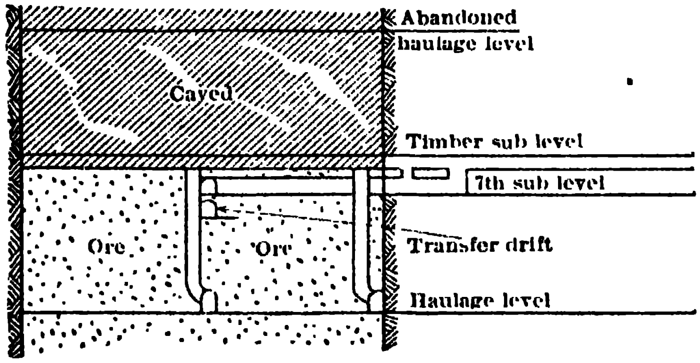
was developed as an intermediate motor-haulage level, consisting of 2 drifts *D*, *E*, connected by crosscut *X* with a transfer chute *C* leading to a shaft pocket on main level. Raises *B* were put up 50 ft apart from drifts *D*, *E*, and from them crosscuts were driven to limits of ore on the 39-ft and 52-ft sub-levels. Sub-level crosscuts were timbered with 6-ft posts and 7-ft caps. Development on lower sub-levels was not undertaken far in advance of the time when it was needed. Slicing began at top of orebody, as indicated at *S*. Drift-slices timbered with 11 to 12-ft posts and 8-ft caps were run half way to adjoining crosscuts. Entire breast was drilled and blasted at one time. Before caving, poles 16 ft long were laid lengthwise on floor of slice and covered with boards laid crosswise. In working under hanging wall, some areas required slices 2 sets high. Timber consumption per ton of ore; lumber, 1.413 lin ft; poles, 1.868 ft; plank, 2.963 ft; lagging, 0.00278 cord. Development as in Fig 483 was planned for hand-loading; length of slices could have been increased for scraper work. Some ore was scraped into cars with slip scrapers and single-drum hoists; sometimes low headroom under hanging wall interfered with free dumping of scraper and increased loading time.



Plan of 7th Sub Level



Vert Sec A-B

Fig 484. Top-slicing, Iron River Distr, Menominee Range

Iron River District, Menominee Range. Data contributed in 1938 by C. D. Bailey, District Engr, Pickands Mather & Co. Fig 484 shows present methods of top-slicing. Ore is massive hematite; it stands unsupported in most sub-level drifts and raises, though some of these and parts of the main levels require timbering. Orebodies being top-sliced either extend up to the overlying sand or have weak hanging wall. Development. Entry is by vert shafts; usually of 3 compts, for 2 ore skips in balance and a man cage. Main haulage levels are 150 ft apart. When a new level is opened, it is customary to drive the intermediate sub-level (Fig 484) at such elev as to halve the length of the main raises. The sub-level interval is 12.5 ft, increased to 14.5 ft when possible. Single raises are used as ore passes, with additional ones for ladder roads, timber ways or handling machinery. The raises are rarely cribbed. Main ore raises are 60–100 ft apart. Mining.

Where orebodies are wide enough, a "square" system of slicing is used. The ore is dropped down one or more sub-levels through small raises, to a transfer drift where it is scraped into a main raise. The slices are parallel and 60–100 ft long. Irregular remnants of ore are mined by radial slicing. Slices are timbered with 3-piece hardwood sets, of 10-ft posts with 8–10-in caps; 12-ft posts are used where the mining height is 14.5 ft. Forepoles and lagging are used for holding the back. When a slice is advanced 5 ft, floor is covered with 1-in boards 16 ft long, overlapping floor in 2 preceding sections and making a triple layer under entire slice. Timber, lagging, and boards are trucked in on the abandoned haulage level, and thrown down to the sub-level where they are to be used. Wet jackhammers, with 7/8-in hex steel, are used in the harder ground; dry auger machines in soft ore. Hoe-type scrapers, operated by double-drum a-c motor hoists, move broken ore into the raises. Each power scraper has 2 extension elec light cords, and permanent lights are installed in levels and raises. When starting a new place, 2 slices are driven before blasting them down, but when slicing alongside a cave, each slice is blasted when finished. This is done by shooting each post on the caved side of the slice in 2 places. Miners are paid by contract, on basis of number of cars of ore produced, or number of feet of development driven; the pay is never less than the district flat rate. Forced ventilation is required. In addition, 2-hp a-c fans, with ventubing, are used for each slice. The ore is drawn from main ore raises into 3-ton rocker-dump cars, hauled by d-c trolley locos to the hoisting shaft. Air gates prevent sticky ore from sliding into the shaft after the skip has left the station. Where main ore raises are wet, ore is scraped from bottom of the raise into the cars to minimize the danger from rushes of soft ore and water. GENERAL OPERATING DATA (aver for district). Production per miner, 22–25 tons per day. Explosive, 0.6 lb per ton; boards, 1.87 bd ft per ton; timber and lagging (variable), 3.7 lin ft per ton aver.

Caspian mine, Menominee Range, Mich. Data from W. A. McEachern in 1911 (288). Early work at this mine is of interest in showing application of top-slicing under difficult conditions. Orebody was massive hematite, overlain by 130 ft of drift containing much water. Entry was by vert shafts sunk in walls. First level was 25 to 30 ft below overburden, level interval was 50 to 75 ft; lateral development on each level comprised a crosscut from shaft, and a drift along deposit from which crosscuts were run to walls at 50-ft intervals. Ore at top of deposit could not be mined until overlying sand had been drained, which was done as follows: 48 small raises were put up from 1st level (sub-level C, Fig 485), at different points. In each raise a 12-ft test hole was drilled ahead, then a round of 6-ft holes was blasted; 1 round was blasted after test hole reached sand, leaving 5 to 6 ft of ore at top of raise, 3 more holes were drilled through this pillar to hasten drainage, which took over a year. Prior to and during drainage operations, production was begun by opening shrinkage stopes between 2nd and 3rd levels; ore was strong enough to stand in stopes 25 ft wide, 100 ft long and 50 ft high, with 25-ft pillars. SLICING (Fig 485). Cribbed, 2-compartment raises *R* were put up from sub-level *C*, about 40 ft apart. Sub-level *A* was opened about 5 ft below top of ore by driving drifts and crosscuts, as shown on plan of sub-level *B*. Crosscut *E* was driven to No 2 shaft for ventilation and handling timber. Blocks between crosscuts were mined in drift-slices, 8 ft wide by 10 ft high, retreating from walls toward central drift. No attempt was made to recover the 5 ft of ore left over sub-level *A*; it aided timbers in forming a mat to prevent sand from mixing with ore. Central drift and crosscut to shaft were kept open for transport of timber to the 2 succeeding sub-levels, by leaving 10-ft pillars on each side. Lower sub-levels were similarly mined. As pillars between shrinkage stopes were sliced, ore was drawn from stopes to let mat settle evenly. Method resembles "panel slicing" at Morenci (Art 72). Scrapers of reversible hoe type (Sec 27) were introduced here in 1922 for loading ore in slices. During last 6 months of 1923, output per man-shift scraping averaged 12.53 tons, for 18 826 tons of ore; aver output per man-shift in hand-loading 94 900 tons during same period was 7.41 tons (482).

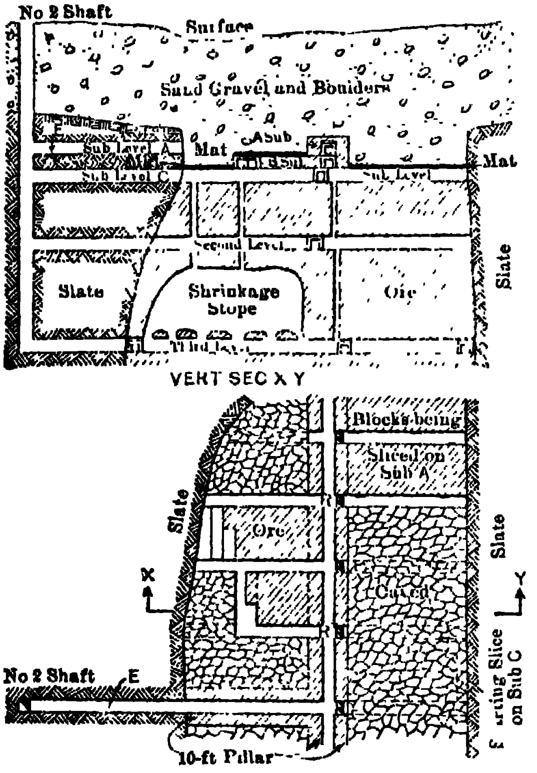


Fig 485. Top-slicing, Caspian Mine, Mich

Marquette Range, Mich. Data contributed in 1938 by Carl Brewer, Chief Engr, Cleveland-Cliffs Iron Co. Orebodies of soft hematite occur generally in flat-dipping (15°) troughs; width to 1 000 ft; thickness, 20–50 ft along the edges, to 300 ft in the center;

Fig 486. Top-slicing in Negaunee Distr, Marquette Range, Mich. Typical Plan. Small numbers indicate sequence of slices. Hatched areas are caved

length, 2 000 ft or more. The troughs are of 2 characters: (*a*) synclines intersected longitudinally by vert intrusive dikes; (*b*) V-shaped troughs between nearly vert dikes and flatter footwalls. Footwalls are slate or jasper. Hanging-wall cappings are usually a leached ore formation (jasper) which, on caving, breaks into gravelly aggregate, requiring careful mining to prevent contamination of ore. DEVELOPMENT. Entry is by vert shafts in footwall, with main levels 100–200 ft apart (usually, 100–125 ft). Orebodies are developed by crosscuts *X*, Fig 486, spaced 150–170 ft apart, driven from a footwall drift *D*, and connected by a similar drift in or near the hanging wall. These crosscuts are parallel on all levels, but those on consecutive levels are offset horiz about 30 ft, so that the bottoms of raises on a lower level will lie about 30 ft to one side of crosscut on the next level above. The orebody is thus divided into blocks, parallel with crosscuts, approx 150 ft wide, and reaching across the entire deposit. Blocks are mined in steps, beginning at hanging wall and working towards footwall. The mining of these blocks is kept not more than 2 subs apart in elev. Inclined (65°–70°) 2-compt cribbed raises *R*, 4 ft 2 in sq inside, are spaced 50–65 ft (usually, 55 ft) along crosscuts for sub-level development. Ore compts are lined with 2-in hardwood plank to prevent excessive wear. Position of crosscuts and raises provides pillars approx 55 by 150 ft to be mined from each raise on each sub-level. Under heavy press, this arrangement is better than a closer spacing of raises. MINING. Sub-level interval is 13–14 ft. Blocks are mined by radial slicing, advancing in only one direction where possible. First development on a sub-level is to make connection between raises for ventilation and safety. Mining on an individual sub-level is usually done simultaneously at all raises along any one crosscut. Not more than 2 slices are allowed to remain open before being blasted. Before caving the back, the floor of each slice is covered with 10-ft poles of 3-in or larger diam, about 1 ft apart and nailed to 3 underlying cross-pieces. Under a new hanging, floor poles are laid side by side and covered closely with one or more layers of lagging with 4-ft wire fencing on top. Where new hanging does not cave readily after blasting the slices, small raises are put up at one side, long holes are drilled into the back, and shot to break down enough covering for safe mining underneath. Sub-level slices take all ore up to floor poles of the overlying sub, which are then blocked above sets of 9-ft caps and legs, 5 ft apart. Legs have batter of 2–2.5 in per ft. Sides and back are closely lagged. Miners work in pairs on contract basis, usually making 1 complete cycle of drilling, blasting, mucking, and timbering in an 8-hr shift, mining 20–30 tons per man-shift. The flat footwall causes an exceptional amount of main-level drifting and raising in rock, but the method is usually preferable, since sub-level transfers are unsatisfactory where excessive wt may cause openings to fail before all overlying ore is extracted. All mucking is done with 42-in box scrapers, operated by 15- to 25-hp, elec, double-drum hoists. Main-level haulage is done with 6- to 10-ton elec locos, pulling 6–8 4-ton rocker-body cars. Excessive wt of ground due to caving usually makes it necessary to retimber raises and main-level crosscuts once or twice during their life. At Negaunee mine in 1937, timber consumption averaged 1.2 bd ft per ton.

Blueberry mine, Marquette Range, Mich. Data from R. S. Archibald and L. S. Chabot, Jr, in 1935 (269). Hematite ore is a secondary concentration in a brecciated zone of iron-bearing sediments. Aver width of ore, about 50 ft; length, 2 000 ft. Dip, from 75° to nearly vert. All development openings require timbering. Mine is served by a 5-compt vert shaft in slate footwall; depth, 1 100 ft (1935). Main levels are 100 ft apart; an intermediate sub-level proved unnecessary and a source of trouble; haulage drifts are in orebody; drift sets have 9-ft caps and posts, latter set with batter of 1 in per ft. Two-compt, cribbed raises, 4 ft 4 in inside timbers, are at 100-ft intervals, closer spacing having proved unsuitable. Radial top-slicing is the principal method of mining. Miners work on contract; a crew of 2 men do all work in a block. A block extends 50 ft longit on each side of raise and full width of ore, making block 100 ft long and about 50 ft wide, in which the longest slice will not exceed 100 ft. Slices are 11 ft high, timbered with lagged sets 5 ft apart; caps and posts, of 8 to 10-in green hardwood, are 9 ft long. Forepoling is used in advancing slices in loose ground. Slicing starts from a raise by crosscutting to one wall. On completing a slice, it is floored with 9.5-ft 3 to 4-in tamarack poles, spiked to cross pieces; bottom and solid side are then covered with wire netting. Posts are bored and blasted down before next slice is driven; the ground is too heavy to allow 2 adjoining slices to remain open. Slicing proceeds radially from raise (Fig 487). Broken ore is handled to raise by 42-in scrapers.

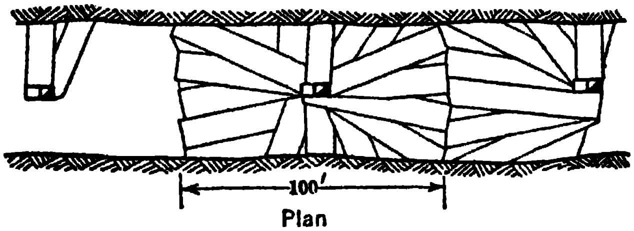

Fig 487. Radial Top-slicing, Blueberry Mine, Mich

Inland Steel Co, Cuyuna Range. In Armour No 2 mine, Crosby, Minn, idle since 1932, a deposit of hematite was formerly mined by top-slicing. Development was similar to Fig 481; sub-level interval, 10 ft. Crosscuts were spaced 70-ft centers, with raises 30-ft centers. As Cuyuna ore is harder than Mesabi, hand-loading was preferred for handling broken ore containing much material over 4-in size; elsewhere loading was done with single-drum hoist and slip scrapers. In older development, raises were 70 ft apart and scrapers were used to load cars trammed to raises. H. T. Middlebrook, in 1938, states that most recent practice on Cuyuna Range adopts radial slicing and use of double-drum hoists with box scrapers. Aver output per shift per miner working in slices ranges from 16 to 20 tons.

Low Moor mines, Va. Data from C. Dixon in 1912 (291). Shallow, veinlike deposits of soft brown hematite were top-sliced; irregular and sudden changes in both dip and strike are common. Country rocks are soft and cave readily. Fig 488 shows work in a deposit about 12 ft wide. Entry was by shaft in footwall or by adits. A main level was driven 7 ft high in the clear and 6 ft wide at top; timbered with 3-piece sets, 4 ft apart. Lagging was required on top of sets and usually on sides. Cribbed, 2-compt raises were driven on footwall at 50-ft intervals; 1 raise was holed through to surface as quickly as possible. Sub-levels were driven from raises at 12-ft intervals; they averaged 1 ft less in dimension all around than main level. Slicing (locally, robbing) started on the top sub-level, when it reached the ore limit; back and sides of sub-level were shot down and sets with 12-ft posts erected. As work retreated, floor was covered with 8-ft lagging laid on cross-sills of round timber 12 ft long, spaced 4 to 6 ft apart. Sets were blasted down after a section 50 to 75 ft long had been robbed; then robbing could begin at end of next lower sub-level; sills were picked up on 12-ft posts in sub-level below. Drilling was done with 2.25-in piston-drills. Sub-levels were so crooked that barrows had to be used to transport ore to raises. This method, which extracts about 95% of orebody, is open to the objection that all sub-levels must be driven to boundaries before robbing begins, and much retimbering is necessary for their maintenance.

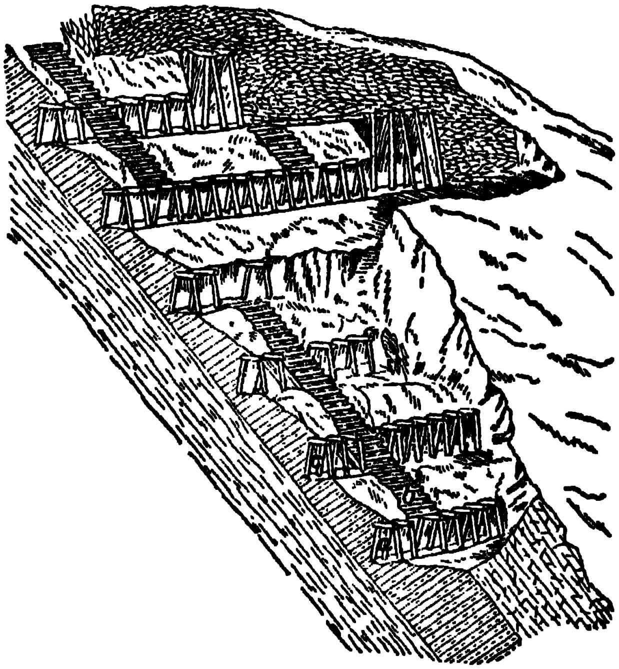

Fig 488. Top-slicing, Low Moor, Va

72. TOP-SLICING IN NON-FERROUS MINES

Morenci-Metcalf district, Ariz. The properties mentioned here are now owned by the Phelps Dodge Corp; the work described stopped about 1923. Data from P. B. Scotland (152, 178), J. R. McLean (279), W. L. Tovote (280), and notes by L. Johnson in 1915. OREBODIES, usually carrying 2–4% Cu, are disseminated deposits in porphyry or fissure veins in granite. Top-slicing was formerly used for shoots of soft ore, some of them very large; thus, the Humboldt orebodies were 80 by 600 ft and 200 by 700 ft in horiz sec. Disseminated deposits are overlain by leached porphyry capping; oreshoots rarely exceed 300 ft in vert dimension. DEVELOPMENT. A haulage-drift for electric or mule haulage was driven near bottom of shoot; intermediate hand-tramming levels were opened above as required at vert intervals of 50–100 ft (Fig 491). Raises connecting with main level were spaced to limit tramming distance to 150 ft. Tramming levels consisted of a rectangular system of drifts and crosscuts which proved shape of deposit and allowed raises to be spaced over whole area on corners of rectangles usually 25 by 30 or 40 ft. This might be done by raising at 25-ft intervals along crosscuts 30 ft apart, or, where deposit was wide, by parallel drifts 30–40 ft apart with raises along them. Raises had a 4 by 4 or 5 by 5-ft chute compartment and 1.5-ft ladderway; they were spaced so that ore could be shoveled direct to chutes, and alined accurately to obviate necessity for constant surveying in slices. Inclined slicing was also used (Art 73).

Slicing. Irregular tops of oreshoots were square-setted (Art 70). Height of slices, 7 to 15 ft; economic height, 11 ft. Slices were timbered with 3-piece, unframed sets. Ariz Copper Co used round caps and posts, both 10 ft long and 7.5 to 9.5-in diam; Detroit Copper Co used similar posts, with an 8 by 8-in cap 6 ft long; slice-sets were about 5 ft apart. Raises at end of oreshoot were connected by a crosscut *L*, timbered with slice-sets (Fig 489). Drifts *K*, connecting with adjacent raises, might be as in Fig 489, or else carried full height of slice and timbered with sets to support mat; they provided exits in case of a sudden cave. Ore on right side of *L* was then mined; the direction of slice-drifts here would depend largely on shape and extent of this area. When this work was completed, slicing began at left of crosscut *L*, and was carried to other end of deposit; the face was advanced by slicing 6 to 10 ft wide across orebody, as indicated by dotted lines *MN*. Sec *EF* shows appearance of the work after a slice was well started. Working faces on adjacent sub-levels were usually kept at least 50 or 60 ft apart. Details varied widely.

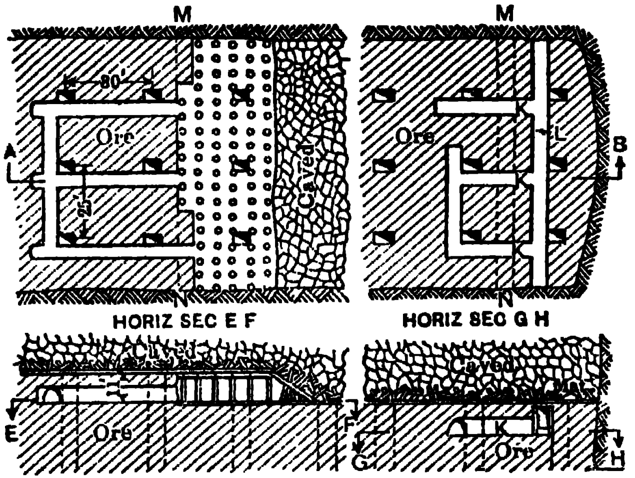

Fig 489. Top-slicing, Morenci-Metcalf Distr, Ariz (diagrammatic)

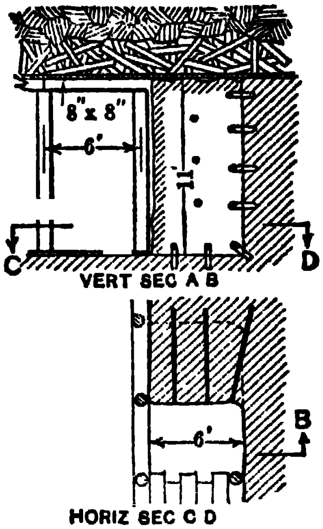

Fig 490. Breaking Ground in Slices, Detroit Copper Co, Morenci, Ariz

Fig 490 shows timbering and method of BREAKING GROUND at mines of Detroit Copper Co. Normally a round of 10 holes, 5.5 to 6 ft deep, broke a block of ore 11 ft high, 6 ft wide, by about 5 ft deep. All drilling was done with hammer drills. Double floors of 2 by 12-in plank were laid on several sub-levels near top of orebody; a single floor was sufficient after a good mat was formed. Floor-plank were 10 to 15 ft long, placed at right-angles to caps of slice-sets. Posts were blasted down as slice advanced, only enough space being kept open for shoveling to raises. Some barrow work was necessary in workings arranged as in Fig 489; to avoid this, Ariz Copper Co used the following modification: When the face had advanced so that direct shoveling was not feasible, miners were transferred to the next raises, where a new breast was opened and worked back to old one. This obviated barrow work, if raises were spaced so that each served an area not exceeding 25 by 30 ft. If orebody widened it was followed into the walls by square-setting, and a mat formed over the new area like that at the top of the deposit. Patches of waste were broken, thrown back from breast and left on

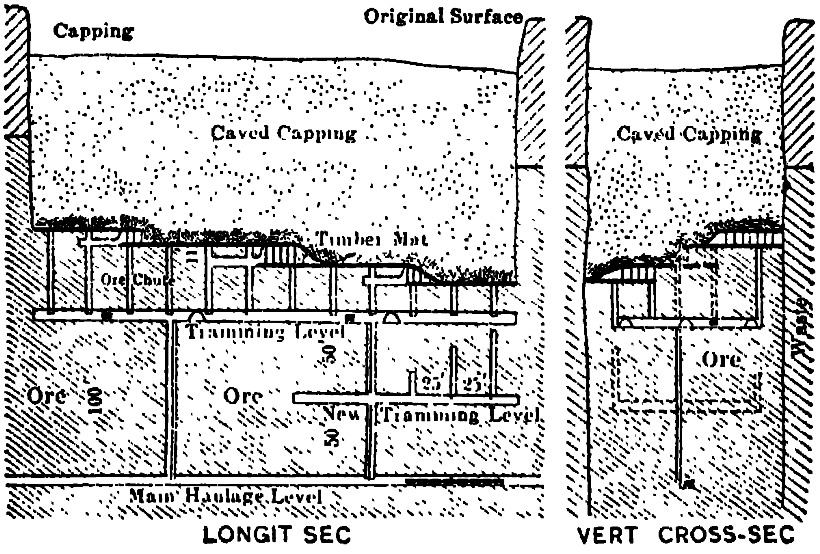

Fig 491. Top-slicing, Arizona Copper Co, Morenci, Ariz

floor. If the mat caved close up to breast, a crosscut was driven parallel to the old face and about 10 ft from it; when the new breast was under way, the 10-ft pillar was shot down and drawn. Should mat come down over a large area before floor was laid, or in case it hung up, the succeeding slice was started 15 ft below; 7 or 8 ft of this slice was mined and a floor laid; the overlying ore was broken with uppers, starting at end of area and retreating towards face of new slice; the broken ore from each round was shoveled away until waste appeared. The weight of mat in wide shoots was controlled by taking each slice in sections (Fig 491); slices were 30 to 40 ft wide; tramming levels, 55 ft apart. Slicing directly over a tramming level caused crosscuts and drifts there to crush; this was avoided by mining ore on and over the level in a slice of double height, timbered with 2 floors of square-sets. Following plan was used by Detroit Copper Co: Ends of 2 adjacent crosscuts on tramming level were connected by a breast stope, timbered with 1 floor of square-sets, 2–3 sets wide. The back of ore remaining over the sets and below the mat was then blasted with long uppers; broken ore filled the sets and was shoveled out, allowing the mat to settle gradually on the set timbers. While one section was being shoveled out, another was opened and timbered; posts of sets in first section were then shot down, and the procedure was repeated. **Panel slicing.** Fig 492 shows a method devised by Ariz Copper Co to eliminate the heavy expense of driving and maintaining raises 25 ft apart. On each slice a central main drift passed lengthwise through the oreshoot, and crosscuts were turned off at 40-ft intervals. The main drift, and crosscuts for 20 ft on each side of it, were timbered with 3-piece sets, 6.5 ft high; elsewhere, crosscuts were opened to mat above and timbered with slice-sets. Slices 40 ft wide were then worked from the walls back toward main drift, leaving a central pillar 40 ft wide which was sliced back from end of orebody after slices on each side of it were finished. Ore was shoveled into cars and trammed to raises spaced at 80-ft intervals along main drift and connecting with haulage level below. While one floor or panel was being worked, the next, 11 ft below, was in preparation. This system dispensed with need for tramming levels. Compare Fig 485.

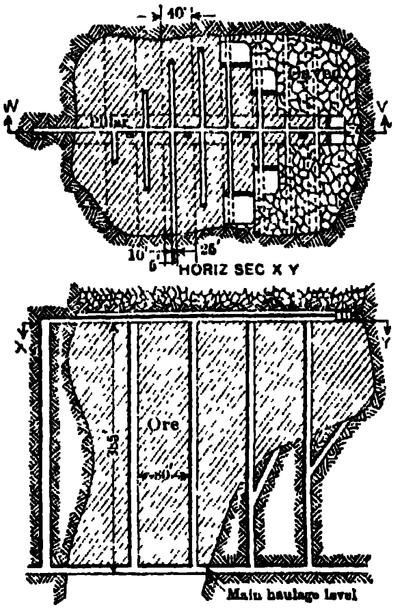

Fig 492. Panel Slicing, Arizona Copper Co (faces under attack shown thus ▬)

Operating data. Ariz Copper Co. P. B. Scotland states that timber consumption in top-slicing, including chutes, ladders and reinforcements, was about 9 bd ft per ton of ore; most of it was round Texas pine and squared Oregon fir, but much cheap cull lumber was also used in top-slicing (178). Detroit Copper Co. J. R. McLean gives following data for Jan, 1914 (279): 124 088 bd ft of round and 322 661 bd ft of square timber were used. Table 46 shows details. Figures in Table 47 do not include 498 tons of

Table 46. Timber Consumption, Top-slicing, Detroit Copper Co

ore from outside properties. Shifts were nominally 8 hr, actually 7.5 hr; 26 working days per month. Output per man-shift underground and on surface, including outside properties, 1.85 tons. Dynamite was of 1 7/8 and 1 1/8-in diam; 40% dynamite was used wherever possible; 60% was required to break some ground. Blasting in slices was done with 5-X caps and double taped fuse. Table 49 covers the mining of 48 042 tons of ore at the 4 mines in Table 47. Mines were comparatively dry; there was little artificial ventilation; underground hoisting item includes cost of hoisting timbers from tramming levels to slices with small tugger hoists.

Copper Queen mine, Bisbee, Ariz. Data from G. J. Young in 1926 (593), and C. E. van Barneveld, 1924 (482). Some areas were top-sliced and the ore scraped into a drift or crosscut ("sub-gangway"), which connected raises on the floor below the slices (Fig 493). Development. Two-compt raises from the levels were preferably on corners of 50-ft squares and connected by sub-gangways. Slicing began at the ore limits, or next to caved ground. In Fig 493, the first slice, 1, would start from top of raise *B*; broken ore was scraped directly to the raise by a hoe-type scraper operated by a double-drum hoist on floor of slice near the raise. In places, it might be possible to leave part of slice 1 open, while slice 2 was being taken; if not, slice 2 was started by raising from the sub-gangway. Ore from slice 2 might be scraped into raise *B*, and from slices 3, 4, etc, into the sub-gangway; then the hoist was turned 90° and the ore re-scraped to raise *C*. This was locally called the Scott system. Slices were 7 ft wide by 11 ft high, timbered with 10 by 10-in square-sets, caps 7 ft, girts 5 ft. Sets in sub-gangway were 3.5 ft c–c. Output per man-shift reached 10 tons where slices could be laid out 50 ft long, as in Fig 493, but decreased to 6.5 tons in shorter slices.

Southeast Extension mine, Phelps Dodge Corp, Bisbee, Ariz. Data from H. M. Lavender in 1939. Top-slicing is used only in some small high-grade areas in this orebody that are not suited to block-caving. The ore is a secondarily enriched porphyry; soft and easy to drill; quite wet, but otherwise ideal for the method. The orebody had been developed for block-caving on the 1 000, 1 100 and 1 200 levels and, wherever possible, this work was utilized in the top-slicing areas.

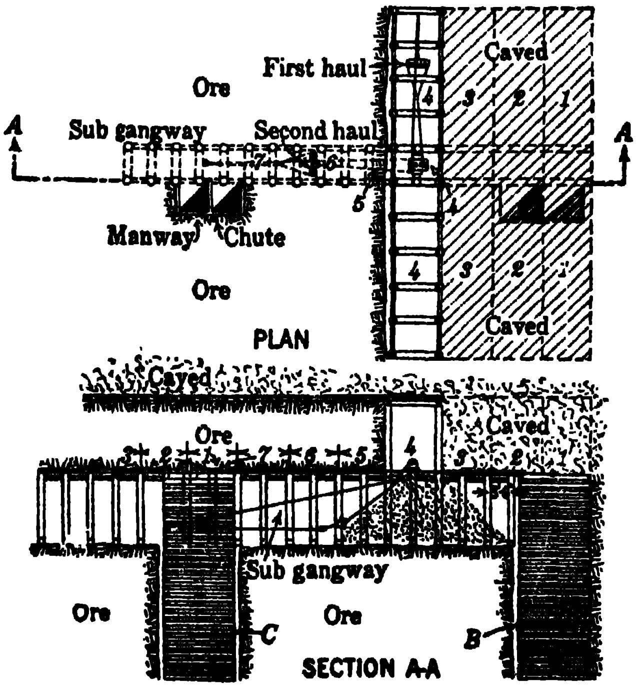

Fig 493. Top-slicing in Copper Queen Mine, as Modified for Scraper Loading

Fig 494 shows one section of the 1 000 level. Two 2-compt raises *A*, from the 1 200 main haulage level, were extended to the 1 000 level. Connections were made between the raises, and to existing work on the level, for ventilation, supplies, and access to the top-slice stope. From raises *A* on the 1 000 level, 2 transfer "scram-drifts" *B* were driven to the ore limits and timbered with 5-ft sq-sets with 8-ft posts; all timbers, 10 by 10 in. From the scram-drifts, two 2-compt raises *C*, 40 ft apart, were driven to top of the ore, where 2 drifts or "leads" *D* were driven to the ore limits. The raises were lined with 6 by 8-in cribbing; compts, 4 by 4 ft in the clear; the leads were square-setted, with 9-ft posts, 10 by 10-in caps, and 4 by 6-in girts 4 ft 2 in long.

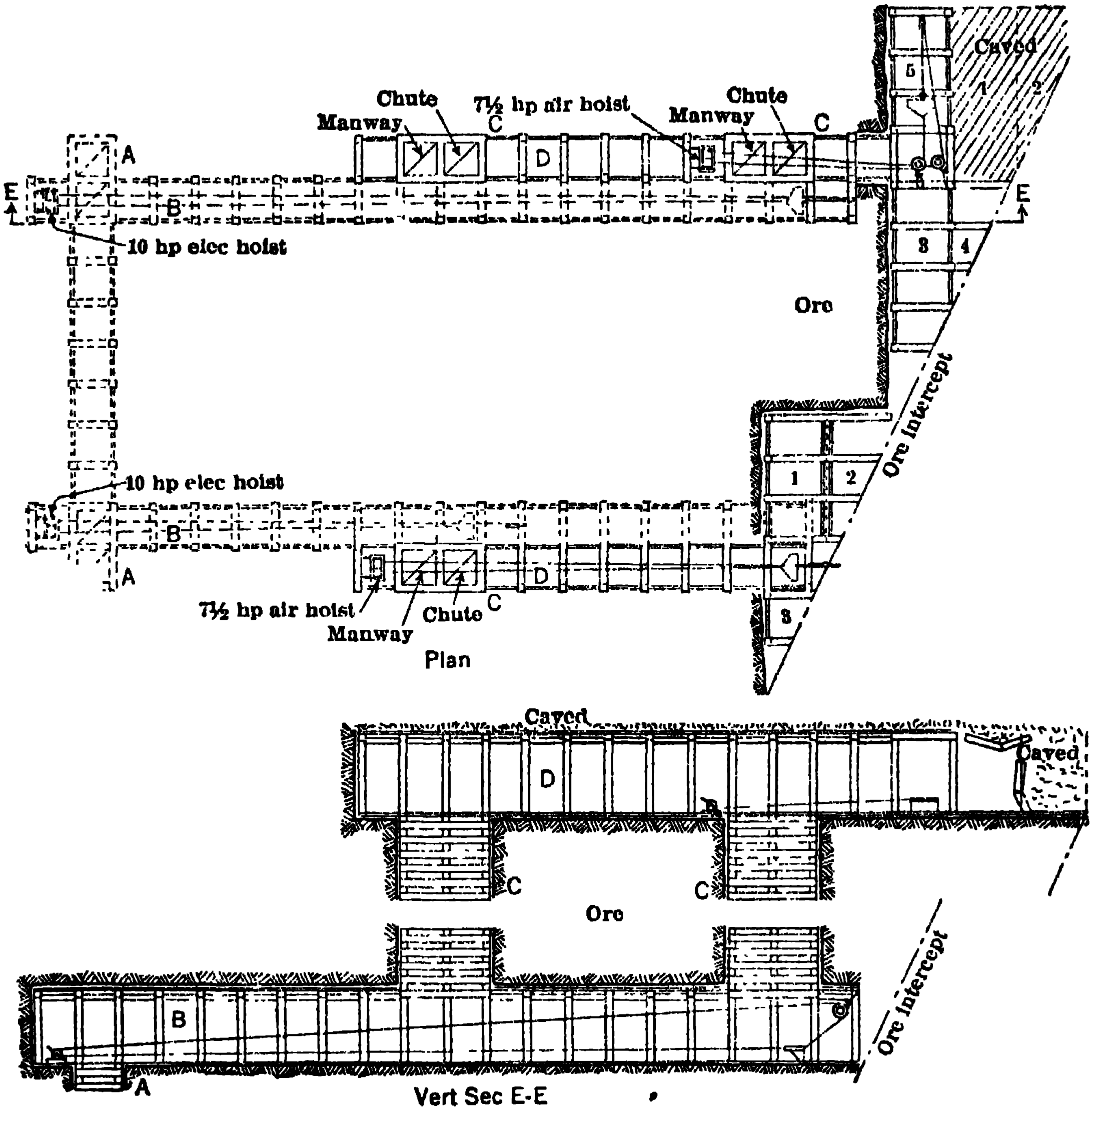

Fig 494. Top-slicing, Bisbee, Ariz

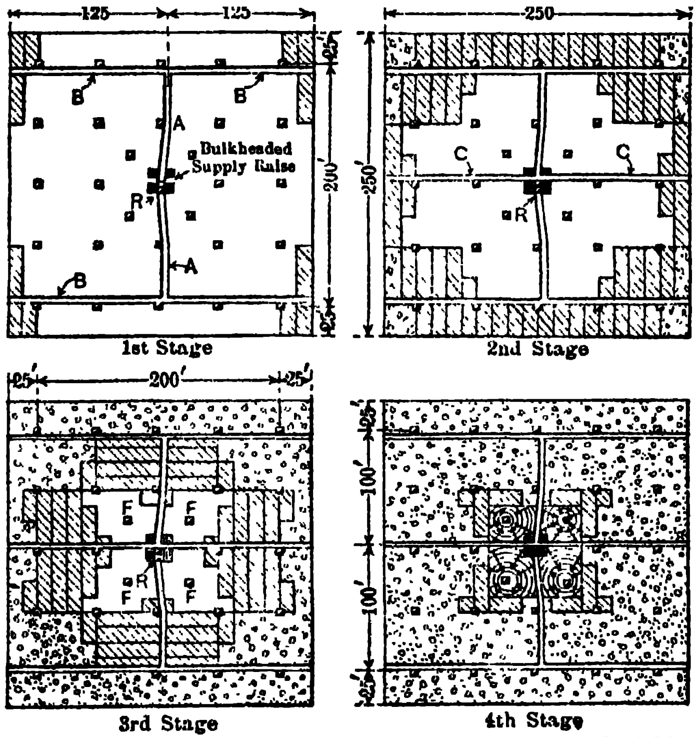
Slicing starts near edge of orebody; slice-drifts are driven at right-angles to leads *D*. Drilling is done with pluggers and the slice-drift is carried to the ore limits, or to a section line. Slice-drifts are square-setted with 10 by 10-in timber, 8-ft caps and 9-ft posts spaced 5 ft c-c. After the first slice-drift reaches the limit of the section, work starts at that point in an adjoining drift and retreats by slabbing successive sets to the main leads *D*. The areas sliced before caving occurs may be 1, 2, or sometimes 3 sets wide. Sequence of work is indicated by numbers in Fig 494. When a section is cleaned out, it is floored with 2 by 12-in plank, 10 ft long and parallel to length of slice-drifts; then the section is allowed to cave. A slice rarely has to be shot down; with the length of cap and post used, the section usually caves soon after the ore is mined. Broken ore is scraped to leads *D* by 7.5-hp air hoists; when enough ore has accumulated in the leads, the hoist headblocks are shifted for scraping ore into chutes *C*, in which it drops into scram drift *B*. Here it is scraped into transfer raises *A* by 10-hp elec hoists, and falls to haulage level. When slicing reaches the first raise *C*, the air-hoist is moved to the next raise. OPERATING DATA: output per man-shift, 12.57 tons. Direct costs per dry ton: labor, 52¢; explosive, 8¢; timber, 14¢; total, 74¢. Wages: miners, $5.48; muckers, $4.84.

Miami Copper Co, Miami, Ariz. Data from E. G. Deane in 1916 (285). Orebody is a large disseminated deposit of chalcocite in schist, overlain by a leached capping about 200 ft thick (Art 10-b). Top-slicing was employed in an area about 800 ft square, in which the ore was soft but considerably harder than the siliceous capping, which breaks into fine particles and runs like sand. These conditions, and the fact that ore in this section was richer than usual, led to adoption of top-slicing, which was partly preparatory to other methods for the lower lifts (see Art 80 for other mining systems). DEVELOPMENT. Haulage levels were 150 ft apart vertically, with 2 sub-levels between at 50-ft intervals, which facilitated building of chutes, and, in connection with artificial ventilation, aided in distributing air to the slices. Haulage levels comprised a series of drifts 50 ft apart, along which cribbed raises were put up on 50-ft centers. SLICING. Attempts to carry a slicing face from 50 to several hundred feet long failed; the long drifts from an auxiliary shaft, required for bringing in timber and supplies, were difficult to maintain, and slicing faces advanced irregularly, due to varying conditions. These troubles were overcome by slicing ore in blocks 250 ft square; locally called BLOCK METHOD OF TOP-SLICING. At middle of each block was a supply raise *R* (Fig 495) with a hoisting compartment 4 by 4.33 ft and a ladderway 2.5 ft wide; timber, steel, etc, were hoisted up this raise by a stretcher-bar hoist. Station sets of 12 by 12 timber with 9 or 10-ft posts were erected at top of raise, which was further protected by timber bulkheads 10 ft high; two bulkheads were 7 by 7 ft and two 7 by 11 ft in plan, as shown. Drifts *A*, *B*, and *C*, usually untimbered at first, were run in the order named. Slicing began at end of *B* and *C*; Fig 495 shows 4 successive stages of work in same block. New slices were started as soon as those alongside had advanced a few ft. As many men as could work to advantage were put on; ore was mined with greatest possible speed, until only 4 central pillars around the supply raise remained (see 3rd stage). Inclined raises *F* were then put up to about the middle of each pillar; crosscuts (not shown) were driven to raises *F* from drifts *A* and *C*; slicing then continued, working from outside of pillars back to bulkheads, which by this time had squeezed down to a height of 4 to 6 ft. On completing this work, the last of the stope was caved; it was found best to let ground settle several weeks before starting another floor. Slices were 10 ft high, timbered, according to the ground, either with single sets, of 2 8-ft posts and a 12-ft cap, or with double sets, of 3 8-ft posts and 2 7-ft caps, all round timber. No floor was laid if mat was thick enough to prevent runs of capping; elsewhere a 2-in floor was spiked to 2 by 10-in sills; 5 by 10 and 4 by 8 sills were tried, but seemed to be no stronger than 2 by 10-in, after subjection to the heat and pressure of a completed slice. Bulkheads of old timber were built where necessary to aid slice-sets; the posts were shot down as soon as possible. All drilling was by plugger-drills, using a water spray. Ore in slices was shoveled to raises or handled in barrows. This method gave good results; weight on timbers did not get beyond control during the time that slices had to be kept open. It was found that pressure on central pillars was not intensified by caving around them. But ore in pillars was fractured, so that lifters were the only holes needed to



PLAN OF WORK ON 1 FLOOR AT DIFFERENT STAGES

Fig 495. Block Method of Top-slicing, Miami, Ariz

break it. This fact, combined with the handling facilities provided by raises *F*, made pillar-ore cost less than that from outside slices. VENTILATION of the blocks was important; without it the heat from mat was excessive and reduced efficiency of labor. Air from a 60 000-cu ft fan was taken to the sub-level below the slicing floor and forced through raises into the slices as desired. Production per shoveler was 20 tons and per total man-shift, 10 tons, these figures being about double those obtained in slicing on long faces without artificial ventilation.

Judge mine, Park City, Utah. Data from G. S. Krueger and E. A. Hewitt (147) in 1938. Ag-Pb-Zn ore occurs as bedded limestone replacements and as fissure veins cutting a series of folded and faulted shales, limestones, and quartzites. Bedded deposits dip about 20° undulating in conformity with bedding planes; they are 2–20 ft or more thick; width, from a few to 100 ft or more; length, as much as 6 000 ft; hanging walls, usually firm limestone, do not require top-slice methods. Fissure veins dip 38°–60°; thickness, normal to walls, about 10 ft. Walls of the fissures are usually limestone, but one important vein has a weak shale hanging wall, wet and heavy. DEVELOPMENT comprises 2 vert shafts, 2 100 and 1 600 ft deep, and 2 tunnels. Main-level interval is generally 200 ft; numerous local intermediate levels are driven as required. Drifts and crosscuts are 5 by 7 ft, timbered with 8-in sets. STOPING. Overhand stopes, timbered with stringer sets, are generally used where walls are strong. Top-slicing is adopted where hanging wall is heavy, and is most effective on the flatter dips; widths of 3–20 ft (aver 10 ft) have been top-sliced successfully. Fig 496 shows ground conditions of a typical top-slice stope in a fissure vein. Fig 497 shows general plan of stope development and order in which slices are taken. In this case, orebody is developed by main-level drifts *D* at 100-ft vert intervals, with 2 sub-level drifts *E* at 33.3 and 66.7 ft above main levels. Double-compt raises *R*, 5 by 11 ft, timbered with 8 by 8-in sets spaced at 5 ft, are 50 ft apart. General plan of retreat is from both ends of orebody toward a central main raise. Individual slice sections, except at ends of orebody, extend from raise to raise. Face of a slice is advanced by a pilot heading, broken by a drift-round with back holes omitted; slabbing rounds complete breaking the face. Where waste inclusions are large or numerous, a pilot heading, best along hanging wall, is carried to end of block being mined. Slice is completed by slabbing on retreat, thus affording space for storing hand-sorted waste. Slices are timbered (Fig 496) with stringer sets 5 ft apart. Sills *H*, 8 by 8-in, are laid at right-angles to strike, and covered with 2-in lagging. Posts *P* are round timber, 8-in diam by 6 ft long. Sills become caps for the next lower slice. Sloping timbers *T*, faced with 2-in lagging and sometimes reinforced by angle stulls *S*, hold hanging wall where it is weak. Scrapers were tried for moving ore to chutes, but as sorting could not be well done, they were abandoned. Ore is shoveled into 0.5-ton cars and trammed to chutes. Caving usually follows without blasting of posts, promoted by fact that hanging-wall press is diagonal to sets. Operations are at such depth that subsidence has not reached surface.

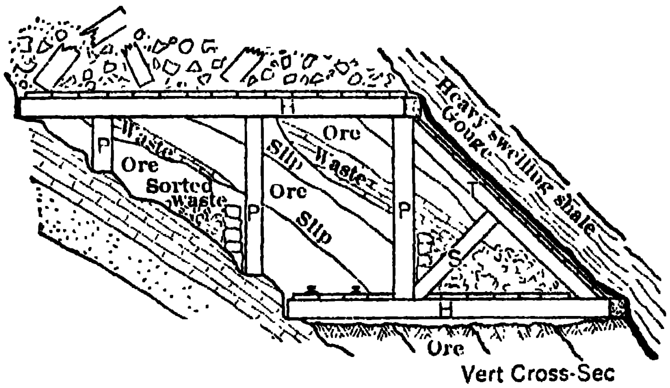


Fig 496. Top-slice Stope, Judge Mine, Park City, Utah (Looking at face of stope)

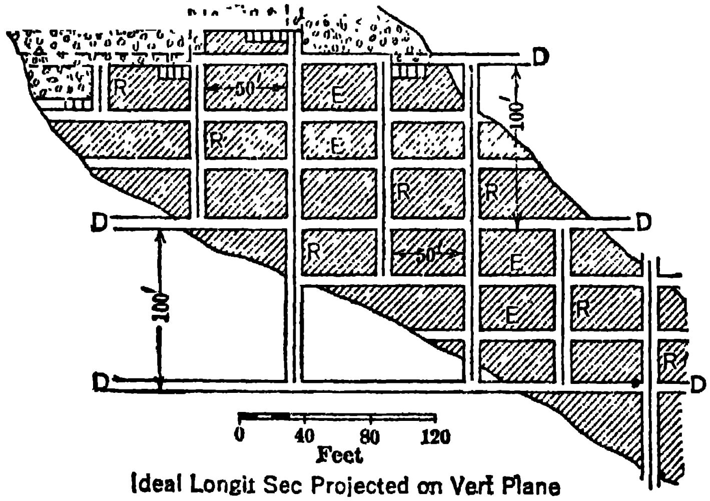

Fig 497. Top-slicing in Judge Mine, Park City, Utah

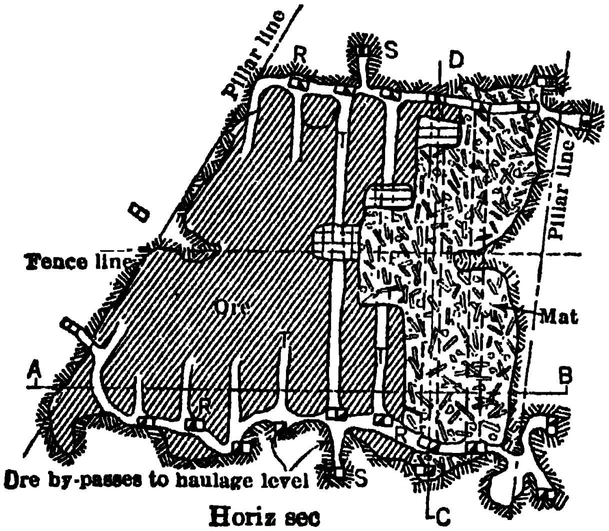
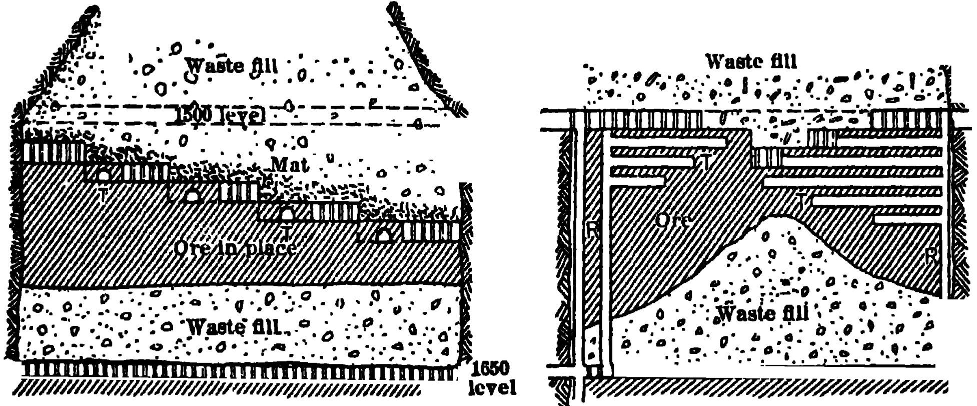
United Verde mine, Jerome, Ariz (227). Data from T. W. Quayle in 1931, and from W. W. Lynch, formerly mine supt. For geol features and general description of orebody, see Art 62. Mining underground was generally by horiz cut-and-fill, lately changed to inclined cut-and-fill, as in Art 65. Top-slicing was used only in a special instance. An attempt had been made to mine as a single horiz cut-and-fill stope a block about 200 ft square, starting at 1 650-level. After the stope had been carried up several cuts, a large block of ground, over nearly the entire horiz area of the stope, fell from the back. This left the stope back in the shape of an arch (Fig 498, vert sec *C D*). Continuance of cut-and-fill was deemed unsafe, and top-slicing was substituted. The block in question was overlain at the 1 500-level by a waste-filled stope, extending to the 1 200-level. Opportunity was afforded to add more fill at the 1 200-level, as the filling dropped due to top-slicing. Preparation. All broken ore from the fall of ground was first removed. Then, before starting top-slicing, as firm a foundation as possible was established beneath the unmined block by complete back-filling of the open space with waste. It was realized that, as the block was thinned by slicing, it would eventually fall. But, with filling tightly packed against the old stope back, settlement occurred gradually, causing no accident to men, nor much interference with slicing. Development. Raises *R*, Fig 498, for disposing of stoped ore were driven in ore from the 1 650-level on 35-ft centers near both hanging- and foot-walls. Service raises *S* within both walls and connected to each slice by short crosscuts were used to bring in timber and other supplies from the 1 500-level. Stoping. Slices were 11 ft high. On each slice-floor, 4 by 6-ft sub-level crosscuts *T* were driven from each chute-raise to center of the block in upper slices, or to the edge of filling in the lower slices. Retreat proceeded from one end of the block to the other, and from a middle line to the walls. Mining was by breasting with mounted drifters. The broken ore was hand-shoveled and delivered to raises *R* in 18-cu ft scoop-body cars, running on sectional 16-lb rails. A double flooring of 2-in plank was laid on 4 by 12-in sills, set 5 ft 4 in apart at right-angles to the sub-level crosscuts *T*. Posts of 10–14-in native pine, unpeeled, with 6 by 12-in headblocks, were placed 5 ft 4 in c–c directly under sills of the floor above; bottoms of posts rested on the ore, sills and flooring being laid after standing the posts. Generally, 3 lines of posts, lengthwise of sub-level crosscuts, were stood before blasting the posts. Posts were bored with air-driven augers; to minimize fire hazard, they were blasted with permissible explosive and elec caps. Top-slicing here proved more advantageous than square-setting, as to both cost and speed of mining. During first 10 mos of 1929, powder consumption was 0.71 lb per ton; timber,



Horiz sec



Vert sec A-B

Vert sec C-D

Fig 498. Top-slicing at United Verde Mine, Jerome, Ariz (227)

9.91 bd ft per ton. Duty of labor was as follows, in man-hr per ton: breaking, 0.383; mucking, 0.651; timbering, 0.837; haulage and hoisting, 0.234; supervision, 0.120; general, 1.020; total, 3.245.

Oceanic quicksilver mine, Cambria, Calif. Data from A. W. Frolli (266) in 1937. Cinnabar occurs disseminated in sandstone. Main orebody is about 600 ft long by 15–40 ft wide; dip, nearly vert. Walls are not well defined; ore and walls are highly fractured and hence weak. In early work, surface ore was mined by open-cut; underground mining was by square-setting, with and without filling. Top-slice method was adopted because broken condition of orebody and walls made most other systems unsafe. Development. As topography is steep, entry to mine is by tunnels; main haulage tunnel is about 350 ft below outcrop; from it a vert shaft was sunk to 750 ft. Level interval is generally 70 ft in upper workings, 50 ft in lower. Stoping. Two-compt cribbed raises *R* (chute and manway) are driven 35–40 ft apart (Fig 499). Slices are horiz and are usually 10 ft high; sometimes, in bad ground, 8 ft. In starting new slice, a drift, usually the height of slice, is driven from the last raise to end of the ore. Stoping begins by widening the end of the drift to the ore limits. General plan is to retreat from one end of orebody to the other. Sills, of 2 pieces of No 2 common rough Oregon pine, 2 by 10-in and 12 ft long, are laid crosswise of the stope on 6-ft centers. On these, and lengthwise of the stope, single sills are laid for flooring. Silling and flooring closely follow the removal of ore, to prevent dilution from sloughing of walls. Roof or mat is supported by pine stulls, 8-in diam, placed 6 ft apart and directly under sills of slice above. When possible, raise cribbing and stulls are salvaged for reuse. When stoping has advanced about 30 ft, or to a point where timbers show wt, timbers are bored with 1.25-in holes 4–6 in deep, about 4 ft from the floor. Holes are loaded with half a stick of dynamite, both instantaneous and delay elec caps being used for better control of caving. Drilling is generally by breast-holing with jackhammers; due to broken nature of ground no systematic round is used. Explosive is 30% dynamite. In 1935, with miners' wages at $4 and muckers' wages $3.50 per 8-hr shift, mining costs per ton, excluding development, were: labor, $1.43; explosives, $0.08; timber, $0.14; other supplies, $0.08; power, $0.08; compensation insurance, $0.12; total, $1.93.

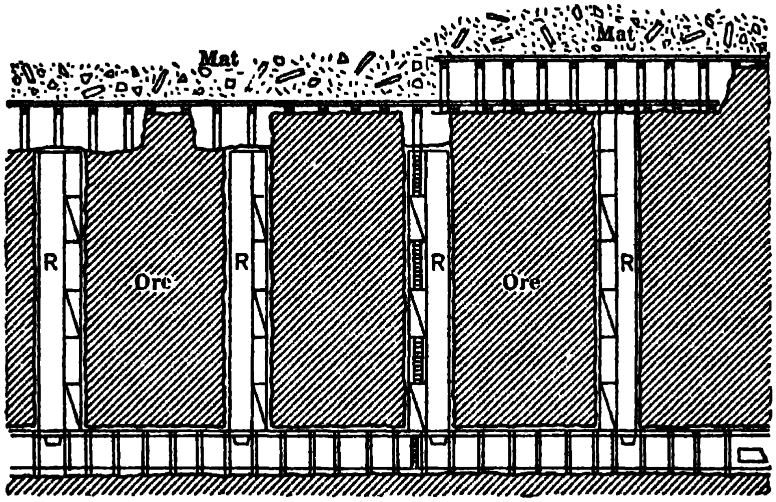


Fig 499. Top-slice Stope, Oceanic Quicksilver Mine, Cambria, Calif (266)

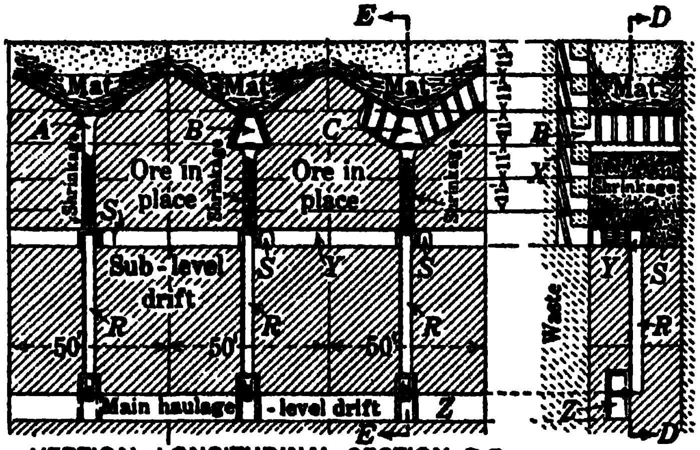
73. INCLINED TOP-SLICING

In this modification of top-slicing, the ore is mined in blocks or panels, and the slice floors, instead of being horiz, are driven on a slope sufficient for broken ore to slide or roll, either to narrow stopes or funneled chute raises on edge of the block. The method was designed to reduce cost of shoveling. It has had a limited use in the Morenci-Metcalf district, Ariz; attempts to use it at Bisbee, by Calumet & Ariz Mining Co, were unsuccessful. Following are examples.

Coronado mine, Metcalf, Ariz. Work suspended about 1923. Data from W. G. Scott in 1918 and P. B. Scotland in 1917 (595). Inclined top-slicing was used in a vein 20–40 ft wide (Fig 500). Ore was mined in blocks 50 ft long, separated by narrow shrinkage stopes through which the ore broken in slices was handled. DEVELOPMENT. Sub-level drifts *Y* were driven 55 ft apart vertically (or other multiple of height of slice, 11 ft); raises *R*, at 50-ft intervals, connected sub-levels and main haulage levels *Z*. Crosscuts *S*, timbered with square-sets, were run to walls or limits of ore at 50-ft intervals along sub-levels; they extended into hanging wall far enough to leave 5-ft pillars between manway and timberway raises *X*, which reached sub-level above. Breakthroughs *B*, 11 ft apart, gave access to the shrinkage stope as it went up and to the slices as they descended. Vert shrinkage stopes 4 ft wide were opened from the back of each crosscut *S* to top of the ore or to the mat above. Chute gates and slides, in crosscuts *S*, delivered broken ore to raises *R*; 2 gates sufficed for a stope 40 ft wide. SLICING. Ore in shrinkage stope was drawn down 11 ft, as at *A*, Fig 500; then the top of shrinkage stope was widened as at *B*; grizzly stulls *G* (Fig 501), 10 ft long and spaced 12 in apart, were laid across the stope. The stulls of the overlying slice were caught up by caps, paralleling the sides of the stope and supported by battered posts, which stood on ore and were braced apart at top by stretchers. The slices, beginning at footwall, were 10 ft wide and ran upward at about 33°, which caused the ore to roll or slide into the stope. Transverse 10-ft sills *M* were laid 5 ft apart (Fig 501), with a floor of 2 by 12-in by 12-ft plank, spiked to them. Sills of slice above were supported by posts, set on the ore at 17° from the vert, which proved best to prevent them from riding and with minimum chance of being shot out. As many as 3 contiguous slices might be taken before timbers were blasted and mat allowed to drop. The method, as applied here, requires ore strong enough to stand in the shrinkage stopes; in weaker ore, close-spaced chute raises may replace shrinkage stopes between blocks (see Humboldt mine, below). OPERATING DATA. Production from blocks 50 ft long in a 40-ft vein width averaged over 2 000 tons per month, with 3 men per shift, 2 shifts per day. The stope crew drew ore from shrinkage stope as required, hoisted its timber and did all other work. Output per man-shift in inclined slicing in mining 29 000 tons in 1917 was 11.2 tons, compared with 4.64 tons for flat-slicing 25 600 tons in 1916; material costs for the 2 methods were about equal. From 1918 to 1923, a number of fires in the mats caused abandonment of top-slicing in favor of block-caving and a combined method described in Art 87 (599).



VERTICAL LONGITUDINAL SECTION D-D

Fig 500. Coronado Mine, Inclined Top-slicing (595)

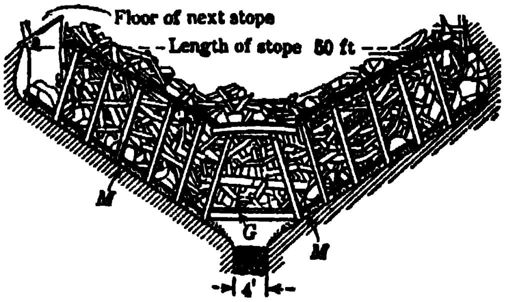


Fig 501. Coronado Mine, Ariz, Longit Sec through Slice

Humboldt mine, Phelps Dodge Corp, Morenci, Ariz. Operations at this property were suspended in 1932. Data from J. P. Hodgson and J. Kiddie in 1922 (594). Inclined top-slicing was used for some large shoots of soft ore; see Art 73 for ore occurrence. Method was similar to that at Coronado mine (see above), but with chute raises instead of shrinkage stopes between blocks. Ore was mined in blocks 50–60 ft long and full width of deposit. In one shoot, 230 by 750 ft horiz sec, a main haulageway was driven in one wall and from it parallel untimbered crosscuts were driven through the deposit at 50-ft intervals, which brought them on center lines of blocks. From each crosscut, at 15-ft intervals, vert untimbered chute-raises were put up to the mat above (44 or 55 ft); in the walls at ends of each crosscut were raises for handling timber and men. Fig 502 is a vert sec through part of a crosscut *L*. First work on a sub-level was to connect tops of raises with heading *M*, starting at far side of the ore; tops of raises were belled out (see sec, Fig 502, and plan, Fig 503); 10-ft cross sills were set in hitches on 2.5-ft centers across floor of heading. The mat was picked up on posts and stringers

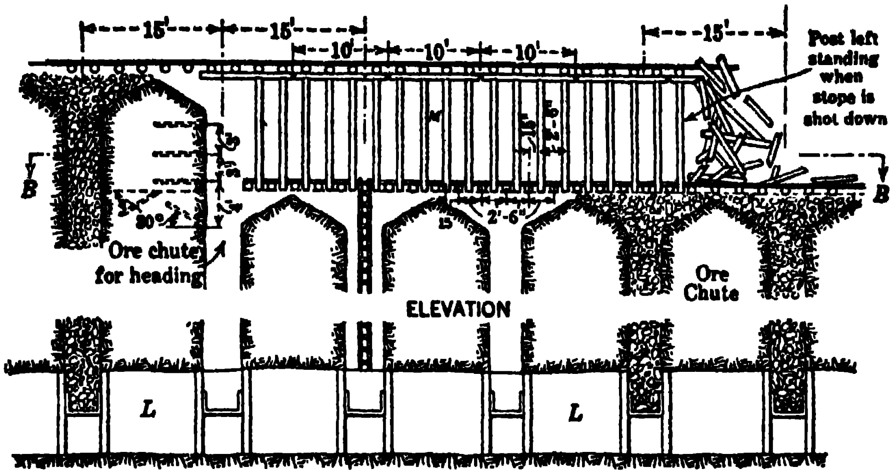

Fig 502. Humboldt Mine, Ariz, Inclined Top-slicing. Sec *A-A*, Fig 503

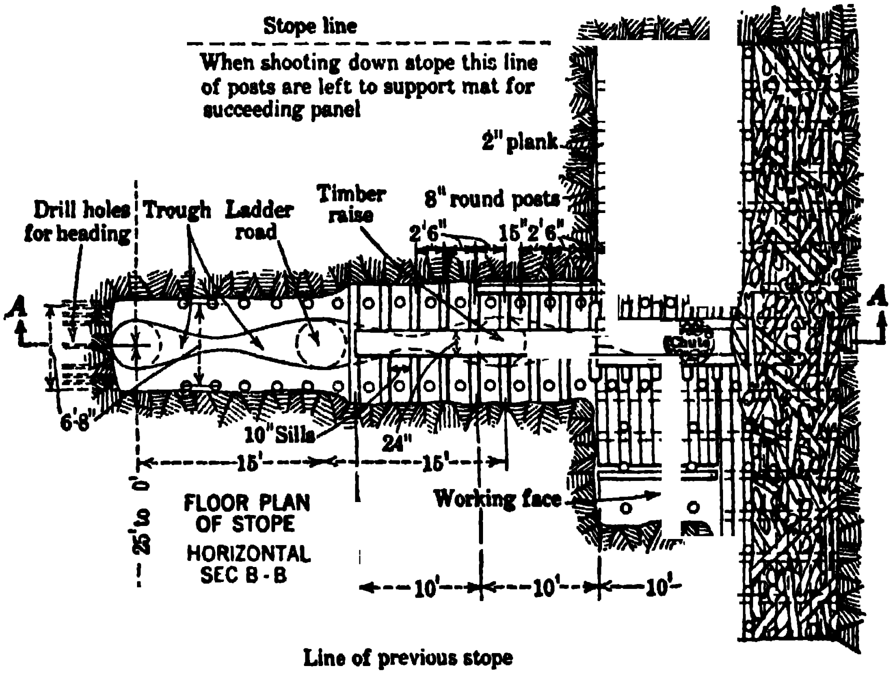

Fig 503. Humboldt Mine, Ariz, Inclined Top-slicing

(Fig 504), as at Coronado. After heading had advanced about 50 ft, slicing could begin. Slices were 10 ft wide, carried upward from heading at 33° until they reached caved ground or the limit of the block.

A comparison covering 4 years showed a reduction in costs of 15% in favor of inclined slicing over horiz slicing. Timber consumption, 1918–1921 incl, for all inclined slicing was 9 bd ft per ton, against 7.9 bd ft for 1915–1921, all flat slicing. In another stope, 285 by 420 ft, crosscuts were 60 ft apart instead of 50 ft, with less satisfactory results. Inclined slicing at Humboldt mine was replaced (600) by another caving method (Art 87).

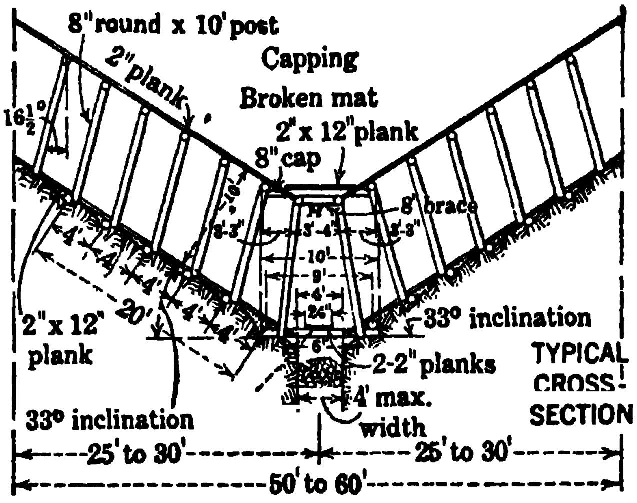

Fig 504. Humboldt Mine, Cross-sec through Wings of Stope

Prince Leopold mine, Katanga, Belgian Congo, uses a modified form of inclined top-slicing, differing somewhat from that at the Humboldt mine. For details, see Bib (274).

74. SUMMARY OF TOP-SLICING

General. Top-slicing is essentially a method for mining deposits with weak ore and walls. Though it may be used under many different conditions (Art 70–73), its commonest application is in orebodies of large horiz section, overlain by material which caves readily. It is well adapted to easily broken, heavy ground, requiring strong timbering and filling if mined overhand (132, 286).

Advantages common to all forms of top-slicing: (*a*) safety; chief danger is that men may fall down raises; (*b*) clean mining; (*c*) high extraction (90–98%); (*d*) it allows close sampling during mining; especially important in certain Lake Superior iron deposits.

Disadvantages are those common to all caving methods (Art 78, 82). Also, much timber is required, natural ventilation is poor, and fire hazard is high. In the older applications of top-slicing, all ore was shoveled by hand. Recent scraping practice in radial slices largely overcomes this disadvantage.

Requirements for successful application: (*a*) Subsidence of overlying ground must neither destroy valuable property nor make mining dangerous; see Art 113 for full statement of these conditions. (*b*) Capping, if of rock, must be weak enough to cave either to surface or sufficiently to cover the mat with a cushion of broken rock thick enough to protect the workings below. (*c*) Ore should be of uniform grade; small amounts of waste may be left on floors, but extensive sorting is not feasible. Large horses of waste may be left unmined, but are troublesome; square-sets must be used to form a mat below the horses, as at top of a deposit (Art 70). (*d*) Ore should break easily, since working faces are small and cost of narrow work increases rapidly with hardness of ground. Also, the heavy blasts required in hard ground dislodge timbers and cause premature caves (284). (*e*) Boundaries of orebody should be regular; irregularities do not prohibit top-slicing, but increase cost, as they usually involve square-setting. (*f*) Top-slicing is best for orebodies the shape, size, and position of which allow stopes with vert or steep-dipping side walls. Trouble arises in vein-like deposits dipping less than 60°, because the hanging wall must be caved and the mat extended under it on each floor; these difficulties increase with strength of hanging and flatness of dip. See Bib (277) for use of top-slicing in a bed 36 ft thick, dipping 9–12°; also Utica mine, Art 71.

Alternative methods. Top-slicing has been substituted for filled square-sets (Art 45) at several mines where it is needless to support the surface or ground containing unworked orebodies. The method then has the following comparative advantages (see also Art 54): (*a*) It allows mining in ground too heavy for economical square-set work. (*b*) In very heavy ground, where square-sets require much reinforcement, it saves timber; elsewhere it may require as much or more timber than square-sets. But, cheap grades of timber are always used, with less and simpler framing, and its erection in stopes takes less time (132). (*c*) It saves cost of filling. (*d*) Rich fines are recovered in slice below; some fines are always lost in filled square-set stopes (Art 47). (*e*) More unskilled labor can be employed; more shovelers and fewer timbermen are needed. (*f*) Stoping may stop temporarily, with a lower cost for renewing or reinforcing timbers.

Relative disadvantages of top-slicing, besides the general disadvantages stated above, are: (*a*) it is less flexible; (*b*) ground is broken by breast stoping, which usually costs more than overhand work; (*c*) a much greater footage of drifts, raises, etc, is required for a given block of ore, and this delays production from any area; (*d*) mining is confined to top of orebody; stopes can not be opened on lower levels; hence, top-slicing in orebodies of small area may not produce the desired output; (*e*) cost of bringing timber into the stopes is usually higher in top-slicing than in square-setting (Art 47). Sub-level caving is the usual alternative caving method (for comparison, see Art 78).

75. SUB-LEVEL CAVING

General. Sub-level caving, a logical development of top-slicing (Art 70), is largely used on the Lake Superior Iron Ranges, but rarely elsewhere in the U S. Other local terms: SUB-DRIFT CAVING, SUB-LEVEL SLICING, SUB-SLICING, SUBBING, SLICING AND CAVING, SUB-LEVEL SLICING WITH ORE CAVING, and TOP-SLICING WITH PARTIAL ORE CAVING.

Suitable orebodies are wide deposits of moderately soft or moderately firm ore, overlain by ground which will cave readily but coarsely, to form a capping which will arch and support itself temporarily over small openings. Latter condition is neither necessary nor desirable in top-slicing. For limitations and requirements of sub-level caving, see Art 78.

General plan. The method resembles top-slicing in that the ore is mined in horiz slices in descending order, so that the overburden, or capping, will break up and subside as the ore beneath is removed. Fundamental difference is that the height of slices in sub-level caving is usually 15–25 ft, as against 10–12 ft in top-slicing. Timbered slice-drifts are driven as in top-slicing, but a back of ore 7–15 ft thick is left between top of the sets and bottom of the mat, this back of ore being removed by mining and caving, starting at far end of the slice-drift and retreating toward the entrance. The slice-drifts are often 18–25 ft apart horizontally, the "caving-back" operation in a given slice-drift then reaching out on each side to lines midway between adjacent drifts. Fig 505 indicates the similarity between top-slicing and sub-level caving, and shows progressive variations in amount of ground taken per slice in the latter method.

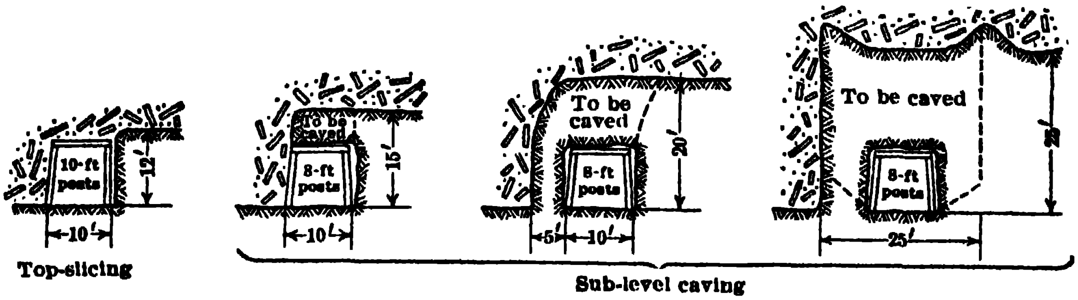

Fig 505. Diagrammatic Vert Cross-secs through Slice-drifts, comparing Top-slicing with Various Methods of Sub-level Caving

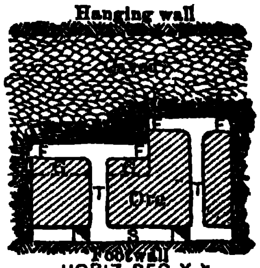
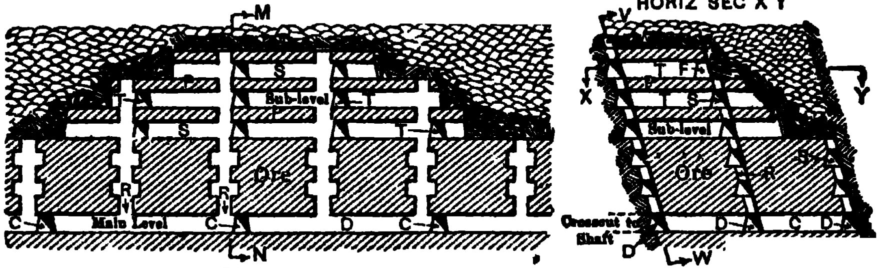
Fig 506 also shows the resemblance to top-slicing in general plan of development, formation of mat, and the manner of retreat in a wide vein. Main levels consist of drifts *D* and crosscuts *C*, planned to facilitate haulage and for proper spacing of raises *R*. Sub-levels ("subs"), opened from raises as needed, consist of timbered drifts *S* and crosscuts *T*, cutting the ore into pillars (Fig 517, Art 76). This development work leaves pillars *P* between the back of one sub-level and floor of that above (Fig 506).

Mining begins on the highest sub-level, the end pillars being attacked first; work retreats toward some central point, as in the longit sec *VW*, Fig 506.



HORIZ SEC X Y



LONGIT SEC V W CROSS-SEC M N

Fig 506. Sub-level Caving in Wide Vein (diagrammatic)

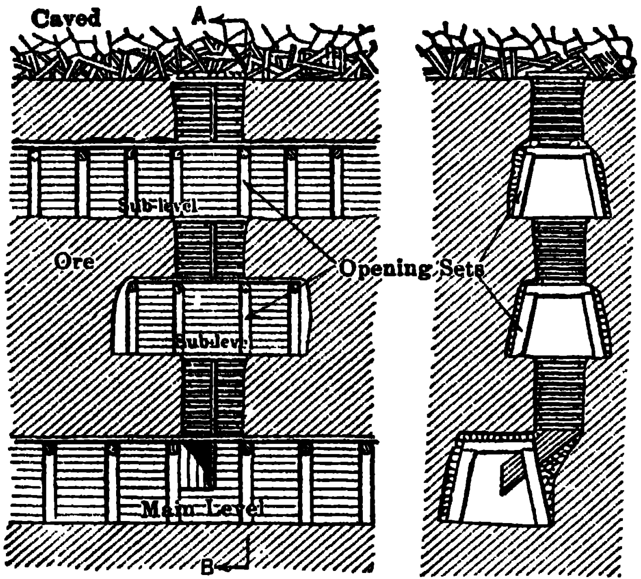
Work on individual pillars may begin at the hanging wall and retreat toward footwall (cross-sec *MN*), or may retreat from both hanging and foot to raises in middle of vein, or may retreat in a direction parallel to the strike.

In Fig 506, a slice-drift or slice *FF* is driven from crosscut *T*, next to caved ground and half-way across adjacent pillars; it is timbered with drift-sets and usually floored with lagging or plank. The overlying ore is caved into the slice-drift in small sections, from points *F* (horiz sec *XY*), and retreats to crosscut *T*. Ore is shoveled into either barrows or small cars and trammed to raise, or loaded mechanically into cars, or scraped direct to raises. Scraping has largely supplanted other means of handling ore. Contiguous slices are successively driven and caved in retreat. Mining of ore alongside and over slice-drifts is called "stoping back," "caving back," or "stripping." Fig 508–512 show details of different modes. Set-timbers and flooring are not recovered; as work descends, a mat of timber and waste (gob) accumulates above. Method requires that gob shall hang temporarily over small excavations, long enough for safe removal of caved ore. Sub-level drifts and crosscuts connecting the raises divide the ore into blocks or panels, which are usually mined one at a time. Several blocks may be mined simultaneously by keeping adjacent working faces in advance of one another (Sec *XY*, Fig 506). In the same way, slicing and stripping may proceed simultaneously on several sub-levels. Main levels are mined like subs, the ore passing through raises to next lower main level.

Variations. Above plan may be adapted to orebodies of various shapes and sizes and to ores of different character by modifying layout of subs, raises, and main levels, the interval between subs, and the details of slicing and stripping (see below; also Art 76, 77).

Development. ENTRY (see under Entry, Art 70). INTERVAL BETWEEN MAIN LEVELS is 75–200 ft; it depends upon same factors as in top-slicing (Art 70), but the relative weight of these factors is different because: (*a*) ores mined by sub-level caving are usually stronger than those worked by top-slicing; (*b*) timber consumption per ton of ore is less in sub-level caving, less timber has to be handled through raises, and cost per ton of ore for hoisting timber to the subs is lower. Hence, somewhat greater level intervals are allowable in sub-level caving. Interval between main haulageways may be increased by employing intermediate levels, as in top-slicing.

At CHAPIN mine, main levels were 200 ft apart vertically, because of cost of crosscutting from the shaft under difficult drainage conditions (153). At some places, intermediate levels were opened 50 ft apart; at others, raises were offset at 50-ft intervals to break the fall of ore and avoid excessive wear in chutes. Layout of main levels at this mine favored mechanical haulage. Oblique crosscuts allowed easy curves into crosscuts. Cars were hand-trammed in most of the crosscuts; only a few contained trolley wires. The disadvantage of oblique crosscuts is that some diamond-shaped pillars are formed on main levels, and also on subs, if these are directly over the main drifts. Slicing and caving are more difficult in diamond-shaped than in rectangular pillars, especially on reaching a stage where a triangular area remains to be mined. Also, ore is apt to be forgotten and lost when drifts and crosscuts are at oblique angles (183).



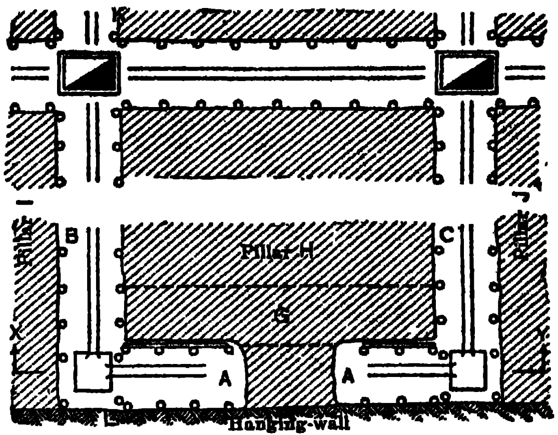
LONGIT VERT SEC CROSS-SEC A B

Fig 507. Timbering for Raises, Sub-level Caving

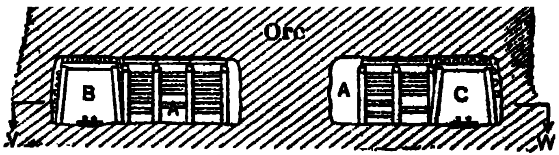
Main levels are planned to facilitate haulage and allow proper spacing of raises for handling ore on sub-levels. In very narrow orebodies, development often comprises a single drift; in wider orebodies, 1 or more drifts parallel to strike, often with crosscuts at 50- to 100-ft intervals; for examples, see Art 76. Original layout should cut ore into pillars suitable for slicing and stripping, or into pillars which can be subdivided systematically for this purpose by subordinate drifts and crosscuts. RAISES are usually close-cribbed; drift-sets ("opening-sets"), Fig 507, are placed in the cribbing opposite each sub-level as the raise goes up; sub-levels are started from these as needed. Chute and ladderway compartments are required in nearly all raises. Raises are usually put up from main-level drifts at intervals of 30–50 ft; branched raises are sometimes used to secure close spacing for hand and scraper loading; see Art 76 for various arrangements. Factors governing raise interval are like those for top-slicing (Art 70); see also below under Sub-levels.

Sub-levels. (*a*) Plan of sub-level development depends on shape, size, and nature of orebody, and character of capping; sub-level plans should guide main-level development rather than *vice versa*. (*b*) To facilitate slicing, sub-level drifts and crosscuts should intersect at right-angles, the pillars thus formed being rectangular. This practice is followed even where slice-drifts are oblique, as in Radial slicing, Art 76. (*c*) Regardless of method of loading, max length of slice-drifts for economical driving and stripping is about 100 ft. Economic length of slice-drifts also obviously influences interval between raises. See Art 76, 77, for various sub-level layouts.

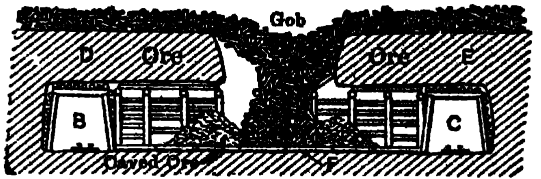
Sub-levels should not be opened far in advance of mining requirements; to maintain them for long periods may require extensive renewals of timbering. New sub-levels can generally be developed quickly, as raises furnish numerous points of attack; but, when the ore from sub-level development is needed to maintain a certain output, the subs are run as soon as they are reached in the raises (76, 270). Drifts on a sub-level are sometimes crushed by pressure caused by mining on the sub above, especially when drifts on adjacent subs are directly over one another, instead of being staggered.



HORIZ SEC V W



VERT SEC X Y (DRIVING SLICE-DRIFT A)



VERT SEC X Y (STRIPPING SLICE-DRIFT A)

Fig 508. Slicing and Stripping Details

Vert interval between sub-levels is 12–25 ft; in a given orebody it is a compromise between following factors: (*a*) a large interval increases proportion of ore broken by caving and hence reduces aver cost of breaking ore for the whole deposit; (*b*) small intervals allow closer control, cleaner mining, and higher extraction; (*c*) max possible interval is a function of strength of ore, pressure of the gob, and time required to open and mine a sub-level. Depending on relative weight of these factors, the normal interval of 15–18 ft between subs is increased where possible and decreased if necessary. For unusual case where interval is 50 ft, see Montreal mine, Art 76.

Methods of slicing and stripping pillars formed by sub-level development vary with character of ore, pressure from caved ground, and thickness and strength of mat; local custom also influences the choice (270, 76, 293, 153, 482).

Fig 508 shows a plan suited to HEAVY GROUND which, in narrow excavations, can be supported temporarily by timber. A slice-drift *A* is driven across pillar *H*, and timbered with lagged drift-sets; when completed, floor *F* of lagging or old timber is laid. Stripping begins by removing top lagging from sets at center of pillar and allowing the ore to run into the drift; the mat follows the ore down as indicated. Stripping retreats each way to crosscuts *B* and *C*, and the process is repeated in continguous slice-drifts until the pillar is mined out. Ore in back of crosscuts *B* and *C*, at *D* and *E*, may be broken as a final step in stripping each slice-drift, or when the adjacent pillars *I* and *J* are mined. The latter plan preserves crosscuts *B* and *C*, so that slice-drifts in pillars *I* and *J* can be driven from both ends. This increases speed of mining and shortens distance between working faces and crosscuts, but the cost of maintaining crosscuts may be prohibitive. An arrangement which avoids this difficulty is shown in Fig 506. If ground to left of *KL* (Fig 508) had been mined and caved, slice-drifts in pillar *H* could be driven from one end only, that is from crosscut *C*; stripping would then begin at inner end of slice.

In Fig 508, lagging on sides of the slice-sets holds back the gob while slice-drifts are being driven and stripped. Fig 509 shows a method permitting CLOSE CONTROL of both lateral and vertical pressure. A slice-drift *AA* is driven as shown, leaving a 6 or 8-ft pillar of ore *PP* next to gob. Work of removing pillar and stripping the slice begins at *A* and proceeds as follows: crosscuts 1 are driven through pillar *PP* and ore over 1 is caved; ore over 2 is then caved, and crosscuts 3 are driven and stripped; then ore over 4 is caved, and so on. The back of sub-level crosscut *C*, at 10, is stripped last; the next slice-drift is driven at *FF* and process is repeated. Fig 510 shows a systematic method sometimes used on Gogebic Range for stripping pillars and slices (482). Sub-level interval is 18 ft; slice-drifts, on 15-ft centers, are 10 ft wide at bottom, 7 ft at top, and 8 ft high. Starting at face of slice-drift *S*, a section of the pillar 1 is broken, usually by blasting; then cuts 2 and 3 are taken by blasting or barring. Without removing the top lagging, holes are drilled in the back of the slice-drift, and cut 4 and the lagging are blasted down; cut 5 is blasted or barred down as conditions require. This work is done in small sections, retreating toward entrance to slice-drift.

Fig 511 shows work in STRONGER GROUND under a strong mat. Drift *A* is a sub-level at end of orebody; slice-drifts *B* and *C* are driven in turn alongside of it. By the time slice *B* is completed, or possibly not until slice *C* is started, timbers in *A* begin to crush. If ore overlying *A* does not come down, timbers at far end of *A* are shot out, and caving is begun there by blasting down the back with light charges. The ideal condition is to have caving start at end of *A* and progress steadily back to crosscut *D*; to accomplish this, some slice-sets may be reinforced and others shot down; similarly, some parts of the back may require blasting and others not. Ore caving into slice *A* is loaded by men who work mostly under protection of timbers in *B*. Broken timbers are thrown back and become part of the mat; slightly damaged timber may be used for reinforcing weak sets. Vert sec *LM*, from B. W. Vallat (76), shows work while stripping is going on in slice *B*. A thick mat will often hang up until stripping is completed; P. S. Williams states that, on the Gogebic Range, Mich, the gob sometimes takes a week to close in (270). Obviously, details may be greatly varied. If parts of pillars crush before they can be mined out systematically, drifts are driven to the crushed area, and ore is drawn as long as it will run. Some of the ore which can not thus be recovered is obtained in stripping the sub-level below; such work is necessarily irregular.

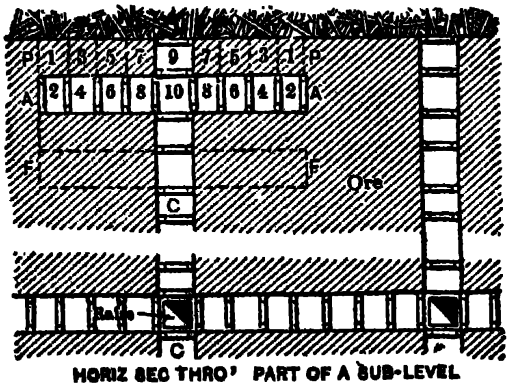


Fig 509. Slicing and Stripping Details

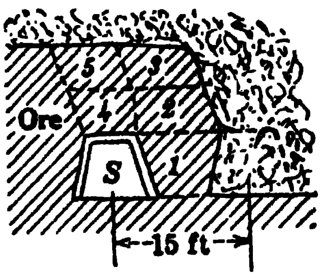

Fig 510. Cross-sec through Slice-drift

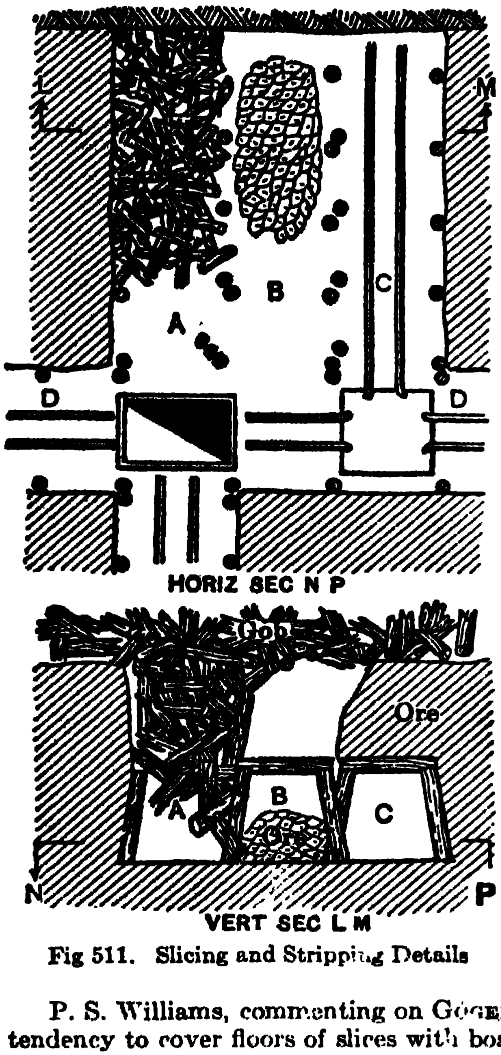

Fig 511. Slicing and Stripping Details

Sometimes work is planned so that the weight of gob will crush part of the ore in sub-level pillars. Fig 512 shows this method at CHANDLER mine, Ely, Minn (see Art 76 for description of orebody). Stripping on any sub-level retreats from the ends of the deposit. Drifts *D* cut ore on the sub-levels into pillars say 10 ft square. Weight of the caved ground above breaks down ore in the back, and splinters the pillars so that they can be mined with pick and bar, without blasting. Where necessary, long props with head-boards support the mat temporarily, as at *C*.

For more recent practice on Gogebic Range, see Art 76.

Breaking ground in slice-drifts is similar to that in top-slicing (Art 70), except that there is no free face at the top; slices like those in Fig 509 are driven as ordinary drifts (Art 20).

Timbering. Cheap timber is used for same reasons as in top-slicing. Simply framed 3-piece sets are nearly always employed for slices. When slicing under a thick mat, FLOORS are often omitted.

P. S. Williams, commenting on GOGEBIC RANGE practice in 1910, indicated a growing tendency to cover floors of slices with boards, even where gob is compact enough to allow good extraction without them. Use of floor-boards sets a definite limit for men to work to in stripping and helps to prevent mixing waste with ore (270). HANDLING TIMBER.

Much slice timber must be hoisted up raises. Where sub-levels are opened in advance of mining requirements, timbers for sub-level drifts and crosscuts can be lowered from main level above. When a pillar of ore is left opposite a hoisting shaft in the footwall, raises can be maintained in the pillar, through which timber for development and slicing is lowered to sub-levels (270). SALVAGE OF TIMBER is not feasible.

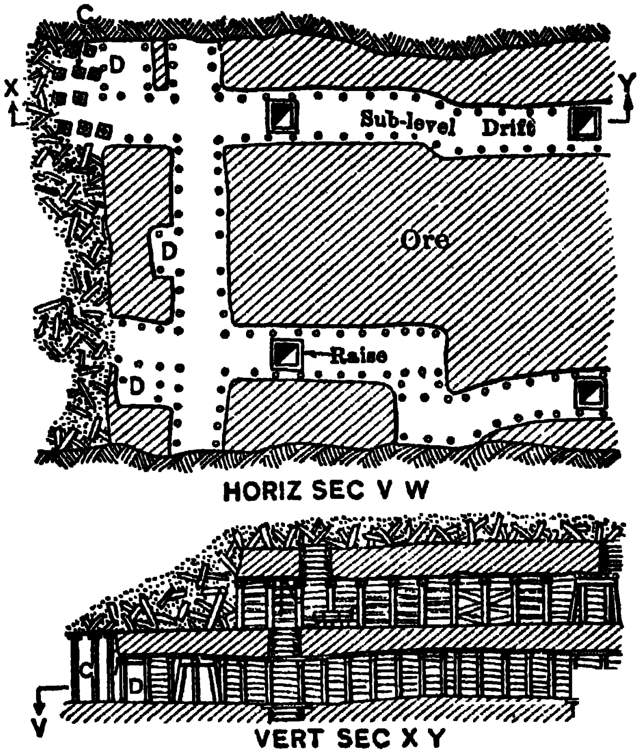

Fig 512. Slicing and Stripping Details

Handling ore. Problems resemble those in top-slicing (Art 70). With hand loading, all ore broken must be shoveled. Barrows, or cars of 0.5–1.5 ton, are used on sub-levels. Some direct shoveling to raises is possible. Mechanical loading (usually with scrapers) is cheaper, increases duty of labor, and shortens time for slicing and stripping. Most of the loading in nearly all Lake Superior iron mines is now (1938) done mechanically, even where original development was planned for hand loading. For examples, see Art 76, 91. Small amounts of waste can be sorted out and left in the slices; floors should be laid where this is done, otherwise, the same waste will appear when slice below is stripped. Extensive sorting is not feasible.

Mat is started at top of orebody by one of the methods described in Art 70; see also Fig 518, Art 76, and accompanying text.

Ventilation problems in sub-level caving are like those in top-slicing. For efficient mining, powder smoke, and the heat and gases from decaying timber in gob, must be swept from the working places. Doors and brattices (Sec 14) are used to control natural air currents; working places which can not be thus ventilated have motor-driven pressure fans. Sub-levels are kept connected with main level above as long as possible, to facilitate handling timber; these connections and those with the timber-raises in shaft pillars greatly aid natural ventilation. For full discussion of ventilating problems in Lake Superior iron mines, see Bib (298).

Extraction. Some ore is lost in the gob, especially near top of orebody. Loss is materially reduced by using floor boards; it becomes less after some thickness of gob has been formed. Pillars crushing prematurely can not always be entirely recovered; such caving may cause further loss by preventing access to other pillars. Different engineers estimate that 5–20% of ore is lost in sub-level caving; no accurate data available.

76. SUB-LEVEL CAVING ON LAKE SUPERIOR IRON RANGES

Gogebic Range, Mich and Wis. Data from C. F. Jackson (281) in 1931. Orebodies occur in several productive horizons in cherty and slaty beds, dipping 55°–75°, as concentrations of hematite in V-shaped pitching troughs formed by intersection of dikes with footwall quartzite or impervious slates (Fig 513). Deposits, irregular in shape, vary from a few ft to several hundred ft in width and thickness, and from several hundred to several thousand ft in length. Hanging-wall capping usually consists of bands of slate and partly leached, cherty iron formation. On caving, hanging wall breaks into blocks or slabs tending to interlock and arch over openings of moderate size. DEVELOPMENT. Entry is by inclined or vert shaft in footwall (Fig 513); recent practice favors vert shafts. Main levels, 110–300 ft apart measured on dip of formation. Orebodies of the smaller widths are developed on main levels by drifts parallel to strike (Fig 514); wide orebodies, by longit drift near footwall, with crosscuts about 100 ft apart (Fig 514). Sub-level vert interval is usually 18–25 ft, sometimes greater; at Montreal mine, 50 ft. Sub-levels are developed from a series of raises from haulage drifts. Where haulage level comprises one or more longit drifts, the raises are on lines parallel to strike; slices usually run across orebody, with raises 18–20 ft apart at the sub-levels, to provide for direct scraping from slices. In very narrow orebodies slices generally run strikewise, with raises sometimes 200 ft apart. Where longit haulage drifts are used, raises are at same inclination as footwall; generally of 2 cribbed compts, an ore-pass and a manway containing a timber slide, compressed-air line, and sometimes a flexible ventilating pipe. If ore has been blocked out by crosscuts on haulage level (Fig 514), raises are crosswise of orebody, and slices parallel to strike. These raises may be vert, but are often inclined at right-angles to the crosscut and driven at an angle of 65°–70°. Regardless of haulage-level layout, raises are often 50 ft apart in starting, but are branched at some point above to give spacing of 18–25 ft at sub-levels (Fig 515). For exceptional procedure, see Montreal mine below. Slicing and caving. Slice-drifts are about 8 ft wide at top, 10 ft at bottom, and 10 ft high. Rounds about 5 ft deep are drilled with hand-held hammer drills and auger·bits. Slice-drifts are timbered with battered sets of round timber 5 or 6 ft c–c, lagged with split or pole lagging. Posts and caps are 7 or 8 ft long; diam from 8 or 10 in to 12 or 15 in. Timber is usually unpeeled tamarack; sometimes hemlock or hard wood. Where line of raises is parallel to strike, slice-drifts are driven from center line of raise to both walls; if crosswise of orebody, slices are parallel to strike in both directions to point halfway through block of ore between the raise lines. When slice-drift reaches hanging or footwall or to the predetermined mining limit, the stoping or "caving-back" operation starts at end of drift (Fig 515). A side cut is first taken next to caved ground, followed by several others, the last cut being always

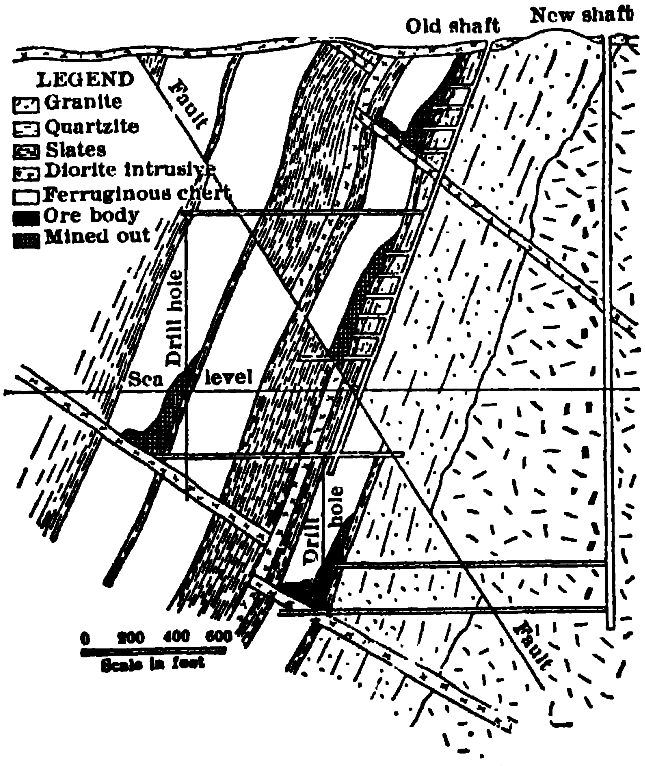

Fig 513. Typical Cross-sec of a Gogebic Range Mine, showing Scheme of Development

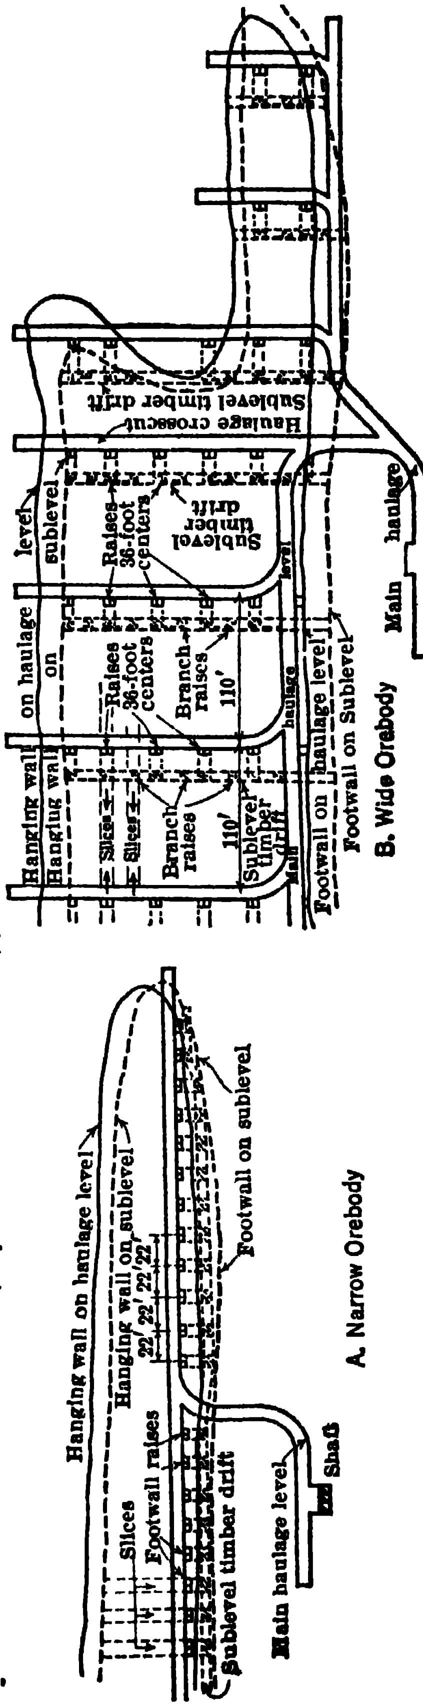

B. Wide Orebody

A. Narrow Orebody

Fig 514. Main- and Sub-level Development, Gogebic Range

over the back of the drift. In making these cuts, lagging is removed from 1 or 2 sets, as required, to permit drilling. The side cuts are at an angle of 45°–50° from horiz; in blasting them, care is taken not to injure the pillar over back of drift. In starting the caving-back work, it may be necessary to mine several sets before the gob will come down. During advance of the slice-drifts and the caving-back operations, the ore is scraped by power scrapers into the raises. Floors are not covered as carefully as in top-slicing before caving of gob, but some covering, often old timber, is usual. The "hog-back" between slices may be blasted before caving the gob; if it is not mucked out, a mat (poles covered with wire fencing) is laid over it to prevent its mixing with gob. Caving-back operations are repeated, retreating to the raise, or to within about 8 ft of it if slicing is to be done on opposite side of the raise. Work is usually planned so that while a slice is being caved back, the adjacent slice is advancing. Miners work in pairs, on contract, usually producing, in caving back, 40–60 tons per man-shift, sometimes 80 or more tons. One mine reports an aver of 40 tons per man-shift for slicing and caving back combined. Caving back is carried on rapidly to minimize timber repair; slice-drifts are driven only in accordance with production requirements. Power scraping has virtually eliminated hand shoveling on Gogebic Range; usual equipment is commonly 15–25-hp elec double-drum hoists, with hoe or box scrapers. At Montreal mine, below, use of scrapers has eliminated loading chutes on haulage levels.

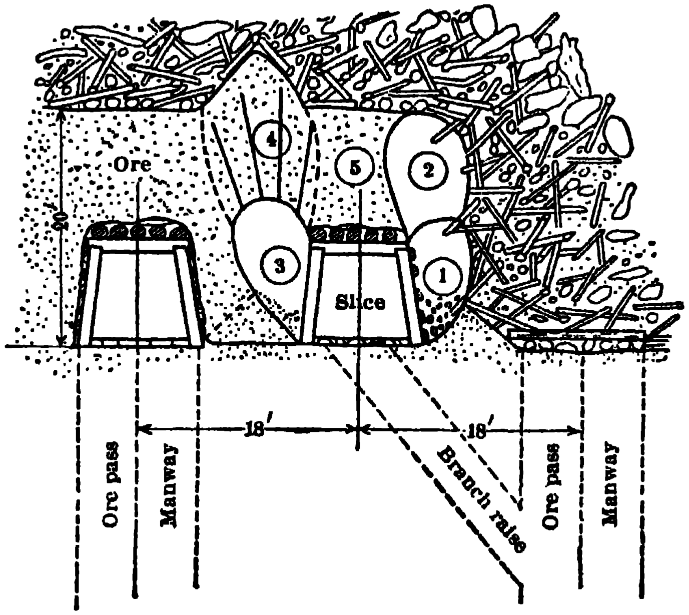

Fig 515. Caving Back

Eureka-Asteroid mine, Gogebic Range, Mich. Data from O. M. Schaus (499) in 1930. Geological features are typical of district (see above). Types of orebodies: (*a*) the usual one consists of masses of triangular cross-section, lying at intersections of diorite dikes with the footwall; (*b*) blankets 5–20 ft wide lying on the footwall. Ore is soft hematite requiring timbering of all openings. Hanging-wall capping is cherty iron formation. DEVELOPMENT. Main shaft is vert, in footwall midway between property lines; depth (1930), 3 275 ft; at 2 000 ft it is 1 000 ft from footwall. Haulage levels are at 200-ft vert intervals. Level development depends on size and shape of the orebody, but usually comprises one or more drifts parallel to strike. Drifts in ore are 9 by 11 ft outside timber; battered sets of 8-ft posts and caps are 5 ft c–c. Untimbered drifts and crosscuts in footwall are 8 by 10 ft. Where ore is in narrow veins or blankets, raises are as much as 200 ft apart; they have 2 cribbed compts, ore-pass and manway. Ore-passes are lined with 1.5-in hardwood plank to aid passage of sticky ore and prevent wear on cribbing. In orebodies 100 ft or more wide, main raises may be 50 ft apart, branch raises splitting the intervening pillar. Inclination of raises is 55°–90°; 65° slope has been found best for ore-passes. Vert spacing of sub-levels is 18–25 ft. Orebodies 5–50 ft wide are opened on sub-levels by drifts; wider bodies, by crosscuts 25 ft apart, with a connecting drift along line of raises. MINING. Slice-drifts are 8 by 9 ft; timbered with 7-ft posts and caps. Scrapers are used both in advancing slice-drifts and in caving-back work. In narrow orebodies, caving starts midway between raises, max economical scraping distance being 100 ft. If ore is no wider than the drift, back lagging is removed between 2 sets of timber and a 6-ft round drilled in the back. After blasting, miners stand on the broken ore to drill next cut, which is fanned out parallel to drift. Before this is blasted, 3 or 4 back-lagging poles are replaced to prevent premature runs of gob. When second cut reaches the caved sub-level above, ore from both cuts is scraped out. In wide orebodies, slices run across them, sub-levels being spaced vert on 18-ft centers and horiz on 25-ft centers. Caving-back follows typical Gogebic practice (Fig 515). Miners work on contract; when slicing, rates are lower in wide orebodies, higher in narrow ones. In 1929, production averaged 5.71 tons per man-shift underground; dynamite consumption (60% in development, 40% in stoping) was 0.71 lb per ton; timber, 3.35 bd ft per ton.

Newport mine, Ironwood, Mich. Data from B. W. Vallat in 1911 (76). This example, though old, is retained to show variations in main-level development, sub-levels arranged for hand shoveling, and work at top of orebody. Entry was by inclined shafts in country rock, parallel to footwall dipping 68°. Fig 516 shows usual main-level development; where possible, drifts and crosscuts were driven on sides of 100-ft squares, but waste horses caused local variations. Vertical raises were 50 ft apart along drifts and crosscuts. Sub-levels were 15 ft apart, beginning 18 ft above main level, where a thicker pillar was left to protect haulageways. Sub-levels were opened by connecting the raises with drifts and crosscuts; the 100-ft pillars so formed were subdivided into 50-ft pillars, just before mining began in any area (Fig 517).

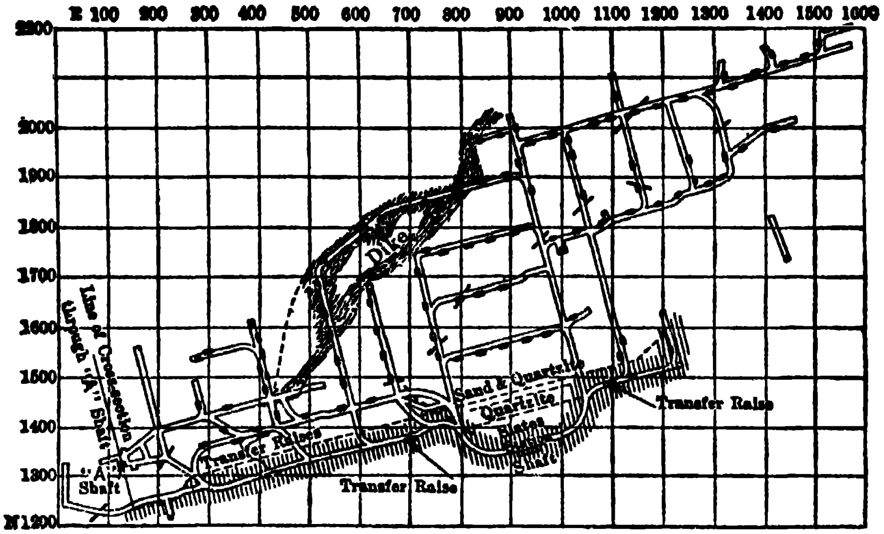

Fig 516. Newport Mine, Plan of 17th Level

Slicing and caving were carried on in sections 300 to 400 ft long by full width of deposit. The contact between ore and rock at top of orebody pitched eastward. The first work on any sub-level started at its eastern end; an area 300 ft long was subdivided into 50-ft pillars (Fig 517). Slice-drifts (crosscuts) *A* and *B* (Fig 518) were driven in succession across a pillar on hanging-wall side. Men working under protection of the timbers in *B* drilled short holes in the ore above *A*, to break it clean without disturbing the capping; the sets were left to stand if they would. The floor of *A* was then covered with old lagging, blocking, etc, which, with the slice-sets, started the mat, on which the unsupported capping kept shelling off. Slice *C* was then driven, the ore over *B* was taken down, and so on over the whole area of sub-level. Meanwhile, areas 300 ft long to the west on same sub-level and 300 ft long to the east under the capping on next lower sub-level were developed (Fig 519). Slicing and stripping under gob proceeded as in Fig 511. On sub-levels, ore which could not be shoveled to raises was handled in 0.5-ton cars ("buggies") on 8-lb rails, with turn-sheets at intersections of drfts. In 1910, Newport mine produced 1 074 800 tons in 307 days, using 0.608 linear ft of round timber and 0.0049 cord of lagging per ton.

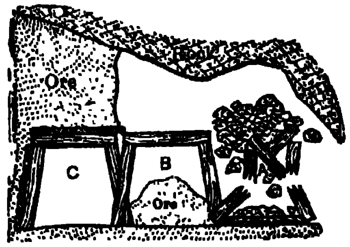

Fig 518. Newport Mine, Slicing and Stripping under Capping

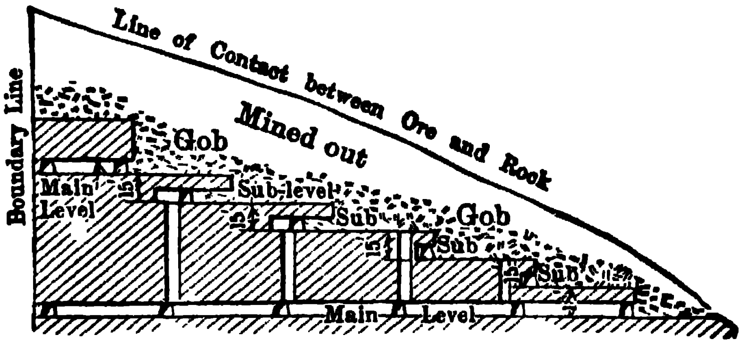

Fig 519. Newport Mine, Relation between Work on Sub-levels. (Vert longit sec, vert scale exaggerated)

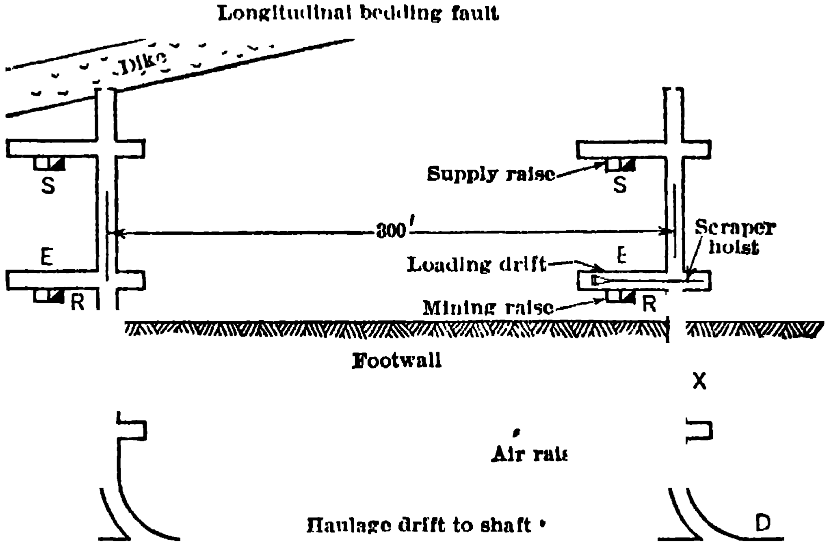

Fig 520. Montreal Mine, Generalized Plan of Haulage Level

Montreal mine, Gogebic Range, Wis. Data from R. A. Bowen, Asst Supt (292) in 1938. Ore occurs as concentrations of hematite in pitching V-shaped troughs formed by intersection of dikes with quartzite or slaty sedimentary formation. Formation dips about 62° N; dikes, 45° S; troughs pitch about 16°. Orebodies up to 180 ft wide and 1 400 ft long are scattered along 2 miles of formation. Ore is "soft," of claylike consistency which is quite strong and permits relatively large openings. Capping is weakened longit by interlaminated ore seams, and transversely by cross-jointing planes; otherwise it is strong and hard, and breaks without producing very large blocks or much fines, tending to arch and hang in caving. The part of capping in direct contact with ore is high enough in iron to permit some ore dilution without destroying commercial value. DEVELOPMENT. Entry is by vert shaft in footwall. Haulage levels are 150 ft apart; sub-level interval, 50 ft. Haulage levels are developed by a drift *D* (Fig 520) within footwall, from which crosscuts *X* are turned off to cross orebody at 300-ft intervals. Main-level entries are either gunited or timbered with battered sets, 5 ft c–c, with 8-ft posts and caps, 11–13 in diam. Near the footwall, a "loading drift" *E*, about 50 ft long, is driven in one direction from each crosscut, elevated 4.5 ft above rail in crosscut. Opposite the entrance to each loading drift a short drift runs in the other direction to accommodate a scraper hoist. From each loading drift a double-compt cribbed "mining" raise *R*, 4 by 4 ft inside each compt, without chute pocket, is driven at the footwall inclination to the second sub-level, 100 ft above. All ore from the mining raises is scraped through the loading drifts to cars in the crosscuts. Nearer the center of the orebody, from drifts similar to the loading drifts, a second raise *S* is driven to handle materials and serve as travelway and airway. Other raises within the footwall connect the main levels for ventilation. On the sub-levels, a "slushing" drift *T* connects the mining raises (Fig 521); crosscuts *U* connect the various raises serving each main crosscut. The ore is blocked out in 50-ft pillars along the strike, formed by 2 crosscuts *V* at 25 ft c–c, each 12.5 ft from the center line of pillar. Sub-level entries are timbered with battered sets 5.5 ft c–c, with 8-ft posts and caps. STOPING AND CAVING. Mining starts in a pillar midway between 2 mining raises, developed by the 2 crosscuts *V*. A manway is raised midway between crosscuts to a point 25 ft above the sub-level and a small, untimbered sub-crosscut *Y* is driven to the ore limit (Fig 522). Beginning near the ore limit, openings *W* from the inside of each crosscut are carried up, enlarging as they progress, until they hole through to one another and connect with the manway. Thereafter the "stope" is enlarged by narrow benches. As "slice" holes are blasted in the sides, the back caves down until it arches over the added width of opening created. The operation is thus carried on until the protecting shell of ore around the stope is very thin. The gob is usually exposed in several places before the stope begins to show weight. At this stage, any supporting ribs are cut, and caving or "dropping" starts. Caving is gradual and may continue for several shifts. By successive mining and caving, the pillar is mined back to the "slushing" drift *T*, and any ore on the footwall side is also stoped. The drift is well propped for passage of air after mining is finished. In sub-level work, a "task" for 2 men in advancing a heading is 5.5 ft per shift; for driving 2-compt raise, 4.5 ft per shift. In stoping, the task is 40 tons per man-shift, including slushing. Bonus is paid for work exceeding "tasks." Miners work in pairs; 2 pairs together in a stope (pillar), one slushing while the other drills and blasts. A slushing drift with one stope in operation, and enough crosscutting to keep ahead of mining, produces about 6 000 tons per mo, working double shift 5 days a week.

Vert Cross-sec

Vert Longit Sec

Fig 522. Stoping Procedure, Montreal Mine

Chandler mine, Vermilion Range, Minn (153, 183, 287). Orebody occurs in a flat-dipping trough (Fig 106, Art 14) capped by jasper. Ore is hard hematite, though shattered and broken, and machine-drills are often needed in driving main levels. Fig 106 shows mode of entry and position of levels and subs. Down to 8th level, main levels were 50 to 75 ft apart; sub-levels, 12.5 to 15 ft apart. Ore in the legs of the trough was about 70 ft thick; main levels usually comprised 2 drifts, near the walls and connected at intervals by crosscuts. Raises were spaced 50 ft apart along drifts. Sub-levels were opened, sliced and stripped, as described in text accompanying Fig 512, Art 75. Sets in sub- and main-levels were 3 to 4 ft apart; top lagging was used in all drifts; little side lagging was needed. No floors were laid in slices. Barrows or small cars (buggies) were used on sublevels. Below the 8th level, shaft stations were cut at 20-ft vertical intervals; intermediate levels were of same size as main levels (Fig 106). Ore on each intermediate level was cut into pillars by drifts and crosscuts, and mined as on upper levels. This saved many raises and allowed greater use of cars instead of barrows.

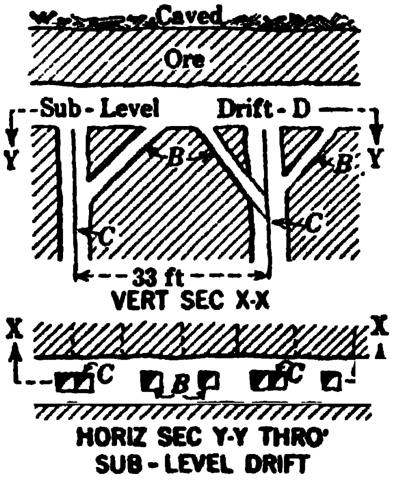

Fig 523. (Diagrammatic)

Scraping in mines developed for hand loading (482) involves use of slides for loading cars (Sec 27), or right-angle turns in scraper leads due to spacing of raises. Fig 523 shows a plan to overcome these difficulties in heavy ground. Level interval is 110 ft; main levels comprise parallel drifts 50–75 ft apart, from which 2-compt raises *C* are put up 33 ft apart; sub-level interval, 18 ft; bottom sub, 20 ft above main level. Short branch raises *B* are put up to each sub-level from chute compartments of main raises. Branch raises start from horizon of next lower sub-level. The drift-slices are on 11-ft centers (see dotted lines); each has a raise opposite its entrance, into which broken ore is scraped. Fig 524 shows a variation of this plan, used in firm ground where the sub-level drift *E* may be driven before slicing starts on the sub above. Vert raises *R* are put up to the upper sub opposite each slice-drift, and timber slides *S* convey broken ore to main raises *C*. In another variation, main raises are 50 ft apart and branched as in Fig 523, to come out on the mining sub at intervals of about 17 ft. Slice-drifts (10 ft wide at bottom) are started opposite raises; half the pillar on each side of a slice is drawn when slice is stripped. In these variations, the scraping hoist is located at the raise and broken ore is scraped directly into it. Such direct scraping gives outputs loaded per contract crew from 75 to 100% greater than in hand-loading contracts.

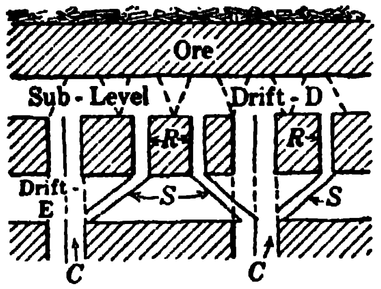

Fig 524. Vert Sec through Sub-level Drift (diagrammatic)

Fig 525 shows a more elaborate system of branched raises, to permit use of scraper loading in sub-level caving of a large orebody, originally developed for hand loading. Main levels, 110 ft apart, comprise parallel drifts *L* on 65-ft centers; raises *R* are inclined 65° and 33 ft apart. On third sub, 56 ft above the main level, the raises are connected by drifts *D*, parallel to drifts *L*. From alternate raises along drift *D*, 2-compt raises *E*, also inclined 65°, are put up to top sub; 4 by 4 ft branches *F* are driven from the horizon of the sub below to top one. A greater width of ore may require an extra drift as at *G*, and the raises *H*. On top sub-level, crosscuts *C*, 66 ft apart, are driven to connect tops of the raises. Slices 33 ft long are driven from crosscuts, as at *S*; intervening pillars are drawn as slices are stripped. Added raises are put up to serve lower sub-levels, as shown by dotted lines in Sec *XY*. This provides short straight hauls for scrapers; it requires a large footage of raises and drifts. Width served by a given set of main raises decreases on successive subs; on lowest subs in a lift, other methods must be used for handling part of the ore.

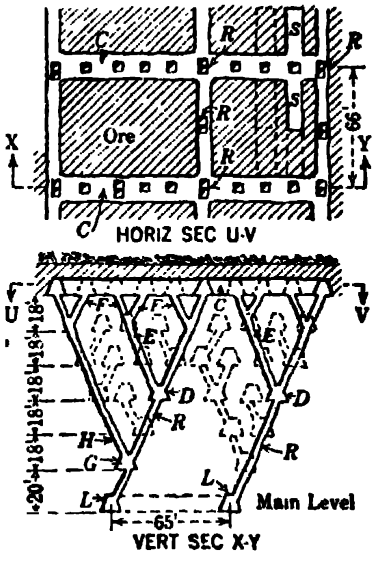

Fig 525. Sub-level Caving. Branched Raises (diagrammatic)

Radial slicing, developed by Oliver Mining Co on Vermilion and Gogebic Ranges, avoids 90° turns in scraping and also branched or other closely spaced raises. Double-compt, 4 by 8-ft raises, on 33-ft centers, are put up from main level drifts, which are 65 ft apart; sub-level interval, 18 ft. On each sub-level the raises are connected by drifts and crosscuts, dividing the ore into blocks about 25 by 55 ft in horiz sec. Successive operations in each block are shown in sketches *A* to *F*, Fig 526. *A* is the first slice-drift. Without removing timbers, the left half of the back of last 3 sets included in shaded area

(1) is then caved. In *B*, posts *a* and *b* are removed and the caps supported by center props *a′* and *b′*. From this opening a diagonal or radial slice is started, which clears first slice-drift in a distance of about 15 ft and then continues parallel to it. Rail or plank are spiked to inside of posts at the curve, about 6 in from bottom, to guide scraper around the corner. Shaded area (2) is then stripped, 1 set at a time, by removing a few side or top lagging, and blasting or barring down the back. In stripping, only the ore which can not be reached from the succeeding slice is taken; as much solid ground as possible is left over the miners. The back is usually caved for 2–2.5 ft from left end of cap. Broken timber and rock from the cave are thrown into first slice-drift and help keep posts from moving. In *C*, a 2nd diagonal slice is started by taking out posts *c* and *d* and putting in center props as before. The back in shaded area (3) is caved into this slice. In *D*, a 3rd diagonal slice is started by changing the timbering at the raise as shown, taking out posts *e* and *f* and placing center props *e′* and *f′*. This slice extends from the raise to opposite corner of block; the back in shaded area (4) is caved into it. Section *AA*, Fig 527, shows that this slice yields a much larger tonnage than the others. In *E*, the 4th diagonal slice again requires changes in timbering as indicated; the back, shaded area (5), is caved into this slice. In *F*, the last diagonal slice is started by making the changes indicated in drift timbering, and the back included in shaded area (6) is caved. Remainder of the back, shaded area (7), is caved into the crosscut. This general plan is modified in detail as required by conditions. Some operators state that radial slicing requires more timber than work with branch raises. Compared with regular slicing and hand loading, radial slicing increases production per man 75–100% and reduces time to mine a block, hence decreases timber repairs. Table 50 compares hand loading in rectangular slices with scraper loading in radial slices at same mine. In radial slicing, the production of a 2-man contract with double-drum scraping is 20–30 tons per shift during slicing-in, and 30–100 tons per shift during stripping; aver output for both slicing and caving, 30–40 tons per shift.

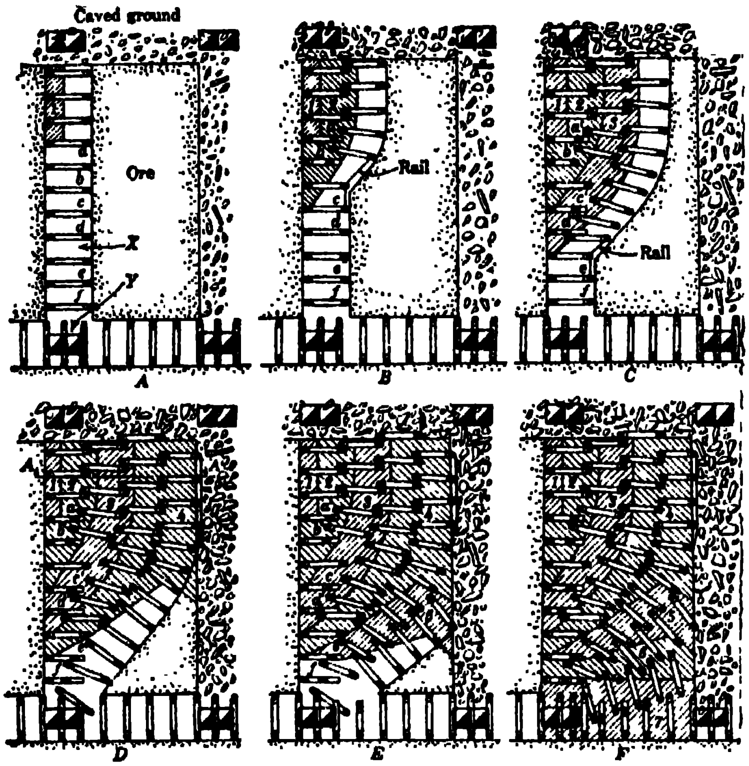

Fig 526. Radial Slicing (diagrammatic)

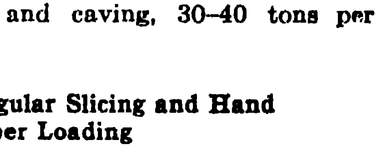

Fig 527. Vert Sec *AA*, of Fig 526 *D*

Table 50. Sub-level Caving. Comparison of Regular Slicing and Hand Loading with Radial Slicing and Scraper Loading

	Regular, hand loading	Radial, scraping		Regular, hand loading	Radial, scraping
Tons mined	10 992	14 886	Tons per timber set	76.87	66.75
Man-shifts	1 344	820	Tons per prop	112.16	323.6
Timber sets	143	223	Sets per 100 tons	1.30	1.5
Props	98	46	Props per 100 tons	0.89	0.31
Tons per man-shift	8.18	18.5	Lagging per set	1/4 cord	3/16 cord

Miscellaneous examples. Fig 528 shows application of scraper loading in mining one leg of a trough-shaped deposit. The ore, about 15 ft thick, lies on a dike dipping about 25°. A tramming drift *A* was driven; back of drift was cut out at intervals of 25 ft, and from these openings inclined slice-drifts *B*, 7.5 ft high by 8 ft wide, were run to limits of the ore. Stripping retreats from upper end of slice-drift; the back and half the pillar on each side of the slice-drift are caved into it; broken ore is scraped to a chute, which loads a car on the tramming level *A*. Aver output per man-shift, 18 tons.

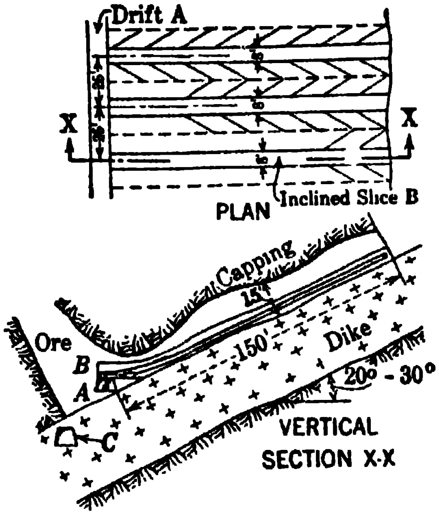

Fig 528. Scraper Loading in Trough-shaped Deposit

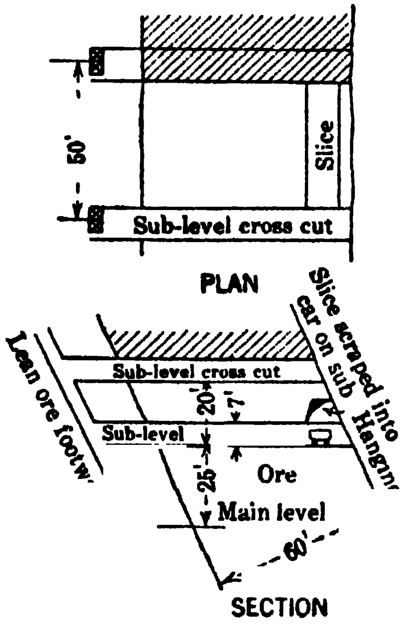

Fig 529

Method shown in Fig 529 was used to mine an orebody 60 ft wide. Main levels and raises from them were in footwall, which was lean ore (35% Fe). Sub-level interval, 20 ft; sub-level development comprised crosscuts 50 ft apart, run from each raise to hanging wall. Slicing started at hanging wall; the back of crosscut was cut out and a slice-drift was driven from the crosscut. Broken ore was scraped from slice-drift into a car standing in the crosscut. (Compare with sub-gangway used in top-slicing at Copper Queen mine, Art 70).

77. SUB-LEVEL CAVING IN UTAH AND ARIZONA

Mercur, Utah. Orebodies are low-grade gold and silver-bearing replacement deposits in tough, hard limestone, underlying sheets of porphyry which follow the limestone bedding planes on both strike and dip. There are several sheets of porphyry, and in places corresponding parallel orebodies overlying each other. Deposits are 4 to 70 ft thick; dip, 0° to 30°. Ore is usually soft, sometimes like clay; drilling is done single-hand or with augers; 30% dynamite is used. The porphyry hanging wall is blocky and generally caves readily. Practice of Consol Mercur Gold Mines Co is described below; this company suspended operations in 1913. Development. Entry was by a compound shaft (Art 16), the lower part being vertical; at each level a crosscut was run through the orebodies, with a drift along each body. Inclines were often sunk in ore from main levels and drifts turned off from them alternately to right and left at 50 ft apart, measured on dip. Thin beds (less than 20 ft thick; description by G. H. Dern, Bib 295). Fig 530 shows part of an oreshoot cut off on one side by a fault. Crosscut *C* was driven to footwall and a raise *R* followed the footwall to level above. Sub-levels, 4 by 6-ft, driven on footwall to the fault at 15-ft intervals, were timbered with 3-piece sets and lagged. An area thus opened was allowed to stand sometimes 2 or 3 months, so that pillars between subs would crush and become well broken; during this period, sub-levels were kept open by easing timbers where necessary. Mining began at fault on sub No 1, by pulling out a set of timber; as the ore caved it was shoveled into a car and trammed to raise *R*, or to special chutes provided for this purpose. A little blasting was required, to bring down ore and to blockhole boulders. When waste rock appeared, the miner retreated one set and repeated operation. When sub No 1 had been drawn back 10 or 12 ft, work started in same way in sub No 2, and so on in lower sub-levels. If two orebodies occurred, the upper one was mined first. Advantages claimed for the method were: small timber and powder consumption, safety, high extraction, clean mining. It was not applicable to deposits over 15 to 20 ft thick. Thick beds could be mined in 15-ft layers or slices parallel to hanging wall, by methods described above. Hanging-wall slice was taken first, followed by lower slices as ground above them was worked out and caved; eventually mining proceeded simultaneously in all slices (190).

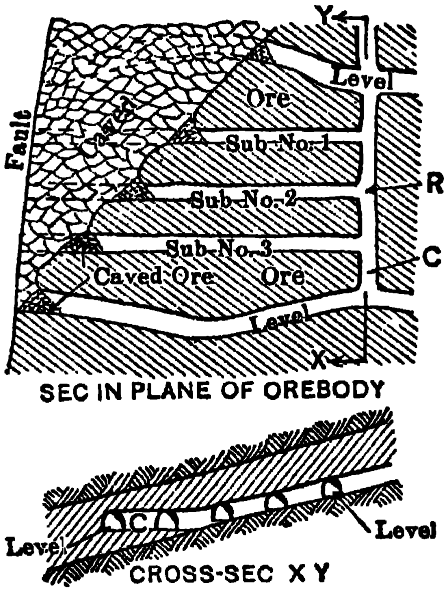

Fig 530. Mercur, Utah. Sub-level Caving

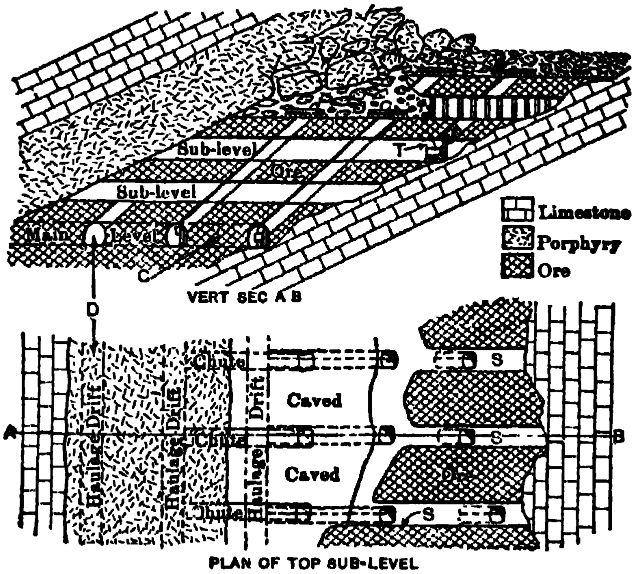

Fig 531. Mercur, Utah. Sub-level Caving

Fig 531, from R. H. Allen (296), shows another form of sub-level caving, for beds up to 70 ft thick. Main levels consisted of parallel drifts *D*, connected by crosscuts *C*, 25 to 50 ft apart. Raises were driven between crosscuts. As the minimum angle on which ore will slide is greater than the dip, new raises had to be started on footwall side of higher sub-levels, as at *T*. Raises nearest footwall had chute and ladderway compartments; others had a single chute-compartment. Sub-levels were 14 ft apart vertically; sub-level development consisted of driving crosscuts *S* from each raise to foot and hanging walls. Mining began on the highest sub-level; ends of crosscuts next to hanging wall were widened out until two or more crosscuts were connected, the roof of excavation being temporarily supported by stulls. To start caving, a few holes were drilled in the back next to the hanging wall. Pillars between crosscuts were worked back toward footwall by driving successive slice-drifts, 6 or 7 ft high, across them; slices were timbered with 3-piece sets. Ore was handled to chutes in barrows. Shoveling along face of cave was stopped when much waste appeared, and a new section of the back was allowed or forced to cave, a safe working place being kept open along faces of pillars. Drilling was all done by hand, no heavy blasts were fired, and light timbers were adequate. Caving was not started in any area until the sub-level above had been worked back to footwall; by mining ore in blocks, caving could be carried on simultaneously on several sub-levels at different points along the strike. Thickness of ore caved on each sub-level was 4–7 ft; thus, 30 to 50% of orebody was broken by caving; remainder was obtained in drifts and slices. Results of work indicated that a

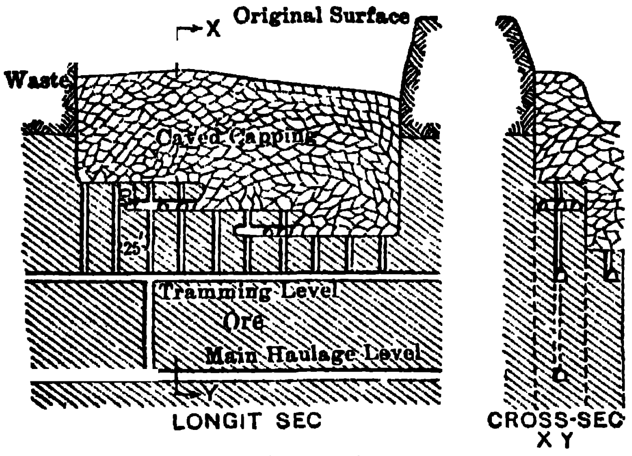

Fig 532. Arizona Copper Co. Sub-level Caving

12-ft interval between sub-levels might be better; a 4-ft back could be kept under better control and gave higher extraction than a 7-ft back. It was difficult to extract all ore along footwall, especially where dip was flat. Where this method was used, ore was fairly firm, hanging wall weak. Timber and powder consumption were low; labor cost, high. Daily output, 700–800 tons; output per 8-hr man-shift underground, about 2.5 tons.

Arizona Copper Co, Morenci, Ariz. Fig 532 (P. B. Scotland, 1915) shows a method once employed in upper part of an orebody preparatory to top-slicing. Sub-levels were 20 ft apart vertically; intermediate hand-tramming levels, about 75 ft apart. Interval between raises, 20 ft; ground was mined in blocks 40 ft wide. No mat was used; grade of ore recovered was seriously decreased by mixture with waste (178). Van Barneveld (482) cites use of a similar variation of sub-level caving on Gogebic Range, using branched raises to reduce handling costs.

78. SUMMARY, SUB-LEVEL CAVING

General. Sub-level caving is adapted to large-scale work in large, weak orebodies (see Suitable orebodies, Art 75). It is safe, and when properly conducted will yield a high extraction and produce clean ore. Disadvantages are in general the same as for top-slicing (Art 74); see comparison below.

Requirements (*a*), (*b*), (*d*) and (*f*) for top-slicing (Art 74) apply directly to sub-level caving; other essentials for the successful application of sub-level caving are: (*a*) Weight of caved ground is necessary on top of workings, and orebody must be wide enough to permit free descent of gob. (*b*) Waste, if in large amounts, prohibits sub-level caving, as it can not be stowed underground. Waste horses must be broken unless large enough to divide the deposit into sections which can be worked independently. Some grading of iron ore is possible. (*c*) Boundaries of orebodies should be fairly regular.

Sub-level caving *vs* top-slicing (Art 74). Relative ADVANTAGES of sub-level caving: (*a*) Cost of breaking ground is lower. (*b*) Less timber is required. (*c*) Larger daily output is possible from a given area. (*d*) Natural ventilation is generally better, and there is less timber to be hoisted to working places; local conditions and plan of work determine whether sub-level caving has any superiority in these respects. Relative DISADVANTAGES of sub-level caving: (*a*) Percentage extraction is slightly less, and there is always a greater chance of losing ore. (*b*) Mining is not so clean; more waste is mixed with ore. (*c*) Less sorting is possible in slices; grading of ore is more difficult. (*d*) Caving of overlying ground is not under such close control.

Factors of relative cost, percentage extraction, clean mining, and control predominate in making a choice. Top-slicing is better in very soft ground. It is used where its higher extraction produces ore rich enough to offset its higher cost, and where admixture of waste would lower the metal content of ore sufficiently to impair its market value. Under other conditions, sub-level caving is preferable. Block-caving is a possible alternative for sub-level caving (Art 82).

79. BLOCK-CAVING

General. Large sections (blocks) of the orebody, sometimes to a height of 400 ft or more, are successively undercut and allowed to slough and cave above the undercut portion. Drawing off the caved ore causes further caving, often aided and controlled as to its lateral extent by weakening the boundaries of the block by narrow shrinkage stopes or superimposed cut-off drifts. The ore caves and crushes by its own weight and weight of overlying capping into pieces of suitable size for handling. Caving usually extends eventually to the surface, the overburden settling as support of the underlying ore is removed. Drawing continues until appearance of overburden material at drawpoints indicates exhaustion of the ore. This method is a natural development of sub-level caving (Art 75–78), through gradual increase in height of ore caved in one operation. Some pillar-caving methods (Art 84–87) may be considered as varieties of block-caving. Following paragraphs presuppose a knowledge of details obtainable from Art 80.

Suitable orebodies are wide veins, thick beds, or massive deposits of homogeneous ore, overlain by ground which will cave readily. The ore must be such that it can be supported while blocks are developed and undercut, and will break up when caved. For other requirements and limitations, see Art 81. The chief field of use in the U S is in the Lake Superior iron districts and the "porphyry" copper mines.

Varieties of block-caving. There are 3 distinct forms: (*a*) Dividing horiz area of orebody into rectangular or nearly rectangular blocks, often square, drawing evenly over entire area to maintain an approx horiz plane of contact between broken ore and caved

capping. (*b*) Dividing horiz area of orebody into panels, either crosswise or lengthwise of orebody, retreating from one end of panel to the other and maintaining inclined plane of contact between broken ore and caved capping. (*c*) No division of horiz area of orebody into definite blocks or panels; undercutting may be from wall to wall, with retreat from one end of orebody to the other, maintaining inclined plane of contact between broken ore and caved capping.

Under (*a*), the Pewabic (Art 80) was the first used and is the type form from which other varieties of block-caving have been developed. Blocks were undercut on main levels and ore was handled by shoveling in drifts driven through the caved mass. Present practice in all forms of block-caving is to undercut on a sub-level, and draw caved ore through vert or branched chute-raises to tramway level below; these methods are called "block-caving into chutes."

Development must be suited to the characteristics of the orebody and form of block-caving used; typical examples are given in Art 80. Remarks in Art 70, 75, on modes of entry, and layout of main and sub-levels, for top-slicing and sub-level caving, apply in general to block-caving.

Size of blocks. (See Table 51). Ratio of ore broken by caving and by blasting depends chiefly on height of block; hence, high blocks are desirable; they also reduce cost of development per ton of ore. Max practical height depends on thickness of deposit, dip of orebody, and character of ore and capping; best guide is experience elsewhere under similar conditions. Among "porphyry" copper mines using block-caving, height of blocks has increased from less than 100 ft to over 300 ft in some cases; King (asbestos) mine, Quebec, has caved successfully blocks 400 ft high. As to horiz area, tendency of Miami Copper Co has been to reduce size of individual blocks; original practice of undercutting from wall to wall and retreating from one end of orebody to other was gradually modified to mining of blocks 150 ft square, largely to reduce maintenance of development openings. F. W. McClennan states (283) that size of block should be large enough to cause the ground to cave freely when undercut and small enough not to throw excessive wt on the extraction openings below; that is, it is a compromise between free caving and low maintenance cost. Such compromise is sought at some mines by caving in panels, where width of block may be 75–200 ft, but length determined by length or width of orebody.

Table 51. Size of Blocks in Block-caving (Details in Art 80)

Mine	Width, ft	Length, ft	Height, ft	Mine	Width. ft	Length, ft	Height, ft
Pewabic	200 (*a*)	200–250	100–125	Miami	150	150	300+
Menominee Range (*b*)	250	250	100	Inspiration	100 (*j*)	100 (*j*)	200 (*f*)
Tobin (Menom R) (*c*)	100	200	125	Ray	200	200	150–300
Mowry	65 (*a*)	180 (*d*)	150	King	160	160	400
Humboldt (above 350 ft)	150	(*e*)	30–100	Andes	110	132	175–250
Humboldt (below 350 ft)	112	200–400	100–180	Climax	....	....	400–600

(*a*) Width of orebody. (*b*) One mine. (*c*) Largest block caved up to 1912. (*d*) Length of orebody. (*e*) See Art 80. (*f*) Aver; varies 70–300 ft. (*j*) Usual size; for exceptions, see Art 80.

Timber mats for separating capping from caved ore are rarely feasible in block-caving. They may be formed as described in Art 70, but can not be built up nor repaired after caving begins (Detroit Copper Co, Art 80). Miami Copper Co tried block-caving under a heavy timber mat formed in mining upper part of an orebody by top-slicing (Art 70). The timbers reached the chutes before all the ore was drawn and had to be transported to surface; many timbers were blasted out of the chutes (601).

Extraction. Figures of percentage extraction attained in block-caving are necessarily based on estimates of original tonnage, assay value, and metal content in the caved area (collectively called the EXPECTANCY); hence, the accuracy of extraction estimates depends in part on accuracy in expectancy estimates.

See Sec 25 for methods of estimating tonnage and value of ore in place. In porphyry copper mines, drill holes (Art 10-b) and (or) underground workings supply data for sections from which expectancy estimates are made. At Miami, tonnage estimates are made from vert sections 25 ft apart and parallel to direction of the drawing operations; ore limits on these sections are obtained from sampling the final drift and raise development, of which there is an aver of 1 ft per 47 tons of ore in place. Assay value calculated from samples is reduced 10%, based on previous experience in checking actual against sampling values when mining large tonnages by top-slicing, where there was no dilution by waste (601). Practice elsewhere is similar.

There is less chance of error in determining actual tonnage extracted and its assay, as these figures are usually obtained by mechanical samplers and weighing devices at mills, and are accurate in total even if the distribution of tonnage to individual blocks or chutes is in error. Careful records of amounts drawn from chutes are essential, to permit calculations of position of the caved overburden and control its subsidence; for practice, see Humboldt mine below, and Miami mine, Art 80.

Figures for tonnage, grade (assay), and metal extraction are all required to give a clear picture of extraction. TONNAGE EXTRACTION is usually larger than tonnage expectancy, because in block-caving there is always some dilution by waste; for same reason, GRADE EXTRACTION is usually lower than grade expectancy. METAL EXTRACTION is the total metal in ore extracted; if the capping or walls of orebody are partially mineralized, metal extraction may be higher than expectancy, in which case grade extraction will be lower than expectancy. Correct figures for extraction by block-caving can not be obtained until sufficient area has been mined to give proper weight to clean ore from development openings and temporary pillars left over main and sub-levels, etc; in the porphyry coppers, final extraction is not determined until a section of the deposit has been bottomed.

Extraction results. Table 52 shows range of tonnage and grade extraction as experienced at Miami mine. From F. W. McClennan in 1930 (283).

Table 52. Extraction Results at Miami Mine (See Art 80 for conditions)

	Expectancy		Mined		Per cent extraction		
	Tons	Cu %	Tons	Cu %	Tonnage %	Grade %	Metal %
Total of 13 completed stopes....	11 038 070	1.0260	12 710 378	0.9124	115.15	88.93	102.40
Best original stope... .	998 016	1.0388	1 210 424	1.0091	121.28	97.14	117.81
Best pillar stope... ...	319 560	1.0640	387 827	0.9348	121.36	87.86	106.63
Poorest original stope .	1 071 535	0.8701	1 053 153	0.7786	98.28	89.48	87.94
Poorest pillar stope.	1 098 313	1.1067	1 025 032	0.8995	93.33	81.28	75.86

Note. Poorest pillar stope was 150 by 300 ft in plan; best pillar stope, 150 by 150 ft. Tonnage expectancy figures do not include narrow "partitions" between certain blocks. At the Ruth mine, Ely, Nev, the results of drawing 10 000 000 tons of ore show a metal extraction of about 87%, with a tonnage extraction of 104%; (data from Co officials in 1938.)

Ore drawing. Chief cause of poor extraction is dilution by waste during drawing; dilution depends largely on: (*a*) nature of ore, walls and capping; (*b*) spacing of draw points; (*c*) experience and care in drawing; (*d*) extent to which gob is consolidated in adjacent mined-out blocks. F. W. McClennan (283) gives following 2 principal objectives in drawing, saying that in practice a compromise between them is reached: (1) To draw a max ore tonnage with minimum dilution by waste capping, the ore should be drawn evenly, so that the contact between broken ore and broken capping will be an even plane, preferably horiz. (2) To regulate the drawing so as to avoid or relieve damaging weight on extraction openings below the broken ore, thus reducing maintenance and ore-drawing costs and interference with the predetermined order of ore drawing.

Theoretically, closely spaced chutes, from which ore is drawn carefully and evenly over a large area under a high block, should give min dilution and max extraction. In practice, the difficulty and cost of keeping drifts and chutes open in large drawing areas under caving ground generally precludes such plan. In block-caving in panels it is customary to undercut the ore in small sections, retreating from one end of a block to the other. The drawing area is bounded by the line across the block on which undercutting is being done, by the sides of the block, and by a line of chutes across the block on which the ore has been drawn to capping, or to the minimum allowable grade of diluted ore. Working thus, the contact between top of caved ore and overlying caved waste is kept as nearly a plane as possible, but the plane is inclined, not horiz, sloping at 30°–60°. Factors influencing slope are summarized by M. Mosier and J. Martin for HUMBOLDT MINE, Morenci, Ariz, as follows (600): A horiz contact is desirable to maintain a flow of clean ore through chutes with minimum dilution, but requires maintenance of a large area of tramming level to produce a given output, also large working capital. A nearly vert slope would minimize wt on drifts and cost of maintenance, but would increase dilution to an impossible max. Between these limits is an angle, which, while allowing moderate dilution, permits a caving area large enough to furnish the scheduled daily tonnage without excessive repair costs. Factors influencing choice of angle are: character of ground, method of caving, thickness of pillars between drawing points, grade and character of overburden, output required, and size of drawing area.

An aver slope of 60° was found best for conditions at Humboldt mine; if wt on workings grew excessive, the drawing area was reduced at times by steepening the slope to 70° (Art 87) Slope of contact between broken ore and waste ("angle of retreat") was calculated on the assumptions: (*a*) that during drawing, ore and waste traveled on vert lines; (*b*) that the relative sp gr of solid and broken ore measured the relative space occupied by each. In this case, the ratio between space occupied by solid and broken ore was 12: 20. Vert sections were made through each line of drawing points at right-angles to line of retreat; the theoretical results of drawing were plotted on these and the angle of retreat was measured. Position of capping or waste was known before undercutting and caving began. As undercutting proceeded and ore was drawn, room was made for the expansion of solid ore from 12 to 20 cu ft per ton; as drawing proceeded, this expansion reached the top of the ore. Further drawing caused the waste to move downward; assuming the movement to be vert, the amount of ore drawn from a line of chutes measured the distance through which the contact between ore and waste dropped. Experience at Humboldt mine proved that the "draw charts" so made were fairly accurate; waste appeared at the chutes very close to the expected time.

The drawing area in a block of given width is determined by distance between the toe of the waste-ore contact *A* (Fig 533) and the point *B*, at which undercutting is completed. If ore caves from the brow *BC* as fast as broken ore is drawn beneath it, the angle of the brow may also be controlled through regulated drawing. The brow may be vert or as flat as 30°, depending on character of ground and overburden and relative speeds of drawing and undercutting. A long overhanging brow may throw wt on adjacent workings; this is relieved, without decreasing the broken ore available, by driving a transverse shrinkage stope *S* (Fig 533) at front edge of the undercut area. If chutes under the brow are drawn more rapidly than ore will cave from the brow, an opening is formed through which waste flows from above. At Humboldt mine it was found that the sloping contact between broken ore and waste should not intersect the overhanging brow, else some ore at upper end of brow would be lost; depending on height of block caved, the distance *CD* should be 20–50 ft.

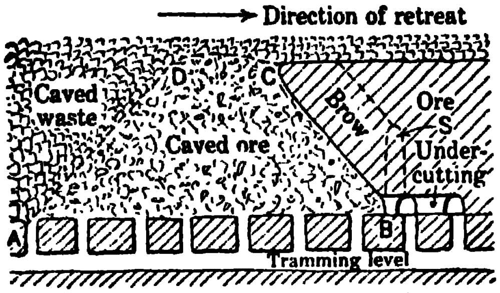

Fig 533. Humboldt Mine, Longit Vert Sec through Blocks (diagrammatic)

Models may aid in determining best methods of drawing; for tests made in 1913–14 for this purpose at Inspiration mine, see Bib (262). In general, a capping that breaks into fine particles gives lower extraction than one caving in large slabs. Finely crushed ore may give trouble by packing (especially if moist), or by channeling through to capping. For further detail, see Examples of practice, Art 80, 81.

80. EXAMPLES OF BLOCK-CAVING PRACTICE

Pewabic mine, Menominee Range, Mich. Data from E. F. Brown (299) in 1898 and R. B. Brinsmade (153) in 1911. This form of block-caving was the first attempted. Method was crude as to ore handling, but principles of caving apply in present practice.

A lens of hard siliceous hematite, about 2 000 ft long by 200 ft wide, and dipping 76° to 90°, was overlain by hard, horizontally bedded sandstone; walls were of slate. Block-caving was used in low-grade ore, constituting most of the deposit; blocks 200 to 250 ft long, 100 to 125 ft high and full width of the deposit were caved in one operation.

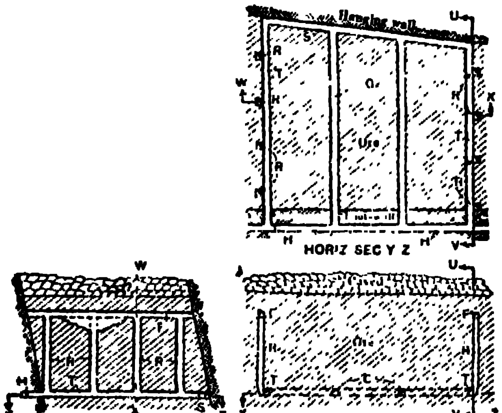

Fig 534. Development for Block-caving, Pewabic Mine

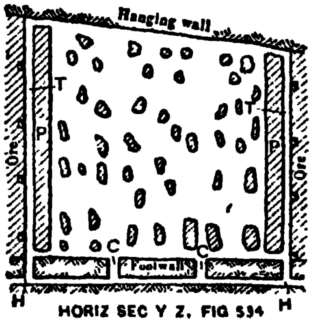

Fig 535. Pillars under a Block

The level interval was 100 to 125 ft. A main haulage-drift *H* (Fig 534) was driven in the footwall about 20 ft from the orebody. Crosscuts *T* ran to the hanging wall at the ends of the block to be caved; usually 2 intermediate and equidistant crosscuts *C* were run in a 250-ft block. The hanging-wall drift *S* aided ventilation. At 50-ft intervals along crosscuts *T*, raises *R* reached to within 20 ft of the level above, with crosscuts *F* connecting their tops. From crosscuts *F*, underhand stopes, 8 ft wide, were then opened from wall to wall and were carried down to crosscuts *T*. Thus both ends of a block to be caved were cut loose from the adjacent ore, except for a height of 20 ft at the top of the block

Meanwhile, a breast stope 7 ft high was carried across the bottom of the block from crosscuts *C*. Strong pillars *P* (Fig 535) were left alongside crosscuts *T*; elsewhere the block was supported on irregular pillars, made as small as was consistent with safety. None of the above work required timbering. Pillars were drilled with numerous holes and blasted out in sections. The block of ore was then free at the top and bottom, and was practically unsupported at its ends. A block took several weeks to settle 7 ft, after which the caved mass continued to "work" and crush itself; in 6 or 8 months, 80% of the ore would pass a 3-in ring.

After the ore was sufficiently crushed, timbered crosscuts *M* (Fig 536) were driven by spiling to the hanging wall from the stub ends of crosscuts *C*; drifts *D* were turned off from *M*, every 25 ft. Short crosscuts might also be driven at 25-ft intervals from nearest drift to hanging wall. Plats were laid at ends of drifts, ore was allowed to run in and was shoveled into cars. When waste appeared, a set or two of timber was blasted down and drawing resumed. Work retreated from the ends of the block to crosscuts *M*, which were kept open. Caved ore remaining between drifts *D* was recovered by driving and drawing a second set of drifts half-way between *D*; caved ore between crosscuts was drawn last. The work of developing and caving blocks was done chiefly during the winter months, when Lake navigation is closed; much ore was drawn from caved blocks during the summer.

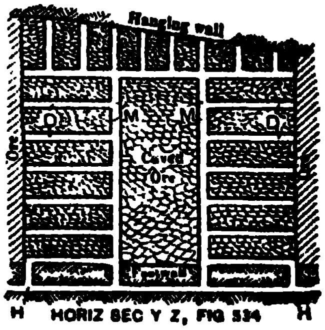

Fig 536. Extraction Drifts

Variations of Pewabic method differ mainly in details of undercutting the blocks and in the mode of isolating stopes. These features are indicated by practice in a large low-grade hematite deposit on the Menominee Range, as described by R. Meeks in 1907 (300).

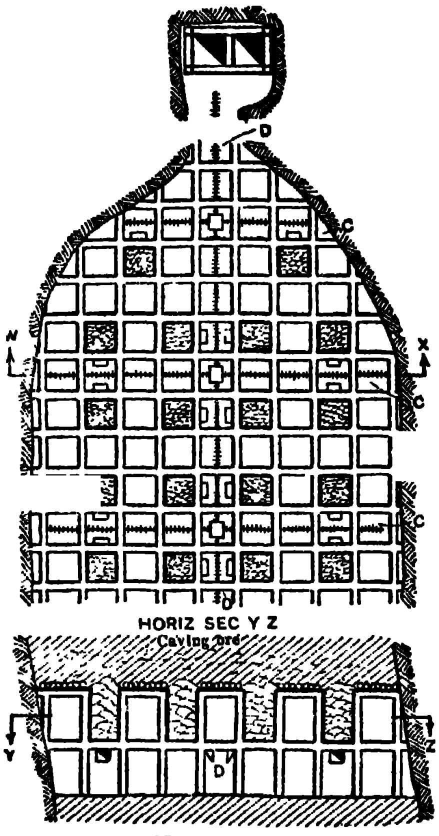

Fig 537. Block-caving into Chutes, Mowry Mine (153)

Main levels, 100 ft apart, were driven in the footwall. Ore was caved in blocks about 250 ft square by 100 ft high. The ore under a block was cut into pillars 30 ft square by drifts and crosscuts, 7 ft wide by 8 ft high. A narrow overhand stope was carried to the level above along both foot and hanging walls. Pillars were then removed in slices 8 ft wide, parallel to the strike. This work started in the pillars along the hanging wall and retreated to footwall; the back of each slice was allowed to cave before starting another. Caved ore was extracted as at the Pewabic mine.

This variation would be used where ore does not separate readily from the walls, or where the walls are irregular; more isolating stopes might be necessary at ends of blocks. Both open and shrinkage stopes have been used for isolating blocks; the former are preferred in the Lake Superior districts (286). This mode of undercutting blocks allows the use of timber for temporary support of ore too soft to stand when undercut, as in Fig 535.

Mowry mine, Ariz. Data from R. B. Brinsmade in 1907 (153). Argentiferous lead carbonate ores occurred in irregular steep-dipping pipes or shoots, on a granite-limestone contact. The ore was mostly soft and crumbly, with much clay, Fe_2O_3 and MnO_2. Fig 537 shows method of mining a shoot about 65 by 180 ft in horiz section. A vert shaft was sunk at each end of the shoot; at vert intervals of 150 ft, the shafts were connected by drifts *D*, from which crosscuts *C*, 25 ft apart, were driven to the walls. A square-set stope (Art 45), 2 sets high, was then opened over the entire area of the deposit. Tops of 1st-floor sets were lagged, numerous chute-gates were built in the sill-floor sets, and the sides of the 1st-floor sets over the chutes were lagged with 2-in plank. The lagging over the chute-sets was then removed and the overlying ore caved into them. By drawing from all chutes uniformly, the ore was caused to settle vertically, and distortion of the sets was avoided; some sets always required reinforcement (Art 51). Boulders which clogged chutes were blasted; occasional areas of siliceous ore, too hard to cave, were removed by carrying square-sets up to the soft ore above; 80% of the ore was caved. This is the simplest form of block-caving into chutes. It has a narrow

field of use, under rare conditions of ore occurrence. Mining is confined to one lift, though a new level can be prepared while caving the ore over the level above.

Tobin mine, Menominee Range, Mich. Data from F. C. Roberts in 1911 (208). A large, vein-like deposit of soft non-bessemer hematite was mined by block-caving into chutes, as shown diagrammatically by Fig 538 (see also Art 43). Level interval, 125 ft. A main haulageway *H* was driven close to the hanging wall, and crosscuts *C* were run 24 ft apart to the footwall under the block to be caved. A small ventilating drift *D* was driven along footwall. Chute-raises *R* (Art 67) were put up from alternate sides of crosscuts *C* at intervals of 15 ft to a sub-level, which was opened from them 25 ft above the back of the main level. Sub-level development consisted of the drift *M*, about 15 ft from the hanging wall, the crosscuts *N*, driven to footwall directly over crosscuts *C*, and a drift *S*, along the footwall. Raises *T* were put up at 45° from *M* to the hanging wall, and opposite each crosscut; they caused the ore to cave along a plane passed through them, thereby leaving an added thickness of solid ore to protect the main haulageway *H* (cross-sec *YZ*). The tops of chute-raises were then connected by drifts *P*, cutting the ore on the sub-level into pillars 10 by 16 ft, in strong ore, these pillars were cut in two by crosscuts *L* (vert sec *UV*). The ground at the ends of the block was weakened by raises *E*, from crosscuts *N*. Crosscuts *F* were driven 25 and 50 ft respectively above the sub-level. The number of raises *E* varied according to the ground. The tops of chute-raises were funneled, and numerous holes were then drilled in the pillars and blasted simultaneously, allowing block of ore above to drop. Through the chute-raise gates caved ore was drawn at as uniform a rate as possible over whole area of the block. Caved ore here contained but few boulders, which had to be blasted in chutes. Pillars between sub- and main levels were caved with the block below. Up to 1912, the largest block caved was 100 by 200 ft in horiz section. Very little timber was required. Main haulage-drifts were timbered with 3-piece sets; posts, 8 ft long and 12 to 15 in diam; caps, 10 to 12 ft long and 12 or 13 in diam. In crosscuts, 8-ft posts and 5-ft caps of 10 to 12-in round timber were used (301).

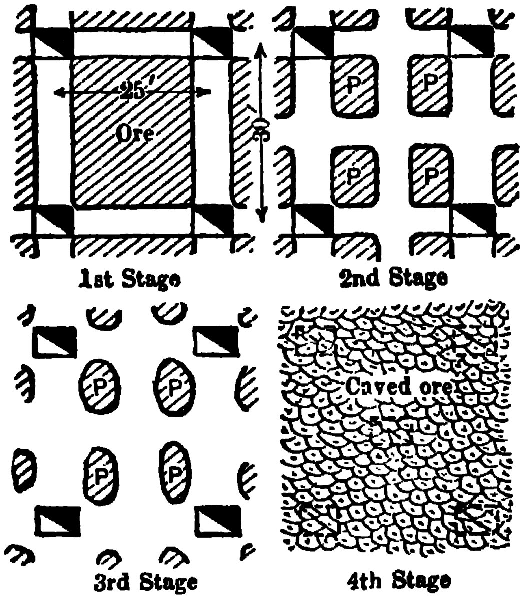

Fig 540. Stages of Work in Undercutting Sub-level Pillars, Morenci

ʳ **Detroit Copper Co, Morenci, Ariz.** (Part of Phelps Dodge Corp, in which work was suspended about 1923). Data from W. L. Tovote in 1910 (280). DEVELOPMENT. Main haulageways and intermediate hand-tramming levels were opened as for top-slicing (Art 73). Two-compartment raises, put up to the capping from the highest intermediate level, were 4 by 6 or 5 by 7 ft in section, and were at the corners of 30-ft squares or 25 by 30-ft rectangles. Sub-levels *S*, Fig 539, were opened as needed, by driving drifts *D* and crosscuts *C*. The vert interval between sub-levels depended on the ease and regularity with which the ore broke; it varied from 20 to 35 ft. CAVING began at one end of the orebody on the highest sub-level. Fig 540 shows the successive operations in any area. Drifts and crosscuts, driven through the pillars formed by sub-level development, subdivided each pillar into 4 small ones *P*, the sides of which were cut away as much as was safe. Ore in the sub-level floor was blasted out around the raises to a funnel shape as at *F*, Fig 539. Numerous holes were drilled in pillars *P*, and 8 to 10-ft holes, 2 to 5 ft apart, in the backs of all drifts. Timbers were removed from the raises overlying a section of a sub-level thus prepared, and all holes fired simultaneously. CAVED ORE WAS DRAWN through the original raises, and through inclined raises *R*, Fig 539, called "jigger-chutes"; these were usually untimbered, and the round that broke a jigger-chute through to caved ore was arranged to flare out its top. Some ore was shoveled on the sub-level to raises near the edge of the caved area. Drawing continued until a chute ran mostly waste. Occasionally boulders blocked the chutes and had to be blasted. GENERAL. Fig 539 shows block-caving on a sub-level 25 to 30 ft below the capping. Raises *T* would have been unnecessary if the contact between ore and capping could have been determined otherwise, but they were useful in weakening the ore before caving. At times (279) the top of an orebody was top-sliced (Art 73), until a heavy timber mat had been established. To secure the advantage of a mat in separating ore from waste, a large area had to be caved on a sub-level before any ore was drawn off, and drawing was done uniformly from all chutes. Even then the mat sooner or later broke up and timbers from it often clogged the chutes.

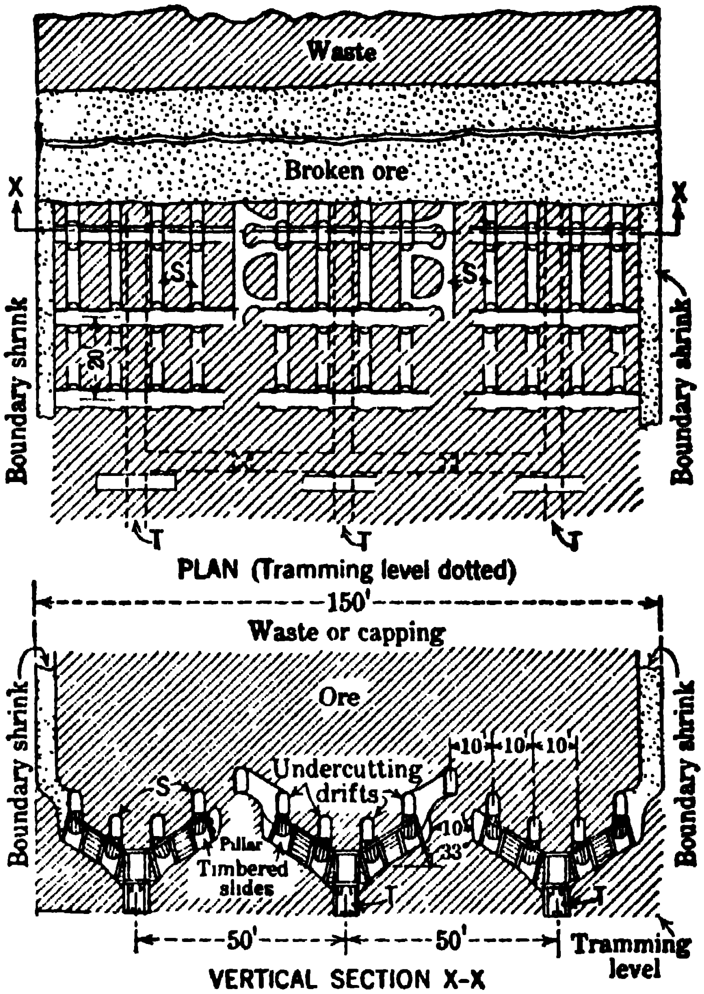

Fig 541. Block-caving, Humboldt Mine, Morenci, Ariz

Humboldt mine, Morenci, Ariz. (Part of Phelps Dodge Corp; work suspended in 1932). Data from M. Mosier and J. Martin in 1925 (600), and M. Mosier and G. Sherman (99) in 1929. Ore is chalcocite in porphyry, carrying about 1.9% Cu in area formerly mined by block-caving; orebody, 2 000 ft long, with max width of 600 ft and vert range of 1 000 ft. Ore is highly fractured in all directions, with fracture planes ⅛–18 in apart and recemented with quartz and pyrite; fracturing makes ground suitable for block-caving; permanent drifts and raises require timbering, but temporary workings usually stand well without timber. See Art 73 for other methods formerly used. Block caving in panels, 150 ft wide by 30–100 ft high, was used in upper 350 ft of the deposit (Fig 541). Hand-tramming drifts *T* were driven under the panel on 40 or 50-ft centers; from them, at 20-ft intervals, raises sloping 33° ("timbered slides") were put up, leaving a 10-ft pillar of ore between tops of slices driven from adjacent drifts (Sec *XX*, Fig 541). For detail of slide timbering, see Bib (600). Next, shrinkage stopes, at least 6 ft wide, were carried up on the ends and along sides of panel, except along boundaries next to worked-out ground. These were rill-face stopes, extending to about 8 ft below top of block to be caved; entry to them was from the ends of stope. UNDERCUTTING retreated from one end of the panel; drifts *S* were driven on 10-ft centers across backs of the slides; 8-ft holes were drilled in backs of drifts *S*; the 5-ft pillars between drifts were drilled; pillar and back holes in any section were fired simultaneously. Drawing. Practice was to draw so that the slope of the contact between broken ore and waste was about 60° (see Art 79 for detail). Block-caving into branched chutes was used later for lifts greater than 100 ft (Fig 542). Panels, 112 ft wide, extended 200–400 ft along the strike, each served by 2 haulage drifts *D*, 10 by 10 ft and 56 ft apart, running parallel with long axis of panel. From both sides of haulage drifts, chute raises, *R*, 28 ft apart, were driven at 75° to intersect the grizzly level, 50 ft above rail, at points 14 ft from center lines of haulage drifts. Grizzly drifts *G*, 4 by 6 ft, were at right-angles to haulage drifts, directly over and connecting tops of raises *R*. Grizzlies were symmetrically but unevenly spaced, certain pairs being 14 ft c–c, others 21 ft c–c. Alternate chute raises were funneled lengthwise of grizzly drifts, to accommodate 2 grizzlies 14 ft c–c, as at *H*. On opposite sides of each grizzly, 4 by 6-ft drift rounds were cut and, from these, small raises *F*, "finger raises," were driven to the undercutting level, 20 ft above grizzlies; finger raises were driven at angles to provide draw points 14 ft apart lengthwise of panel and about 19 ft apart crosswise. Tops of finger raises were belled out and widened to permit large boulders to be drawn well down toward grizzlies for convenience in breaking. Preceding undercutting, shrinkage stopes *S*, 6 ft wide, were carried up along vert boundaries of panels high enough to cut ore free from adjoining ground and guide the line of shearing; extent of shrinkage stoping accorded with judgment of operating staff in each case. Undercutting drifts *N* ("dog holes"), 4 by 6 ft, connected tops of finger raises laterally and longit, forming a grid of drifts and leaving rectangular pillars about 10 by 14 ft. Final step of undercutting consisted of drilling and blasting pillars and backs of undercutting drifts. In opening a new panel, it was

(*a*) Includes: (1) boundary shrinkage stopes; (2) undercutting; (3) belling finger raises; (4) chute tapping; (5) stope repairs; but excludes all development. (*b*) All shifts on payroll, including men on salaries. (*c*) Shifts charged to mining, including all labor, as mechanical, electrical, carpenter, and other surface departments occupied on work chargeable to mining.

necessary to undercut a length of 84–196 ft to start caving freely, even though the new panel might be against caved waste in a completed section. A distinctive feature of Morenci practice was use of 16-in grizzly openings instead of customary 10–12-in spacing; wider spacing was necessary because ore broke coarsely. Chute tappers wore safety belts as protection against falling through grizzlies. Blasting boulders at grizzlies and starting hung-up raises by blasting were done electrically for safety and to eliminate smoke from fuse. Chute-tapping effic was about 120 tons per man-shift. During initial stages of drawing, angle of retreat was about 60°; as stope extended, this angle was decreased to 50°, or to even less if weight did not interfere. Following rules were based on experience: (1) ore must be completely undercut; even small unbroken areas act as pillars causing excessive press at the grizzly level; (2) enough ground must be cut through in boundary shrinkage stopes to permit blocks to begin caving without delay after undercutting, but not enough to cause entire collapse; (3) press on grizzly level is resisted best by leaving as much unbroken ground as possible around grizzly drifts; this is done by making these drifts small and reducing number of finger raises to a minimum; spacing of finger raises is a compromise between requirements for good drawing, which prescribe close spacing, and need for controlling wt on development openings; (4) grizzly-bar spacing should be as wide as conditions of haulage and hoisting permit; chute-tapping labor is thus reduced and speed of drawing increased; (5) haulage raises should have enough storage capac to make ore-drawing and haulage independent of one another. Table 53 shows results for 1927 and 1928.

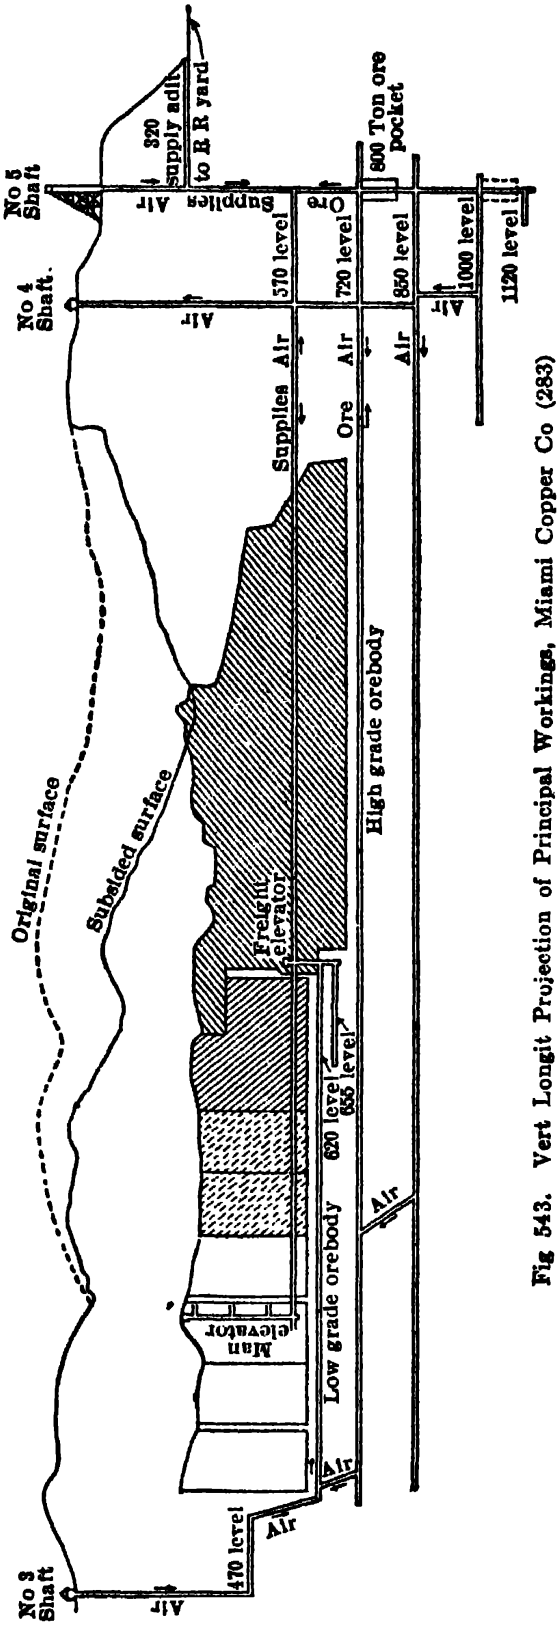

Fig 543. Vert Longit Projection of Principal Workings, Miami Copper Co (283)

Miami Copper Co, Ariz. Data from J. H. Hensley, Jr, in 1923 (601), G. W. Young in 1926 (593), and F. W. McClennan in 1930 (283). Mineralization consists of complete or partial replacement of primary cupriferous pyrite by chalcocite, usually occurring in seams and to a lesser extent disseminated through altered schist. Tenor is about 1% Cu. Orebody is a flat-lying massive deposit, with an area of about 50 acres and an aver thickness of about 200 ft, overlain by barren capping, 320 ft thick aver. GENERAL PLAN OF MINING. Early mining was by top-slicing, replaced later by shrinkage stoping with sub-level caving of pillars. Present method is block-caving. Caving practice at first involved undercutting and caving orebody across entire width (500–600 ft), starting at one end and retreating along length; drawing was planned to maintain plane of contact between broken ore and capping at angle of 40°–60° from horiz. This proved unsuccessful, because excessive wt was thrown on extraction openings, causing heavy maintenance costs and interference with orderly drawing. Later practice was to cave and draw alternate panels 150 ft wide, across entire orebody; a little later. when waste rock which had settled into original panels had consolidated, pillar panels were caved and drawn back across orebody; this was satisfactory with existing moderate thickness of ore, but was modified to caving on smaller blocks where thickness of ore was 300 ft or more. Original blocks were 150 by 300 ft, but experience indicated that blocks 150 by 150 ft gave best results, and this was made standard. Order of mining blocks is such that adjacent blocks are not

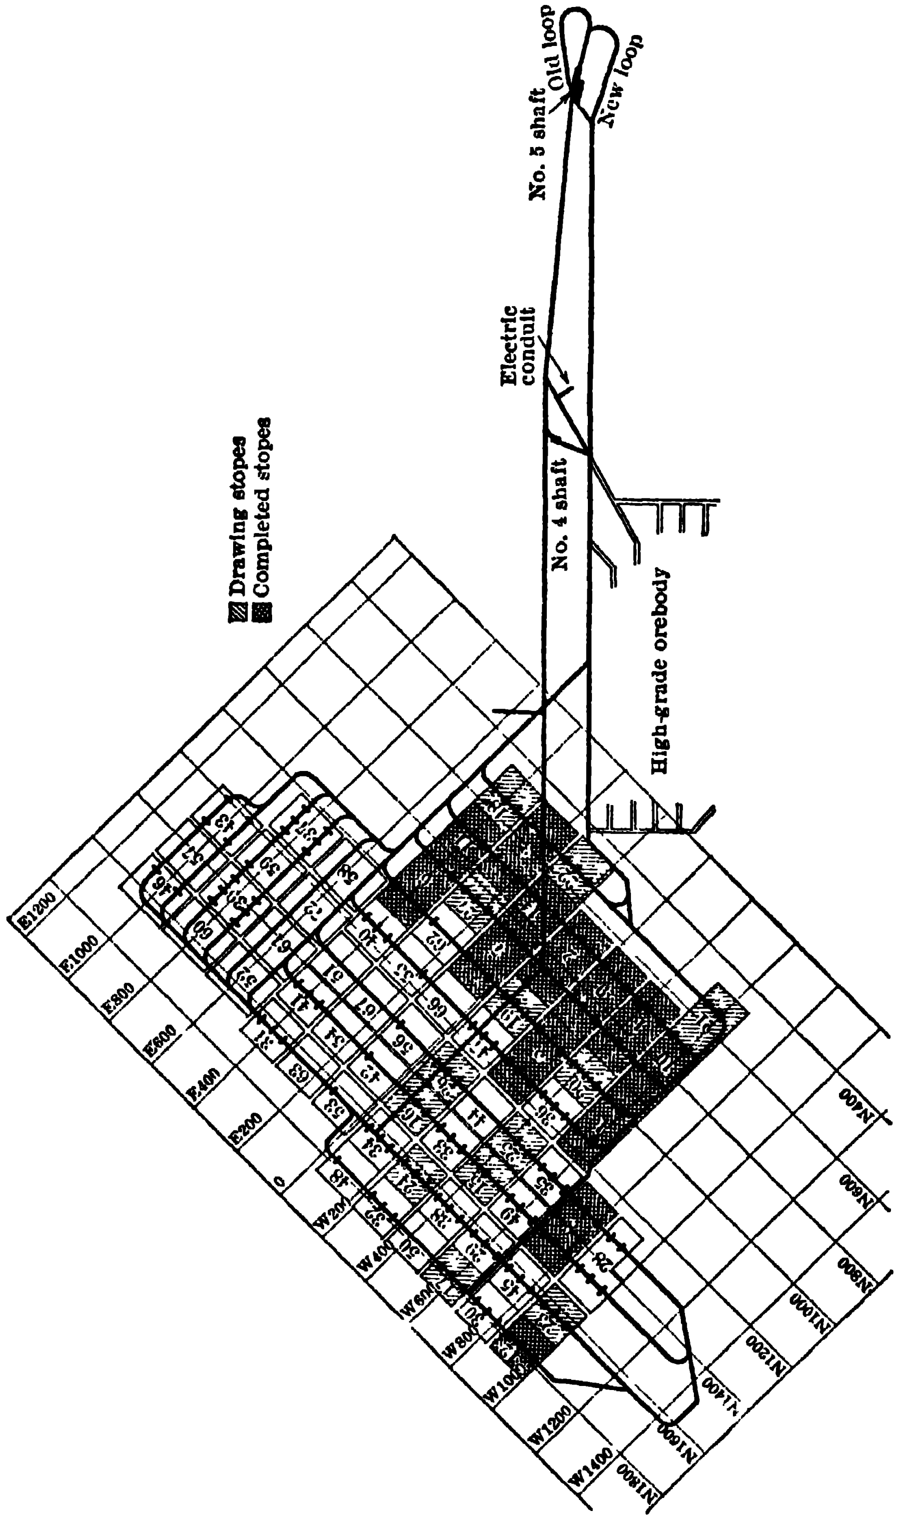

Fig 544. Plan of 720-ft Haulage Level, Miami Copper Co (283)

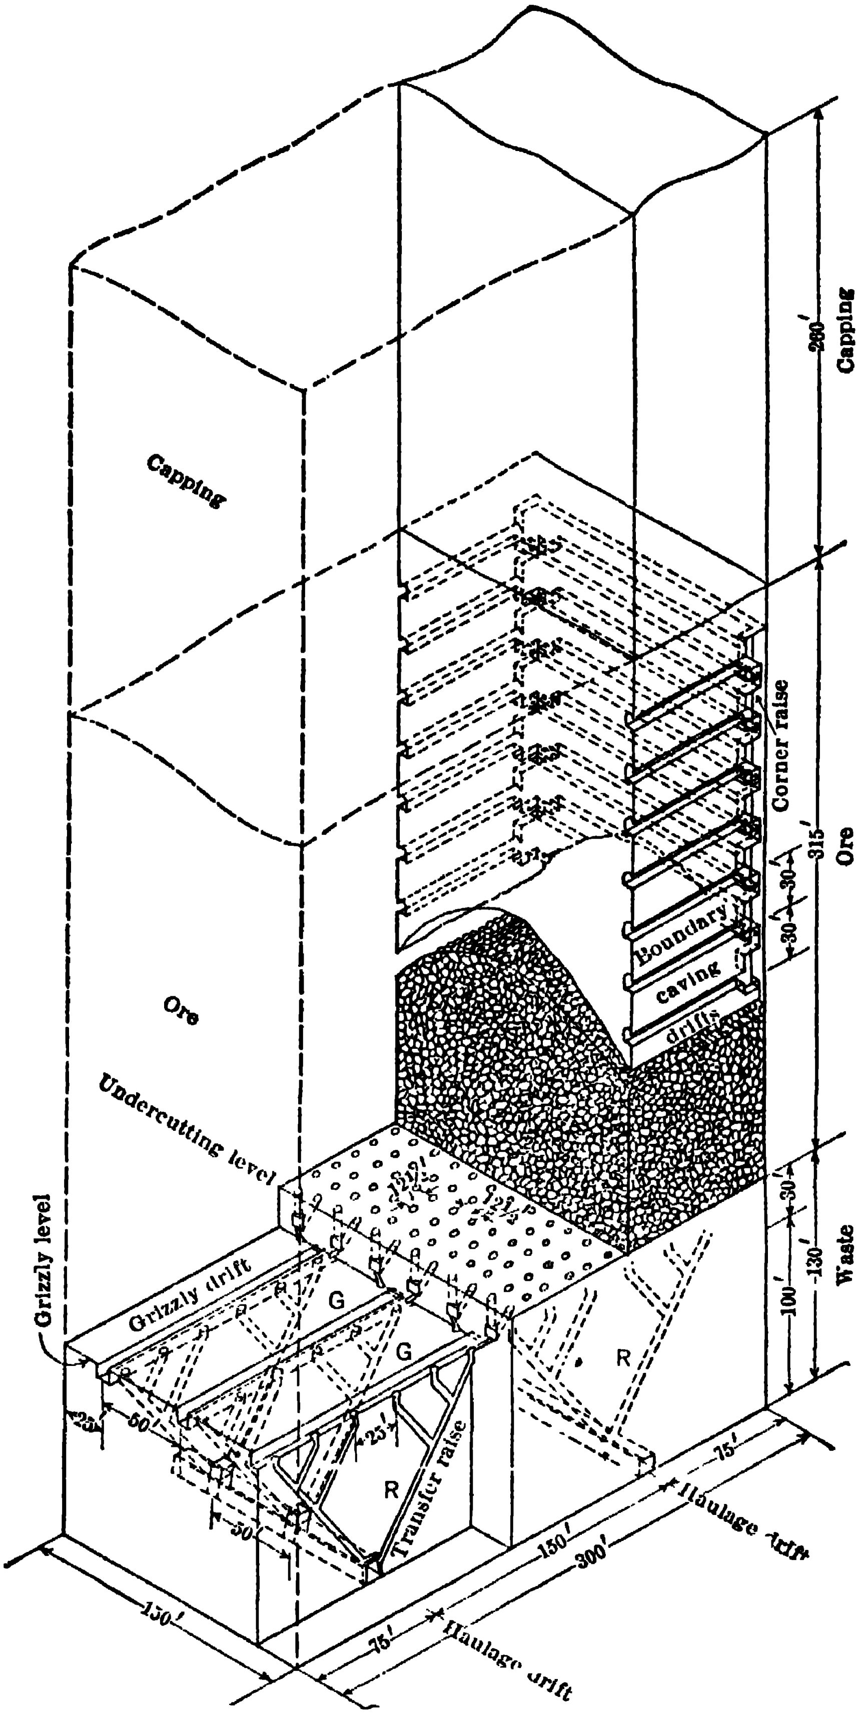

Fig 545. Isometric Drawing of Stope 150 by 300 Ft, Miami Copper Co

mined until waste fill along any boundary has consolidated for several months. Advantages claimed for block as against panel system in high lifts are: (1) min wt on extraction openings and hence min maintenance costs; (2) min dilution; (3) more working places, hence better standardization and higher production; (4) less congestion and delays on haulage level. DEVELOPMENT. Main entry is a 4-compt vert shaft sunk outside of ore-

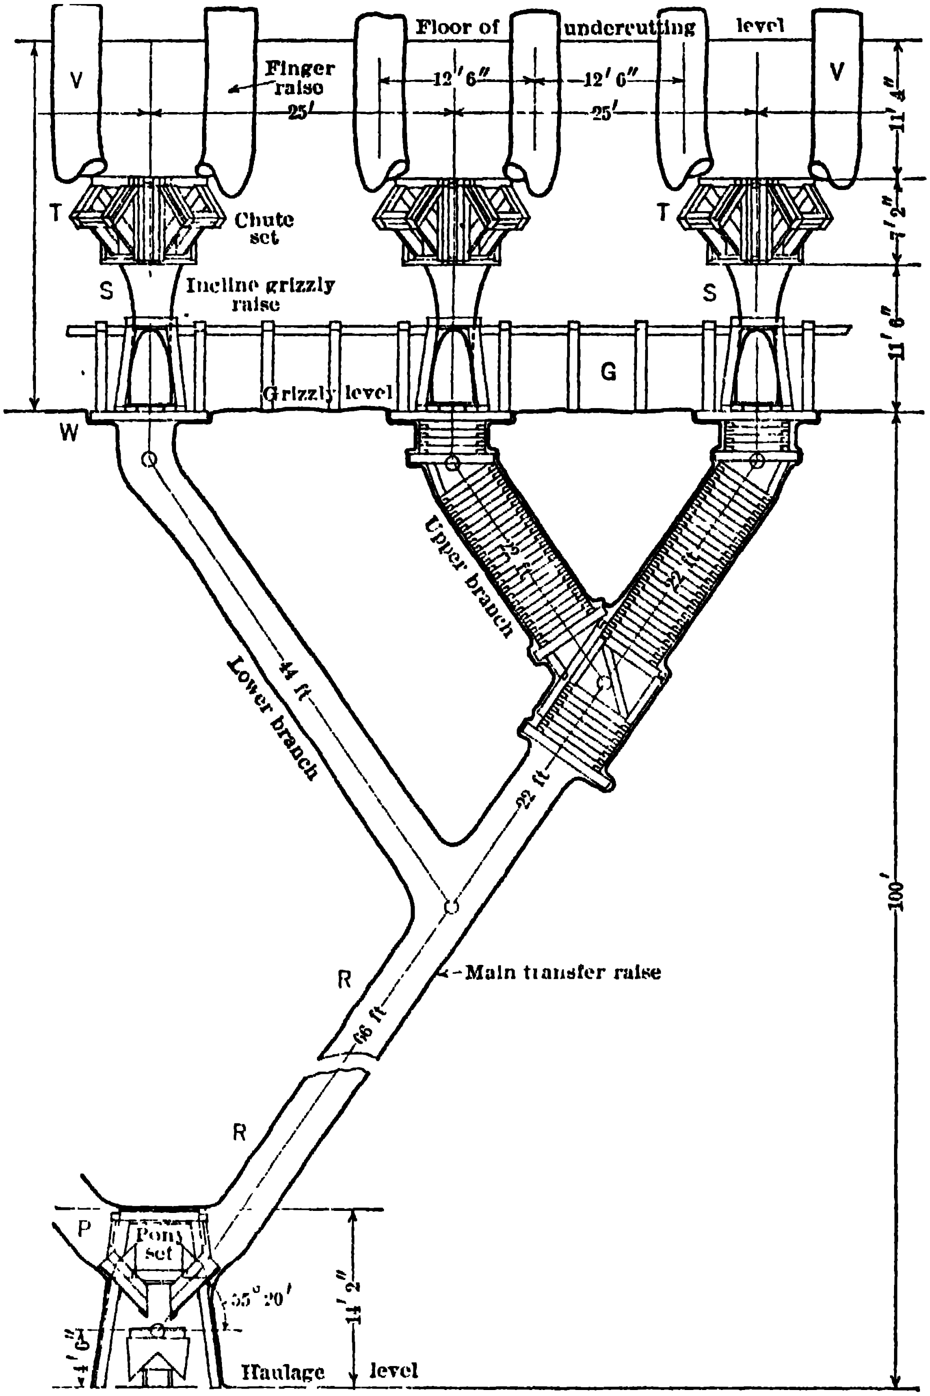

Fig 546. Vert Projection of Ore-transfer Raise System, Miami Copper Co (283)

body; 2 other shafts, beyond opposite ends of ore area, serve for ventilation. Fig 543 shows the shafts and spacing of levels. Ideal plan is to drive main haulage levels 130 ft below horizon of undercutting, with grizzly level 100 ft above haulage level. Grizzly level serves also as main supply level and ordinarily is connected to shaft. This procedure was modified above 720-level (Fig 543) only to take advantage of existing workings. Fig 544 shows development of 720-haulage level, in general, drifts are 150 ft c–c, timbered with

3-piece sets of 10 by 10-in, 6.25 ft c–c. Fig 545, 546 show development above haulage level. Sequence in preparing a stope 150 by 150 ft: Pony sets and chutes *P* (Fig 546) are installed at 3 points over the haulage drift, the middle one directly under center of the block; the others 50 ft on each side. Six transfer raises *R*, inclined at 55° 20′ above horiz, are driven at right-angles to haulage drift from both sides of the pony sets. At same time, 3 grizzly drifts *G* are driven at an elev 100 ft above and at right-angles to the haulage drifts, and vert over the transfer raises. Following the connection of the tops of transfer raises with grizzly drifts, grizzlies are installed over the raises. To avoid a large opening at tops of branch raises, a one-round vert winze cut *W* is taken from the drift bottom at the point where the raise will break through and a long drill steel is left projecting from center of the winze as a

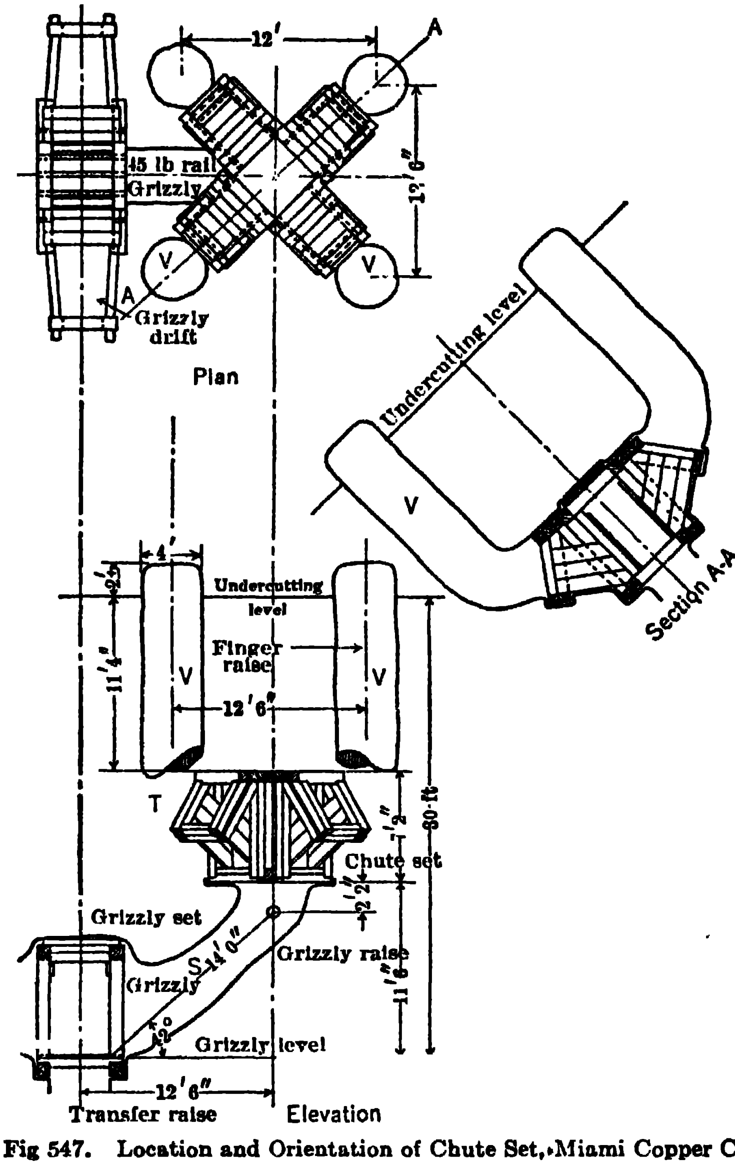

Fig 547. Location and Orientation of Chute Set, Miami Copper Co

guide in making the connection. Grizzlies are of 45-lb rails, placed crosswise of the drift and 12 in apart, supported on 10 by 10-in stringers. From the sides of each grizzly, a 3.5 by 3.5-ft raise *S* is driven at right-angles to the grizzly drift, inclined at 42° for a distance of 14 ft and thence vert for 10 ft (Fig 547). At the proper elevation, room is made for "chute set" *T*, which is carefully alined to assure proper spacing of the draw points above; chute sets are oriented at 45° with grizzly sets. Four finger raises *V*, 4 ft diam, are driven from the chute openings, inclined to a point 8.85 ft horiz from center of the set and thence vert to the undercutting level, 30 ft above the grizzly level. Drawholes are thus established 12.5 c–c over the entire horiz area of the block (Fig 545). **Undercutting.** Fig 548 shows procedure. Chute sets are numbered 1 to 36 and draw points lettered. Undercutting level is opened by driving 4 drifts *E* of small cross-sec,

parallel to grizzly drifts through every third line of drawpoints, 37.5 ft apart and equidistant each side of the central grizzly drift. These drifts are connected along both ends by "fringe" drifts *F*. In conjunction with undercutting, a narrow, vert shrinkage stope *G* is carried up 2 or 3 rounds along one end-boundary line (Fig 548) and usually advancing along the sides and other end of the block as undercutting progresses. To assist caving further and confine it to boundaries of the block, vert raises are driven at the 4 corners, and "boundary caving" drifts *H* are driven completely around block at vert intervals of 30–45 ft, depending on character of ground; bottom and back of drifts are usually drilled and blasted for added weakening. Undercutting begins by driving drifts *J*, 8 ft wide, at right-angles to the small "opening-up" drifts and directly over center-lines of grizzlies; it is completed by drilling and blasting the sides and backs of the drifts. Direction of retreat is diagonally across the block (Fig 548). Once started, undercutting proceeds as rapidly as possible. Tops of finger raises are funneled as undercutting progresses. Unless ore tends to pack, drawing is rarely started until stope is completely undercut. Table 54 gives data of typical stope preparation; Table 55, the development and preliminary stoping necessary each month to maintain production of 525 000 tons per mo from the part of orebody served by 720-level. Table 56 gives other working data and costs per unit and per ton for 1925–1928. ORE DRAWING. Objectives are: (1) to draw max of ore tonnage with min of dilution; (2) to minimize wt on extraction openings and thus reduce maintenance costs. Effort is made to maintain even, horiz plane of contact between ore and capping in individual stopes. As a guide, marker blocks are planted 25 ft apart in all boundary-caving drifts; the blocks are 12-in wooden cubes, marked with a

Drilling and blasting boundary, caving corner raises, per raise	68 439	87.407	0.00128
Total stoping			$0.03448(*a*)

(*a*) Based on extraction of 12 710 378 tons from stopes completed to late 1929, equivalent to 115.15% of tonnage estimated, the cost for development and stoping per ton of ore extracted would be reduced to $0.0905 and $0.0299 respectively.

countersunk copper tag, which shows the original elev of the block and the number of the chute over which it was placed. The blocks are large enough to be caught on the grizzly and their arrival shows the position from which the accompanying ore has come; also that the stope is caving to its boundary. Stope engineers inspect stopes daily and issue drawing orders. Tapping crew (blaster and helper) usually draws 12–15 finger raises per shift, blasting 5–8 times and drawing about 400 tons. Chute blasting is by elec caps and hand batteries. General plan is to draw chutes in rotation, but variation in routine may be required by: appearance of capping in a given chute; necessity of repairs; need of relieving wt on timbers; requirements as to grade of ore; need of proper distribution for economic operation of trains on haulage level. Drawing continues until grade drops below economic limit. Care is taken in measuring and recording tonnage from each finger raise. Measurement is by count of cars on haulage level, but accuracy requires close coordination between tapping of finger raises and drawing of transfer raises. To maintain daily production of 18 000 tons, 13 or 14 stopes must be in drawing stage, but production from stopes in initial or final stage of drawing is relatively small. EXTRACTION. Table 52 gives tonnage, grade and copper extraction from 13 completed stopes; terms "best" and "poorest" refer to relative combined results. COST DATA. Over 4-yr period, Oct 1, 1925 to Sep 30, 1929, aver tons produced per man-shift underground was about 27; timber consumed per ton, 1.045 bd ft; explosive (40% gelatin), 0.2225 lb per ton; for drawing alone, 19.7 tons of ore were drawn per lb of powder used; power consumed in mining department was 1.9 kw-hr per ton of ore. Mining costs per ton during same period were: development, $0.100; stoping, $0.136; electric haulage, $0.053; hoisting, $0.033; ventilation, etc, $0.021; general underground, $0.011; engineering and sampling, $0.014; mine surface, $0.020; mine accident, $0.011; total, $0.399.

Inspiration mine, Ariz. Data from A. C. Stoddard (642) and G. J. Young (655) in 1929; revised in 1939 by Co officials. Orebody is a large, irregular deposit of low-grade copper ore in fractured schist and granite. Ore minerals are chalcocite, azurite, malachite, and chrysocolla, largely distributed along fracture planes, but occasionally disseminated through ground mass. Length of mineable ore was given in 1929 as about 8 000 ft; aver thickness, 200 ft. Thickness of capping varies from nil to 500 ft. Since beginning operations all mining has been by caving. A method using a so-called "square-set control" was formerly employed (later practiced by Miami Copper Co). Procedure varied but following description of practice in 1919 illustrates general method. DEVELOPMENT. Haulage drifts were on 100-ft centers; as at present, they were 7.5 ft high, 9 ft wide at rail and 7.5 ft wide at cap, inside of timbers. Pony sets with chute pockets on both sides were placed 25 ft apart; from them inclined raises were driven to floor of grizzly level, 30–35 ft above. If untimbered, raises were from 3 by 3 ft to 5 by 7 ft; if timbered, 3 by 3 ft to 4 by 4 ft inside cribbing. Grizzly drifts were parallel to and 25 ft on both sides of center line of haulage drift. When untimbered, grizzly drifts were 4 by 6 ft to 5 by 7 ft; if timbered, sets had 7-ft posts and a cap to give 3.5-ft width at top. Grizzlies, of rails 10 in apart, were placed over each raise. From each grizzly, 2 raises were driven, one in each direction at right-angles to the drift. For the first 18 ft, these raises sloped 40°–42°; then turned vert to accommodate a 4-post square-set. From the square-set, 4 finger raises were driven to the undercutting level, 30 ft above the grizzly level, resulting in a spacing of one drawpoint for each 156 sq ft of area. UNDERCUTTING consisted of driving small drifts on 25-ft centers on undercutting level, with eventual drilling and blasting of intervening pillars. Above-described practice was often modified as to spacing of grizzly drifts and drawpoints; for example, in 1925, grizzly drifts were 42.5 ft c–c, each drawpoint controlling an area of about 133 sq ft. A disadvantage in the so-called "square-set" system of control was that men had to go above the level into the square-set to draw ore, making supervision of drawing difficult; also, maintenance costs were high. "GRIZZLY CONTROL" system was introduced to correct these faults and is still in use throughout the mine. Unit blocks are usually kept small, about 100 ft square, though some are 85 ft wide by 133 ft long, others 170 ft wide by 100 ft long. Spacing of the haulage drifts is a function of the distance from drifts to bottom of the ore; the less this distance the closer the spacing of haulage drifts. Length of block is determined by the area which, it is judged, will cave readily. A block may have 1 or 2 haulage drifts beneath it, each serving an area of which the width is a multiple of 16.6 or 17 ft, where capping overlies the ore. Where there is no capping, and a block to be drawn reaches to surface, there is no fixed multiple. Pony sets and chutes are installed 25 or 33.3 ft apart along the haulage drifts. Each of these distances is a multiple of a mine-car length, and allows cars to be loaded from one or more chutes with one spotting of train; the smaller interval is used where careful control of drawing is necessary, the larger, where careful control is unnecessary. From the pony sets, and on both sides of a drift, inclined raises *R* (Fig 549, 550), with branches, reach to the grizzly-level drifts *D*. The latter are 35–70 ft above and at right-angles to haulage drifts, and spaced to correspond with the raise interval along them. Grizzly interval along the grizzly drift is 16.6 or 17 ft, sometimes 21.25 ft, depending on the care demanded in control. From opposite sides of each grizzly, raises *S* are driven to a vert height of 18 ft above the grizzly level. At this elev, the tops of the raises are spaced at the grizzly interval in one direction; while at right-angles the spacing is alternately 14 ft and 11 ft, when the grizzly drifts are 25 ft c–c; increased proportionately when these drifts are farther apart. The lesser distance is always between the tops of the 2 lines of raises in the pillar between 2 grizzly drifts. Undercutting drifts *T* are driven at right-angles to the grizzly drifts and over the line of raises from them. Their spacing is therefore the same as that of the grizzlies, and the pillar between adjacent drifts is approx 5 ft narrower. Crosscuts *V* are driven as necessary. Undercutting is started from the corner of a block, if possible from a corner having unbroken sides, and is finished at whatever point may be safest. It is done as rapidly as possible, and is carried horiz in the plane of the undercutting drifts. Drawing is controlled at the grizzly level, the raises being drawn equally to bring the caved ore mass down evenly. During 1938, ore was mined at rate of 21.86 tons per man-shift chargeable to mining. Timber consumption, 1.164 bd ft per ton; powder, 0 128 lb per ton.

Ray mine, Ariz. Data from R. W. Thomas (294) in 1929, confirmed by Company officials as substantially representing practice in 1938. Orebody is a disseminated-copper deposit in quartz-sericite schist; chalcocite is the predominant ore mineral. Shape is irregular in plan and section; length, about 7 000 ft; aver width, 1 500 ft; thickness, 40–400 ft. Capping is 40–600 ft thick, aver about 250 ft. In caving, ore breaks coarser than at most mines using caving system. Timbering is required for all permanent openings. DEVELOPMENT comprises 2 vert ore-hoisting shafts, 2 inclined shafts for supplies and waste, and 1 vert shaft for men. There are 4 main haulage levels, 150 ft apart, as made necessary by shape and dip of orebody. MINING METHODS. Ray mine was first in the Southwest to use large-scale caving. Recent practice is the result of evolution from original shrinkage-stope and pillar-caving (Art 85). Fig 551 shows block caving, as used

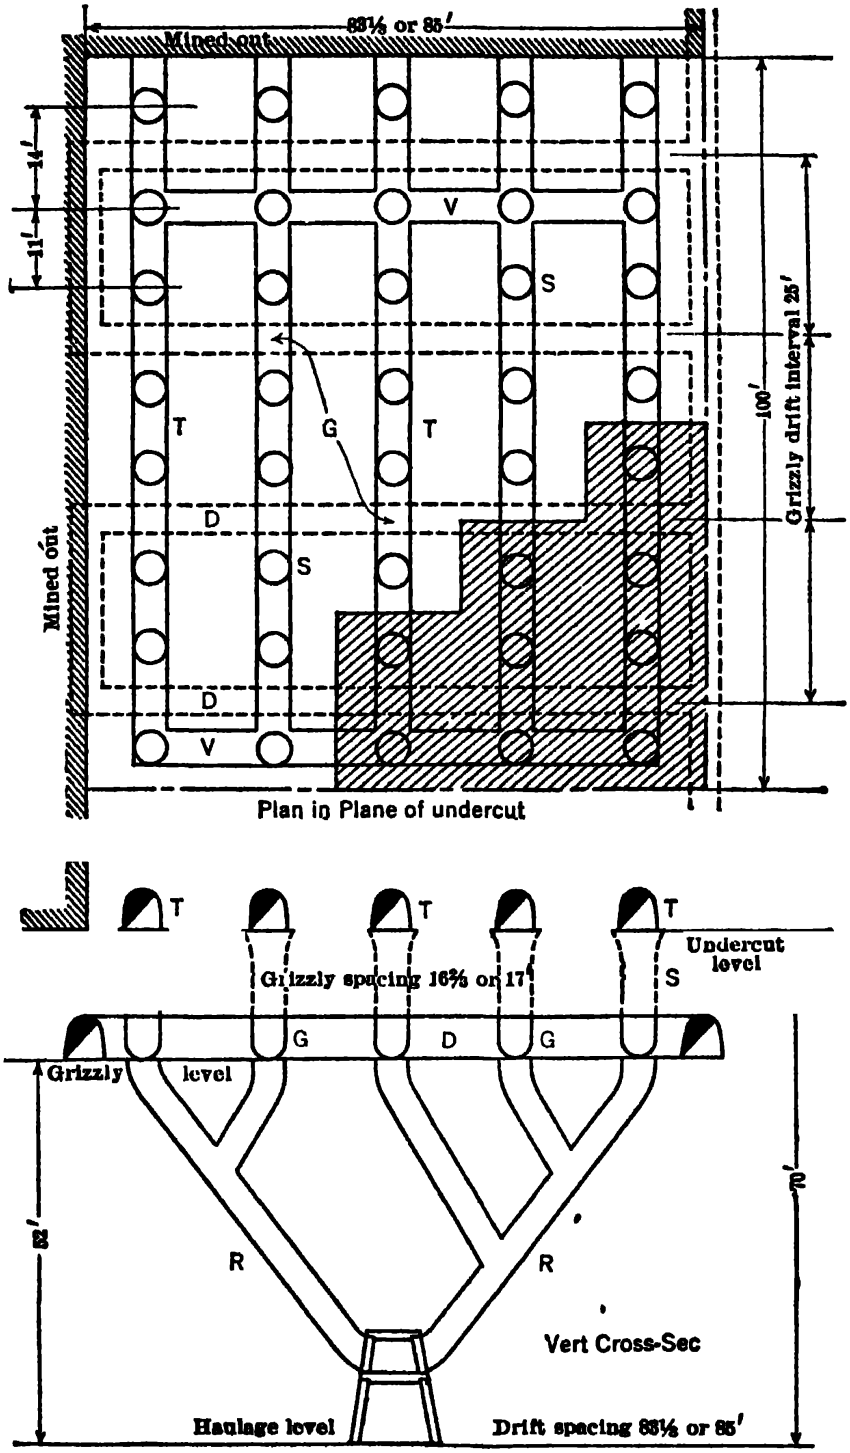

Fig. 549. Block Caving, Inspiration Mine, Ariz. Max haulage-drift spacing for highest ore horizon

where height of ore is 150 ft or more above haulage level. Panels, 200 ft wide, are developed by 4 motor-haulage drifts *D*, 50 ft c–c. These drifts are 7 ft high by 7.5 ft wide, inside timbers. From each side of them, chute raises *R* are driven 25 ft apart to grizzly level, 40 ft above rail. The raises are inclined so that grizzlies will be 25 ft apart, crosswise of panel, but staggered symmetrically as to those in adjacent drifts; they are

4 by 4 ft if untimbered, or 4 by 4 ft inside cribbing if timbered. Grizzly drifts *G* ("laterals"), 3.5 by 5 ft, are run over center lines of chute-raises at right-angles to haulage drifts. Grizzly bars have 13-in openings. "Fringe" drifts connect the laterals along panel boundaries. The ends and sides of a stoping block are "cut off" by shrinkage stopes *S*, about 10 ft wide, which are carried to the capping or to a previously mined area above. These stopes, obviously unnecessary on sides adjoining mined-out sections, are usually mined in 2 lifts, the upper section being mined first and the shrinkage ore hand-trammed to transfer raises. Development for undercutting starts by driving "throat raises" *T* from each side of each grizzly, so that, on reaching a height of 7 ft above top of

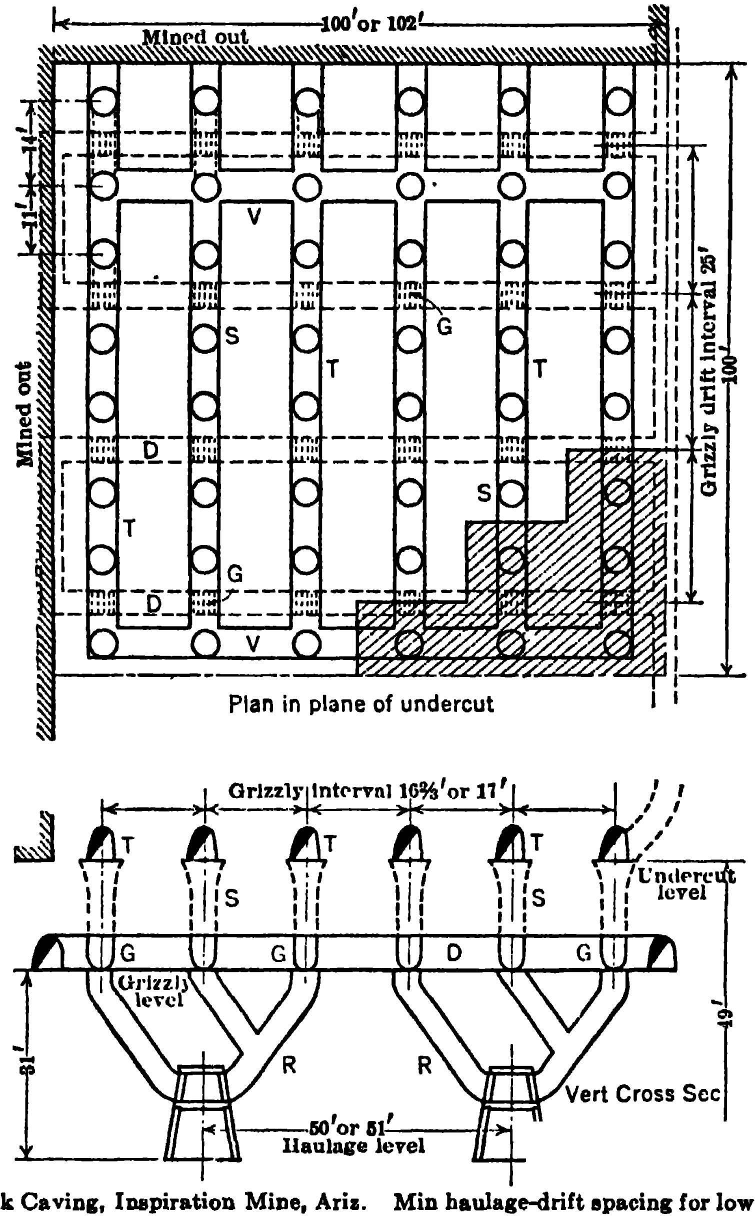

Fig 550. Block Caving, Inspiration Mine, Ariz. Min haulage-drift spacing for lowest ore horizon

grizzly set, they are on 12.5 ft c–c lengthwise and crosswise of panel, but staggered as in Fig 551. From these points, 45° raises are driven parallel to grizzly laterals until connected with similar raises starting from tops of adjacent throat raises. Ground between diverging raises and above throat raises is blasted down to give a flat-backed, saw-tooth slot *W*, 4 ft wide, across the entire block; the center line of each slot becomes the center line of a shrinkage stope. Alternate stopes are termed "undercut stopes" *U* and "pillar stopes" *P*; the former are carried to height of 40 ft above tops of grizzly sets; the latter, to 32 ft. Stopes *U* are widened toward top, so that the final round, breaking a width of about 18 ft, completes the undercut between stopes *U* and *P*. Undercutting is carried on progressively from one end of block to the other, followed by drawing on a limited scale. This gradually removes support from under the main mass of ore and sets up cantilever action, causing ore to slough and break up. Uniform drawing starts after block is completely undercut.

Ruth mine, Nevada Consol Copper Corp, Ruth, Nev. Data kindly furnished by W. S. Larsh, Asst Gen Mgr, in 1938. Orebody of disseminated chalcocite and chalcopyrite in monzonite porphyry is oval in plan; major axis, 2 400 ft; minor axis, 1 200 ft; aver thickness, 190 ft; aver dip 15°. Formations overlying orebody, some of them oxidized capping, are 110 to 1 000 ft thick. Ore and inclosing sedimentary rocks close to the contact are soft and heavy; some swelling ground. After trying several methods, a form of block-caving, known locally as "BRANCH-RAISE CAVING," was adopted. DEVELOPMENT. Haulage drifts are driven below the orebody at such intervals that 50° inclined raises from them will reach bottom of orebody at an aver of 60 ft vert above the level floor (min distance, 40 ft; max, 80 ft), which has been found the most economical height. The raise systems are spaced 25 ft apart along the haulageways and run at right-angles to them. Branches from the main raise are designed to reach bottom of orebody at 12.5-ft intervals (Fig 552). To start a raise, pony sets *P*, Fig 553, 5 by 6 ft and 6.5 ft apart, are erected over the drift. From them the main legs of raises *R*, and the branches from them, are driven on a 50°–65° incline. Near top of main raise and its branches, a curve brings

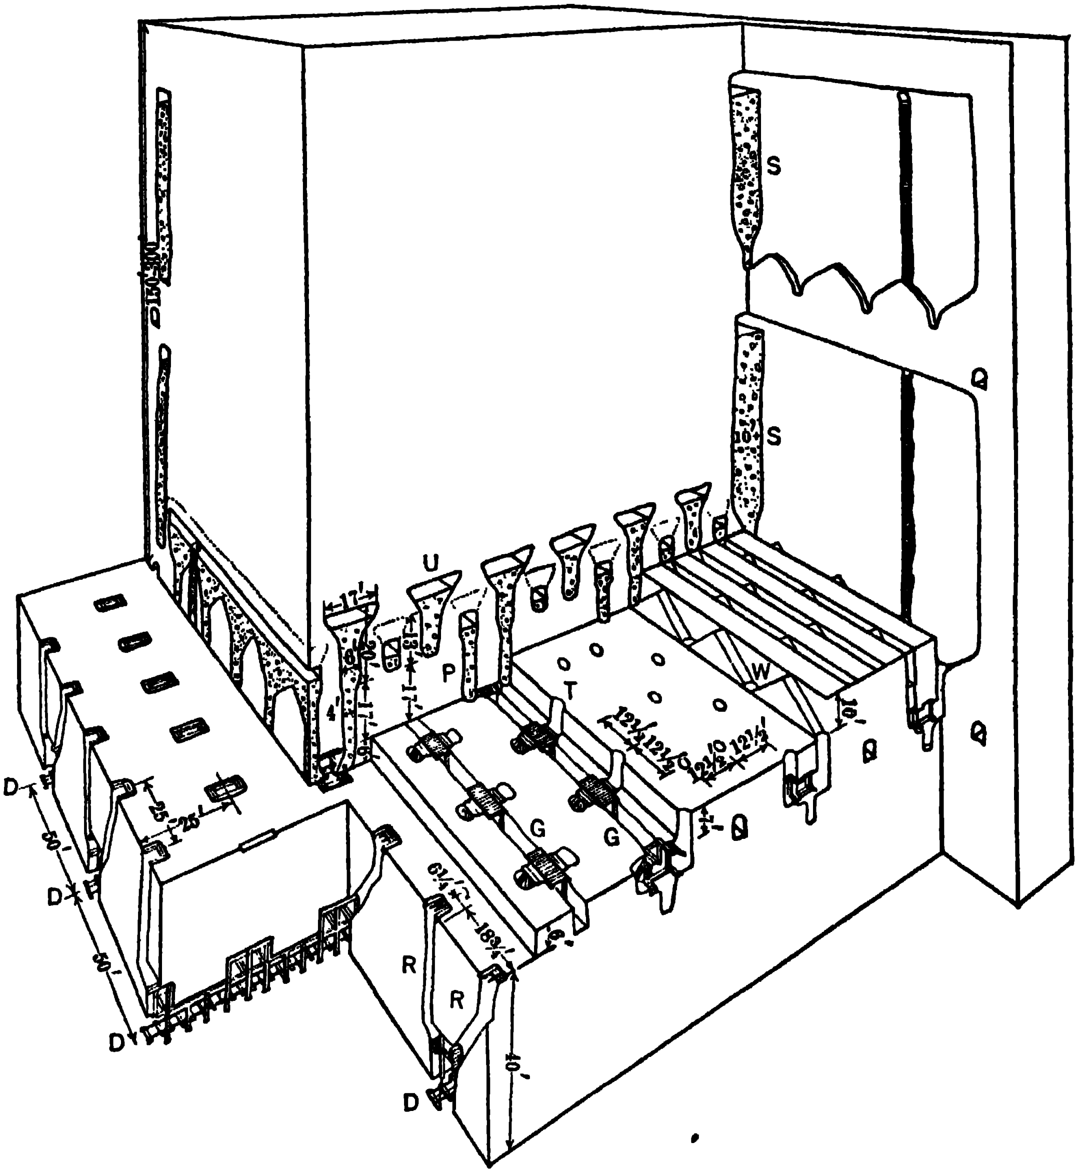

Fig 551. Sublevel Undercut Caving Method, Ray Mine, Ariz (294)

them to the vert when they are finished. Raises have 2 by 3-ft manways and 3 by 3.5-ft chutes, with 4-in dividers; cribbed with 4 by 12-in or 6 by 12-in timber, with about a 2-in spacing. A square-set, *S* Fig 553, is erected at top of each branch and 2 finger raises *T*, Fig 554, are put up from each square-set at right-angles to the plane of the main raise, their tops being spaced 12.5 ft c–c. Finger raises are 3.5 ft square inside 6 by 12-in cribbing. Plank gates are put in the square-sets; a grizzly *G* of old rail is laid with 10-in spacing in each square-set over the chute compt of each main raise; steel arc-gates are placed in the pony sets at the level. The plane or slightly warped surface connecting the tops of the fingers is the "draw" level, although no level exists there. Caving. Small drifts *D* (Fig 552, Sec *B-B*) are driven over the tops of finger raises and connected by crosscuts over alternate branch raises; pillars are then blasted. Undercutting is done in panels and enough area must be undercut to start the cave; after which, crosscuts are run to the cave, and the intervening pillars blasted. If the ground is too heavy to permit undercutting drifts, as much of the work as possible is done from tops of the finger raises. After the draw from the fingers is about half completed, board gates are put in the other 2 sides of the square-set, but no finger raises are driven. Drawing is done carefully; the "expectancy" of each draw set is charted and a model made showing the estimated position of the capping. The amount to be drawn from each finger raise is determined by the engineering staff, which furnishes "draw sheets" to each shift. Drawing is calculated to keep the contact between broken ore and capping on a 30°–40° slope. Chute tappers and draw bosses estimate the amount drawn from each finger; these estimates, reported to the stope engineer, are adjusted to balance against the number of motor-hauled cars drawn from main raises; adjusted figures are applied to charts and model daily. The ore drawn from each finger raise can not be measured precisely, but differences between estimates and actual number of cars loaded are not great and tend to compensate. The chute tappers become adept in making the estimates, being materially aided by the standard size of the raise cribbing. Extraction. Figures on about 10 000 000 tons are about 87% of the copper and 104% of the tonnage. The draw level

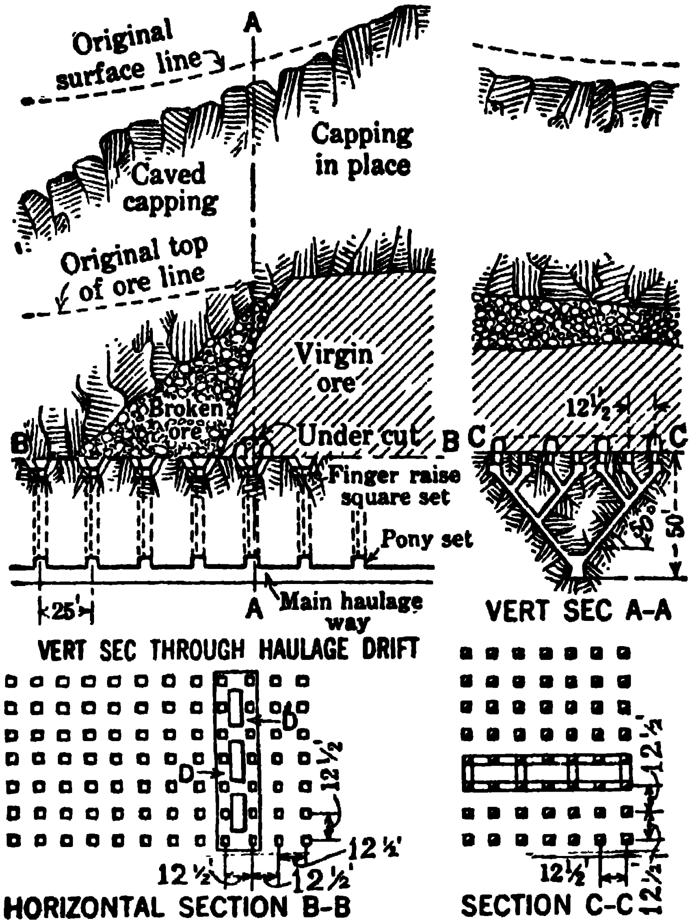

Fig 552. Block-caving, Ruth Mine, Ely, Nev (diagrammatic)

is placed at the bottom of the ore as nearly as possible, and the whole orebody taken in one lift. Better results in extraction are obtained in drawing over a fairly large area than in a high narrow orebody, as the ore has a better chance to cave. Drawing too rapidly causes chimneys (channels) to run through to the capping (always to be avoided).

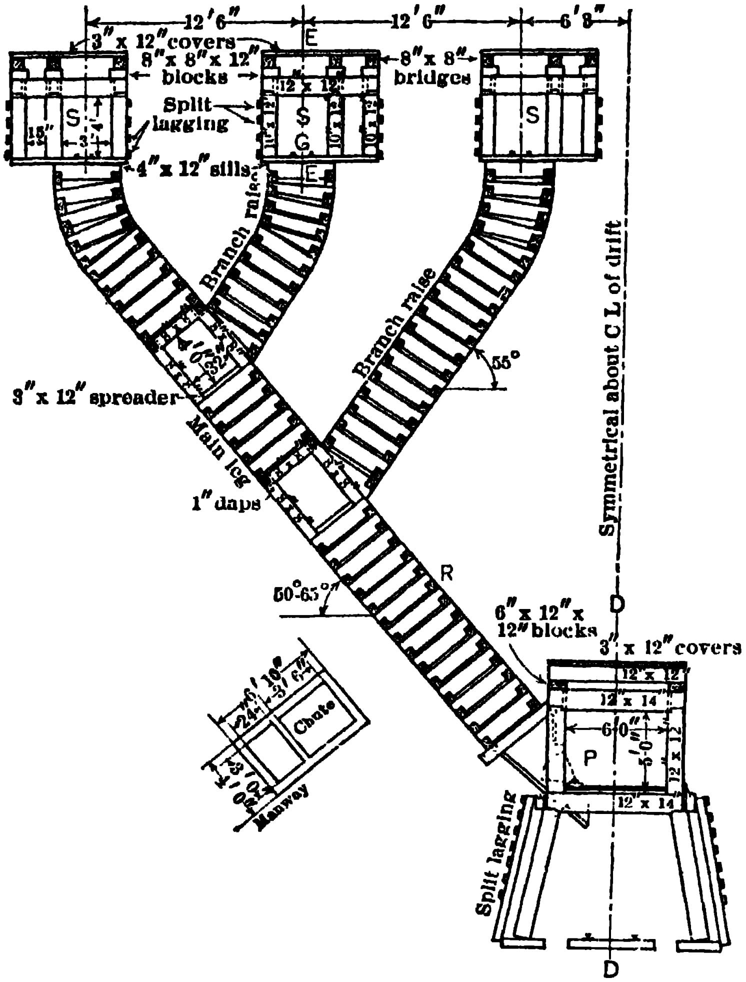

Fig 553. Raise-chute System, Ruth Mine, Nev

King mine, Quebec. Data from J. G. Ross and others of Co staff (250) in 1934 and 1936. Asbestos occurs in a large mass of highly fractured serpentinized peridotite and also in small veins or as fibrous development on slippage planes. Original mining was by open-cut (Art 96). First underground mining was by shrinkage, later replaced by sub-level stoping. Block-caving was finally and successfully adopted. There are 2 unusual features: (*a*) proximity of property boundaries, R Rs, and buildings requires avoidance of subsidence in the area surrounding the ground being mined; (*b*) detrimental effect of wood fiber in final product precludes use in mine of wood in any form. Subsidence problem is solved by mining in blocks (160 by 160 ft) rather than panels (see Miami Copper Co, above), and keeping subsided area filled with dry mill tailings, of which much had been accumulated nearby (Fig 555). Following methods avoid use of wood: (1) 6-in and 8-in H-beams are used for drift sets, with steel plate or old rails for lagging; (2) steel track-ties; (3) ore chutes and ladders are all-steel; (4) head blocks for drill columns are of strips of rubber belting clamped or riveted together; (5) wedges are of a composition of hard rubber and asbestos; (6) tamping sticks are copper tubing with copper plug in one end; (7) picks and shovels have metal handles; (8) metal survey plugs; (9) workmen are supplied with lighters, no matches being allowed in the mine; (10) dynamite is transported into mine in waterproof canvas sacks. **Development.** Haulage drifts are on the 500-ft level. Each block, 160 by 160 ft, is served by 2 parallel 8 by 9-ft drifts, each 40 ft from center line of block (Fig 556). Grizzly level is 45 ft above haulage level; undercutting level, 20 ft above grizzly. Grizzly drifts are parallel to haulage drifts, on 40-ft centers, spaced symmetrically with haulage drifts. Grizzly drifts are lined with sets of 6-in H-beams, 2.5 ft c–c, lagged with scrap rails 1 ft apart. Whole structure is concreted flush with inside faces of posts and caps, leaving a section 6 ft high, 3.5 ft wide at bottom, and 2 ft at top. From each side of haulage drift 4 chute raises are driven 40 ft apart and inclined at 55°. At a point 20 ft from chute, each raise branches 2 ways, to cut grizzly drifts at 20-ft intervals. Thus, grizzlies are 20 ft c–c in direction of drifts and 40 ft c–c at right-angles to drifts. Grizzlies are of 80-lb rails on 6-in steel H-beam sills, with 16-in slots 4 ft long across the grizzly drift. From each side of the 32 grizzlies in a block, a raise is driven to a point 20 ft above grizzly level and 10 ft from center line of grizzly drift. Thus, draw-points are 20 ft c–c in 2 directions over entire area of block. At each of 4 corners of block, 6 by 6-ft vert raises are driven almost to surface. Boundary-caving or cut-off drifts, 4 by 6 ft, are driven entirely around the block at 40-ft vert intervals. Before caving starts, the drift backs are drilled and blasted with 3 vert 7-ft holes 4 ft apart. **Undercutting** level is opened by eight 7 by 7-ft drifts parallel to the grizzly drifts and above the draw raises; 8 by 8-ft drifts are driven across the ends of these drifts, along the 2 opposite sides of the block at right-angles to the grizzly drifts. Backs and walls of undercutting drifts are drilled with fan-shaped rings of 7-ft holes, 3 ft apart. Each underlying draw raise is drilled so that, on blasting, it will be cup-shaped rather than conical; this permits large boulders to settle nearer grizzlies, where they are more readily drilled and blasted. Starting in a corner of the block, undercut drifts and underlying raises are blasted in areas 40 by 40 ft, in diagonal retreat toward opposite corner. Drawing starts after finishing undercutting. Before caving starts, markers (numbered steel plates) are distributed at regular intervals in the fringe drifts. As these are recovered in drawing, the dates and positions are recorded, to serve as a guide to determine how close to the proper limits the

caving action has reached. Caving follows fringe drifts closely, and back-filling keeps subsidence within anticipated limits. It is stated that it would seem practicable to cave from a depth of at least 600 ft within 20 ft of a property boundary without disturbing the area beyond it, provided backfilling is adequately supplied.

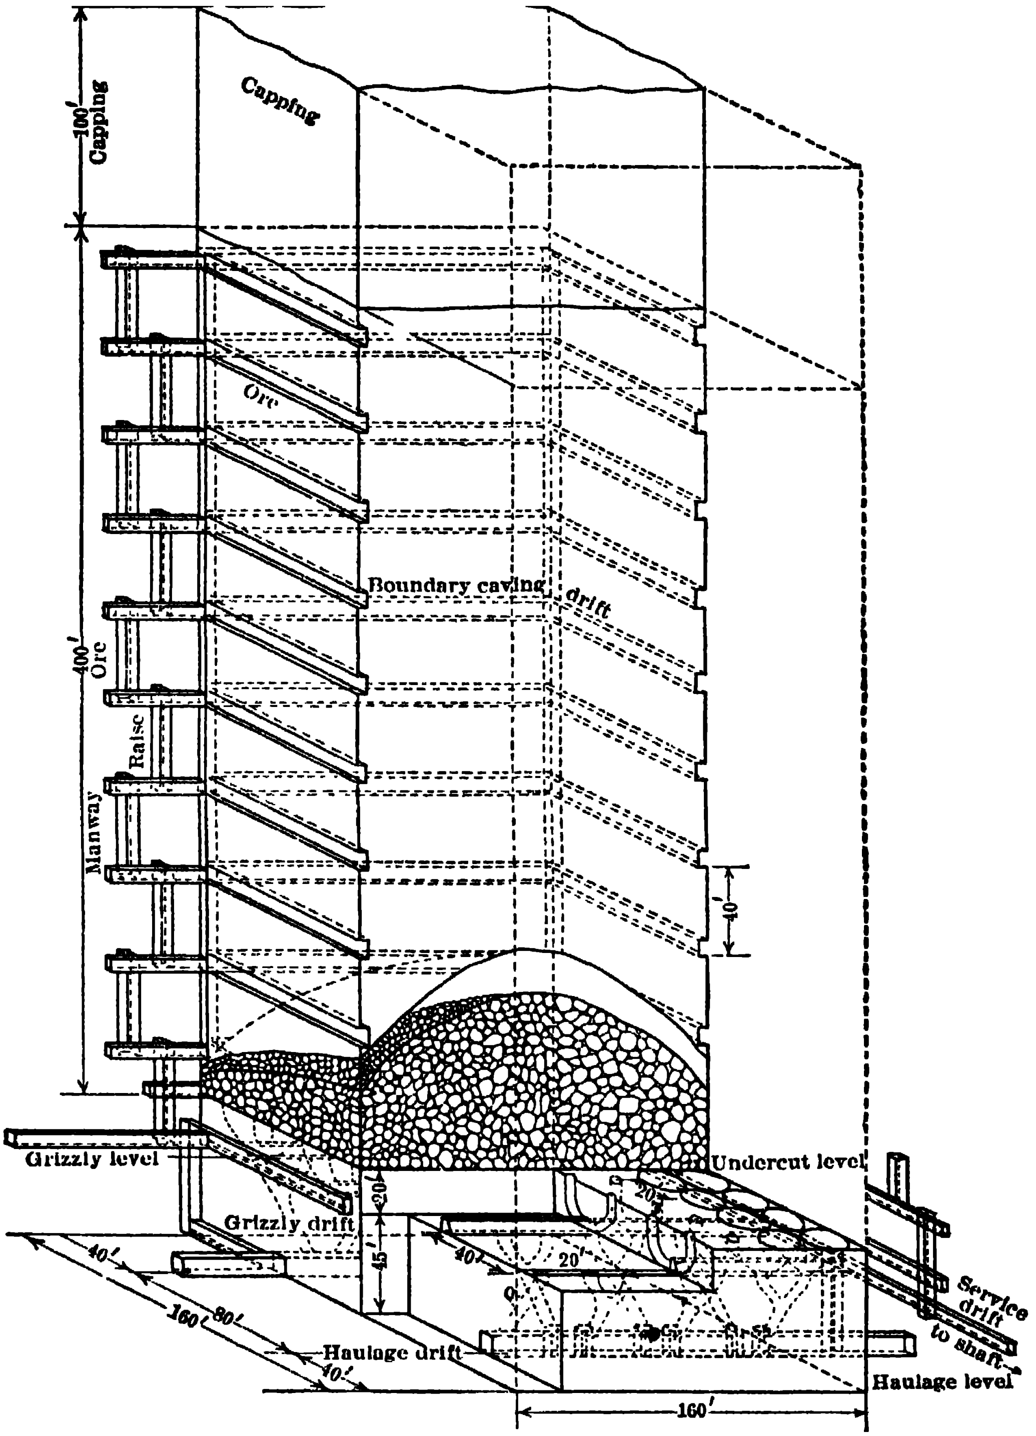

Fig 556. Isometric Drawing of Stope Block, King Mine, Quebec

Braden mine, Sewell, Chile. Data from J. S. Webb and T. W. Skinner (289) in 1932; additional data from management in 1938. Large, irregular, crescent-shaped deposits, carrying chalcocite and chalcopyrite, occur in highly fractured zones in andesite, around a neck of volcanic tuff. Ore dips steeply; tuff contact forms hanging wall; footwall is commercial limit of workable ore in andesite. Width of ore zone, 328–1 968 ft; oxidized capping extends 164–328 ft below surface. **Development.** Topography is steep and main entry to mine is by adit below operating levels, to which ore is delivered through ore passes for haulage to mill bins. Level interval was formerly 50 m (164 ft), but present development has 100-m (328-ft) lifts. Parallel drifts are driven on caving level 12 m (39.4 ft) apart. Gathering raises cut the bottoms of these drifts to provide dumps 30 m (98.4 ft) c–c (Fig 557). Haulage drifts are 10 by 10 ft; raises used as main and gathering ore passes are 6.5 by 6.5 ft; caving-level drifts, 9.5 ft high by 7.5 ft wide. **Stoping.** Former use of shrinkage-stope and pillar-caving (Art 87) has been replaced by block-caving. Blocks are 100 m high. General plan of retreat is from one end of orebody to other, undercutting extending from footwall to hanging. Shrinkage cut-off stopes are carried up along boundaries according to judgment of mine officials. **Undercutting.**

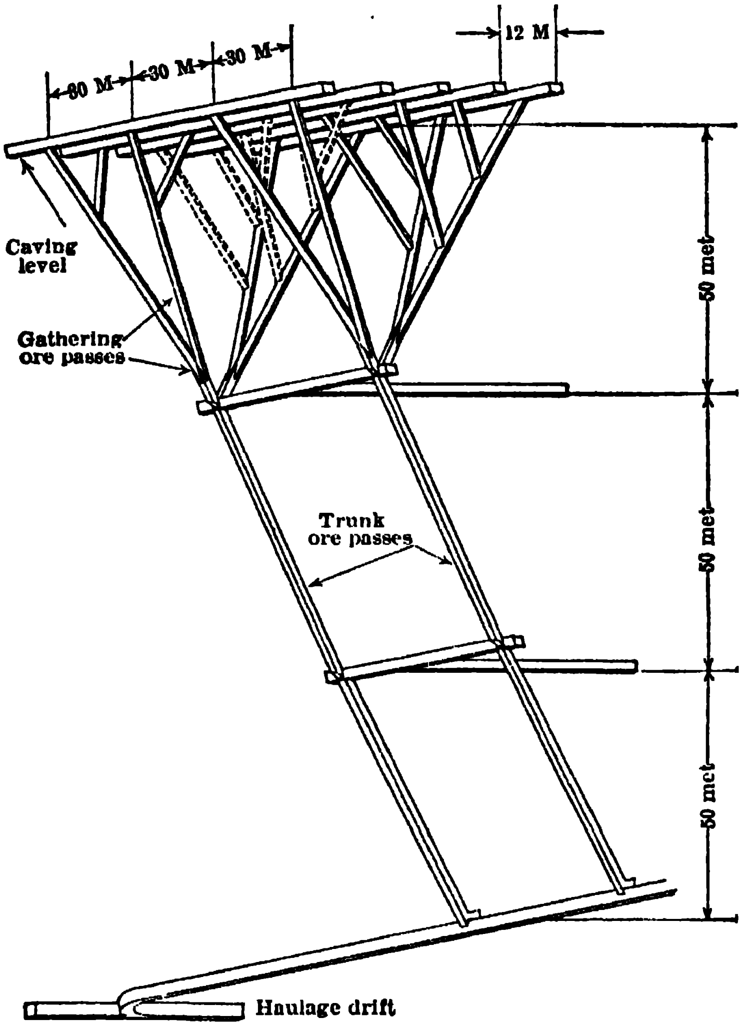

Fig 557. Ore-pass System, Braden Mine, Sewell, Chile (289)

Caving-level drifts are timbered with heavily reinforced sets, 5 ft c–c; posts, 8 ft long; caps, 7 ft. On each side of these drifts, chute pockets are installed in alternate sets, chutes on one side being staggered with those on the other. Starting at one end of orebody, next to a cut-off (shrinkage) stope, undercutting proceeds toward the other end in undercutting units 6 m (19.68 ft) lengthwise by 12 m (39.36 ft) across the orebody (at right-angles to drifts). For a given unit, the stages of undercutting are shown in Fig 558. Along a 6-m section of drift a 6-ft fan-shaped round is drilled and blasted (Fig 558, A). The ore thus broken is drawn out through the chutes, leaving an open stope about 7 ft high above the drift timbers. Before the initial blast, a small manway raise *M*, from the next drift to center line of the intervening pillar, is driven on a slope of 48°, and at an angle of 8° 30′ from the perpendicular to the drift, to meet a similar raise *N*, driven from the last chute in the undercut stope. This connection is completed before making the second widening blast in the undercut stope, thus providing safe entrance and exit. Three more undercutting rounds are drilled and blasted successively (Fig 558, B, C, D), forming a small shrinkage stope. The ground usually shows signs of weakening after the third blast, but to assure safety to the miners, the back is stulled after each blast. The final blast breaks to the adjacent caved area. Before regular drawing is started, undercutting continues in adjacent drifts until sufficient area is weakened to produce a continuous caving action. An undercut crew consists of 3 miners, who work on contract basis of lineal meterage undercut. Stoper drills are used. On caving level, ore is drawn into 1-ton cars and trammed to tops of gathering raises. Each trammer is assigned a minimum of 10 chutes. With dumps 30 m (98.4 ft) c–c, max tram is 15 m (49.2 ft). Trammer receives daily orders as to number of cars to be drawn from each chute, and record of tonnage drawn is kept. Trammers are paid according to number of cars, with guarantee of base wage. Accurate count of cars is obtained by an automatic counter on each car. Trammer must load a full ton into car and dump it before the counter registers. Counters

on each car are read at beginning and end of each shift, and at intervals during the shift.

Andes Copper Mining Co (Anaconda Copper Co), Potrerillos, Chile. Data from I. L. Greninger, Asst Gen Mgr, in 1939. Copper minerals, chiefly chalcocite and chalcopyrite, are disseminated in porphyry, forming a large, massive orebody. Porphyry intrusion has left enclosing sediments tilted at 50°–60°. Orebodies within intrusive generally have same dip as sedimentaries. DEVELOPMENT. As topography is steep, entry is by adits; main adit is at elev of 2 974 m (9 754 ft) and is 4 787.82 m (2.97 miles) long. Ore passes extend from main adit to 3 intermediate haulage levels at 3 032, 3 112, and 3 184 m. On each intermediate level, parallel haulage drifts are driven, 30–33 m c–c. Development above the haulage levels, to prepare for undercutting, is shown in Fig 559, which is a vert section through the central orebody. Fig 560 shows details of a typical block. This method was developed at the Inspiration mine, Ariz. Fig 561 shows the raise system. Control in drawing is maintained at the grizzly, whereas in earlier practice at Andes (see E, Fig 559), "control sets" were placed between the grizzly and undercutting levels; the control set was a 4-post square-set, from which 4 finger raises were driven to the undercutting level above; each finger raise was controlled by a chute gate at the control set. For details see Bib (643). HAULAGE DRIFTS are timbered with sets of 10 by 10-in Oregon

pine, 8.5 ft wide at the cap, with 9-ft posts battered 1 in per ft. Grizzly drifts, formerly lined with masonry (643), are now timbered as in Fig 562. Main raises are lined with 6 by 12-in cribbing skin to skin, each piece protected by a 3 by 3 by $^3/_8$-in angle iron at its upper edge. Fig 560 shows undercutting details. Area to be undercut is divided by 6.25 by 6.25-m pillars, which are shot out successively, retreating from one corner of the block to the diag opposite corner. Blocks are now 50 by 60 m in horiz sec. **Ore drawing** is in accordance with written orders, a close check being kept on tonnage and grade drawn from each branch raise. Main raises are calibrated by successive filling and drawing off. A check is obtained by counting the cars drawn from each chute. Data on tonnage drawn from branch raises are posted daily on office stope sheets, from which graphic charts are made, and copies carried by underground foremen and bosses. In 1939, for direct labor underground, production was 40–45 tons per man.

Climax, Colo. Data from W. J. Coulter (303) in 1929 and W. E. Romig (304) in 1937. Molybdenite occurs in disseminated form; also in veinlets along fracture planes in altered schist and granite. Ore area' lies concentrically around a large dome of silicified and sparsely mineralized granite. Wall limits are determined by assay values; dips are steep; horiz width of ore is 300–700 ft. Former mining was by shrinkage-stope and pillar-caving; now by block-caving, with lifts of 400–600 ft. First practice in block-caving involved use of grizzlies, 60 ft above haulage level, 50 ft c–c, both lengthwise and crosswise of orebody, from which finger raises extended to stope bottom. Difficulty in maintaining grizzly chambers, due to blockiness of ground, led to a novel system, in which scrapers eliminate need for grizzly levels. **Development.** Present (1937) vert interval between haulage levels is 465 ft, but 500-ft lifts are proposed for future. Level development comprises parallel haulage drifts, 11 ft high by 13 ft wide, and 200 ft c–c. At intervals of 75 ft, "slushing drifts" extend from both sides of and at right-angles to haulage drifts (Fig 563). At intersection with haulage drift, bottom of slushing drift is 8 ft above rail, or 1 ft above top of cars, thus allowing ore to be scraped directly into cars. Slushing drifts usually extend 100 ft on each side of haulage drift, and are driven on a +15% grade. At 50-ft intervals along these drifts, chute raises are driven as in Fig 563. Undercutting is done by slabbing the sides of the upper branches of these raises, pillars being left temporarily as required. Undercutting is completed by drilling and blasting simultaneously

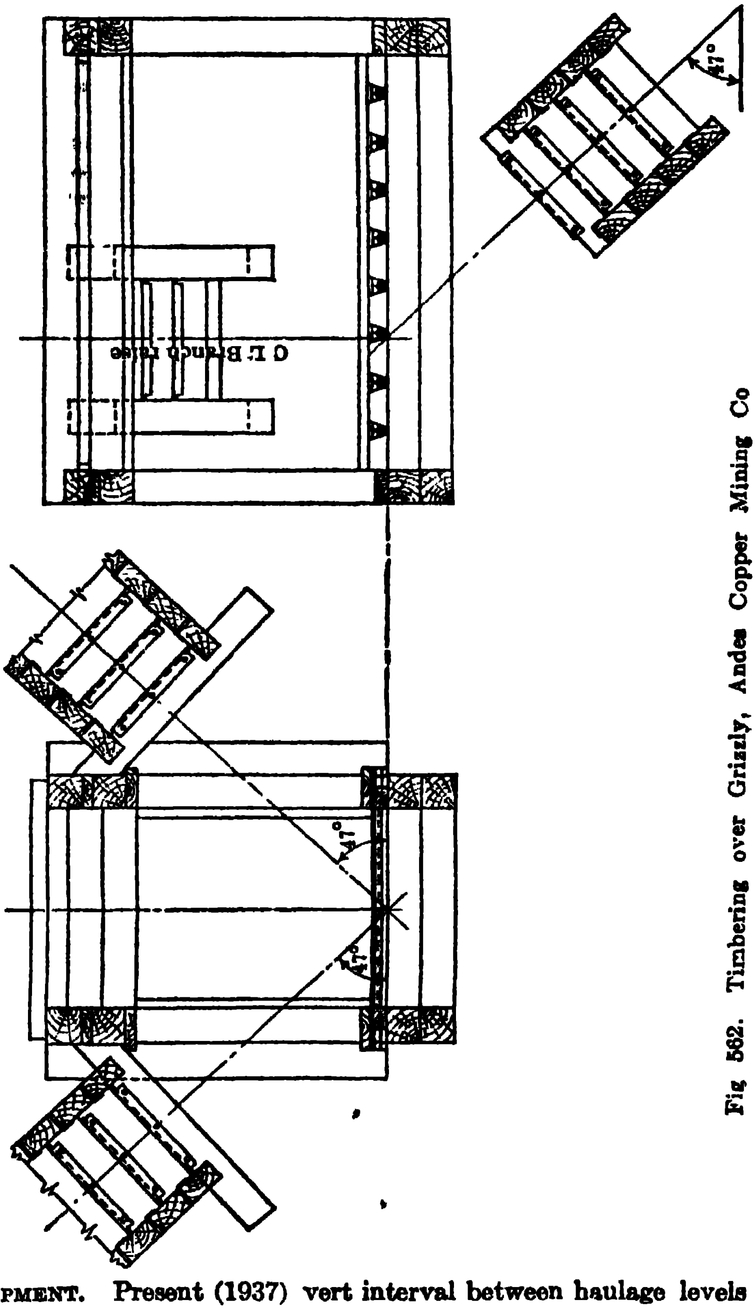

Fig 562. Timbering over Grizzly, Andes Copper Mining Co

a number of pillars. Thereafter, ore caves by its own wt, and drops through the chute raises to the slushing drifts, whence it is scraped into hoppers discharging directly into cars in haulage drift. Scraper hoists have double drums, and 150-hp motors; 72-in, hoe-type scrapers are manganese-steel; rope is $1^{1}/_{8}$-in, plow-steel. Hoppers over haulage drifts (Fig 564) are of structural steel, 34 ft long by 10 ft wide, with sides 3 ft high; bottom slopes up on 15% grade from a 4 by 7-ft discharge hole in center. A 24-in log is placed across slushing drift at each end of hopper. Planks, 3 by 12 in, are dapped into logs and extend to discharge hole; 60-lb rails, with heads up, are fastened to these planks and bent over the logs, ends of rails being set in concrete. Scraper hoist is mounted on a frame which can be moved from end to end of hopper, permitting scraping from either branch of slushing drift. Advantages claimed for the " slushing system " over " grizzly system " are: (1) less development, hence lower cost and greater speed in bringing blocks into production; (2) less distance between undercutting level and haulage level, hence more ore developed for a given lift; (3) greater flexibility; (4) better draw control; (5) safer. Disadvantage is in less storage space between stope and cars. Accompaning statement shows comparison of development and major equipment for each system for a block 600 by 400 ft horiz area and 410 ft high. Results obtained in 1929 indicated a saving by slushing system of $0.027 per ton in operations and $0.044 per ton in development; total, $0.071 per ton.

Utah Copper Co, Bingham, Utah. A large, low-grade deposit of disseminated chalcocite is mined by power shovels (Art 96). Caving was employed in the earlier development, to produce ore and break up the capping for the shovels without blasting. Rooms were opened; then the pillars were weakened until they caved, and the ore was handled in cars or barrows to the chutes. This plan was modified later by putting up raises to caved areas for drawing off ore. Finally a branched-raise caving method was developed. Fig 565 shows the development. Two main levels were opened from tunnels 200 ft apart vertically. The ore on lowest or main haulage-level was cut up by drifts and crosscuts into pillars about 75 ft square. Main raises were inclined at 50° to 60°, each serving an area 70 to 75 ft square. Sub-levels were at vertical intervals of 17 ft; later this was increased to 25 ft and then to 33 ft, which was the largest at which caving could be controlled. Numerous branch and sub-branch raises (not shown in Fig 565) were driven from main raises between

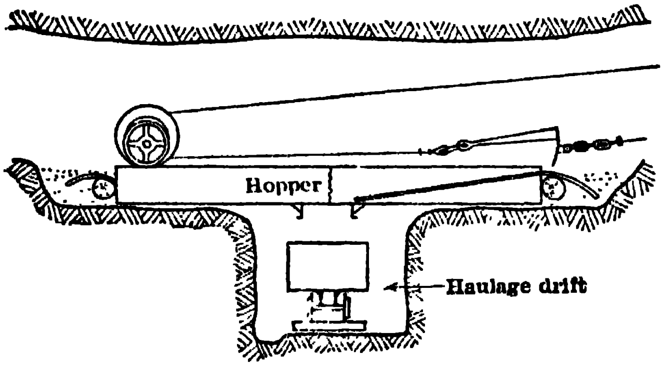

Fig 564. Vert Cross-sec through Haulage Drift, showing Slusher Platform, Climax, Colo

subs. The collars of branch raises on subs were approx on corners of 15-ft squares. A block of ore was caved by enlarging the tops of all raises under it, and finally mining the remaining pillars; for further detail, see Bib (114, 190, 305). Loss of ore by mixing with capping was high.

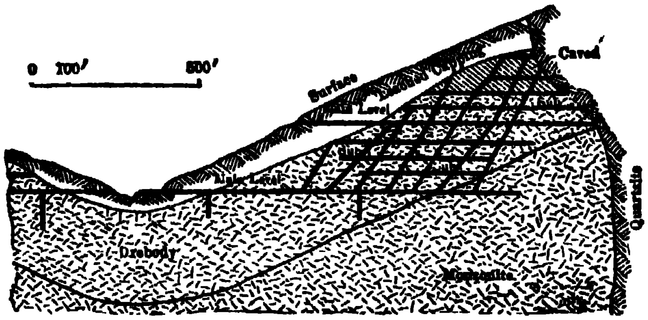

Fig 565. Utah Copper Co. Cross-sec through Part of Orebody

81. SUMMARY. BLOCK-CAVING

General. Block-caving, where applicable, gives a lower mining cost per ton than any other underground method. It requires relatively large capital expenditure for preliminary development, and is essentially for large-scale work. In its different forms (Art 79, 80), it is applicable to deposits of various shape and to ores of various strength, but has rigid requirements and limitations. In unsuitable deposits, or where carelessly conducted, the loss of ore may exceed that of any other method; systematic work, careful supervision and good judgment are essential to success.

Requirements, besides those common to all caving methods (Art 82), are: SUITABLE OREBODIES. For general applicability of method see Art 79. Orebodies must have enough horiz area to cave freely and without excessive dilution by waste rock from side walls. Large massive deposits meet these conditions. Vein-like deposits must be wide, and dip over 65°; ideal conditions are strong walls from which ore parts easily; isolating stopes may be used to free ore from walls if their cost is justified by ore tonnage so released. Block-caving may be used in flat beds if thick enough to warrant cost of development; usually minimum thickness is 70–80 ft. Block caving is not a selective method; as underground sorting is not feasible, a fairly uniform distribution of values in the orebody is necessary. Outlines of the orebody should be fairly regular; small extensions of ore into walls are not recovered and tongues of wall rock jutting into the ore can not be left unmined. Some dilution and loss of ore are inevitable in block-caving; their amounts affect the economic min and max grades of ore to which the method is applicable. PHYSICAL CHARACTERISTICS OF ORE which will break up under block-caving have not been exactly defined; some ore successfully mined by block-caving contains numerous small veinlets or other planes of weakness; behaviour of a given ore is determined by trial. Block-caving is adapted to moderately soft or moderately hard, but not to very soft or tough ores. CAPPING must cave when underlying ore is dropped; wt of overburden is essential to aid in crushing the ore. The most favorable capping breaks into large pieces; soft, brittle capping decreases extraction by breaking fine and sifting into the ore, or by "channeling" through to the chutes. Capping differing in appearance from ore is desirable, for ready detection at chutes at end of drawing operations.

Advantages of block-caving: (*a*) Safety. (*b*) Cheap mining, since but little drilling, blasting and timbering are done per ton of ore; amount of development is relatively small. (*c*) Production is centralized, allowing efficient supervision. After caving begins, a large and easily varied output is obtained from one level. (*d*) Natural ventilation is good, compared to that in other caving methods.

Disadvantages of block-caving: (*a*) Preparing the blocks for caving requires time and large expense. (*b*) Cost of maintaining drifts in drawing area is high and this work interferes with production. (*c*) Variation in rate of production to meet changes in demand for product is difficult. Stoppage of drawing for a considerable time may result in complete loss of the development openings in the area involved. (*d*) Extraction is sometimes low, and there is constant danger of losing large amounts of ore. (*e*) Method is inflexible; once started, a change to another underground method is difficult.

Choice between different forms of block-caving (Art 79). Dilution with waste is least when surface between caved ore and capping is kept approx horiz by even drawing from chutes. To accomplish this, the ore area must be divided into blocks, mined successively; maintenance of sub-levels under caving ground of large horiz area is difficult and costly, hence trend is toward use of smaller blocks where sub-level block-caving is used. The Pewabic method is practically obsolete under modern conditions in the U S, due to necessity for driving and maintaining extraction openings through the caved ore and for shoveling all the ore; block-caving into chutes has replaced it.

Block-caving methods in which the surface between caved ore and capping is an inclined plane, and undercutting progresses either through panels or through entire length of orebody, minimize the sub-level area which must be maintained for a given daily production, but do so at expense of increased dilution (see "Drawing ore," Art 79). An attempt is made to strike an economic balance between the above factors as modified by size and nature of orebody and the output desired. Experience at other properties guides initial work, but the final plan of a large block-caving operation is generally the result of long experiment under the local conditions.

Vertical *vs* inclined or branched chute-raises. Relative advantages of inclined chute-raises: (*a*) Easier to construct, and, if properly arranged, less apt to clog. (*b*) For given spacing they require less drifting and crosscutting on tramming-levels and subs where ore is undercut. Conversely, for a given first cost of lateral development, they may be spaced closer than vert chutes, which is essential for uniform drawing. (*c*) They are applicable in softer ground, since with vert chutes the ore must stand practically unsupported while tops of raises are funneled out and sides of sub-level pillars are cut away. (*d*) They collect ore as drawn at comparatively few points on the sub-level below the caved block. Grizzlies may be installed at such points and large lumps spalled before entering the chutes to main haulageways. With vert raises, ore must be collected and trammed from many different points. (*e*) Gates can be operated in branch-raises a few feet below floor of the sub where the ore is undercut; hence, when drawing is finished, the capping is drawn down only a short distance into the chutes.

Block-caving into branched chutes is limited to orebodies of large horiz area; one disadvantage is that branch and finger-raises are complicated and must be set by survey to come out at proper intervals on the undercutting floor.

Block *vs* sub-level caving (Art 78). Relative advantages of block-caving: It is cheaper, gives larger daily output from a given area, requires less development per ton of ore, natural ventilation is better, and, by caving into chutes, shoveling is eliminated. Sub-level caving is possible in softer ore and smaller orebodies; caving is better controlled, and yields cleaner ore, with a higher percentage extraction. These factors may outweigh the advantages of block-caving.

82. SUMMARY OF CAVING METHODS (See also Art 74, 78, 81)

General conditions leading to use of caving methods: (*a*) large-scale work; (*b*) orebodies of large horiz area, as wide veins, thick beds, or masses, usually overlain by a capping varying from glacial drift to firm rock; (*c*) ore which is weak or which, if hard, is thoroughly fractured; (*d*) deposits of cheap minerals or low-grade ore, in which loss of ore or contamination with waste is less serious than for high-grade ore (Table 57).

Large output from given area	BC	SC	TS

BC = Block-caving. SC = Sub-level caving. TS = Top-slicing. (*a*) Fire hazard varies directly as timber consumption.

Requirements for top-slicing, sub-level caving and block-caving are stated in Art 74, 78, and 81. Absolute requirements common to all caving methods: (*a*) The overburden must cave and "follow down," as the ore beneath is removed. A method requiring weight on top of the workings is useless unless that weight is obtainable from the overburden. The capping need not always cave to the surface, but it should cave sufficiently to protect the workings and furnish the necessary crushing force. Capping which hangs up and then drops suddenly over considerable areas is very dangerous; both the workings and the men may be destroyed. (*b*) Surface subsidence must not injure valuable property nor make underground work dangerous. This precludes caving under structures which can not be moved to a safe place, or under streams which can not be diverted, or under lakes, swamps, etc, which can not be drained. Presence of known orebodies, or of virgin ground likely to contain ore, prohibits caving in an underlying deposit.

Orebodies specifically unsuited to caving (P. B. Scotland): (*a*) Those which are flat and thin, or small and high-grade, or very irregular in shape. (*b*) Deposits containing much waste which must be sorted underground. (*c*) Deposits containing mixed sulphide and oxide ores, or milling and smelting ores, which must be kept separate for treatment.

General comparison. Note, in addition to the summary in Table 57, that top-slicing is best adapted to very soft, heavy ores; sub-level and block-caving, to stronger ores. A weak, friable capping favors top-slicing; strong capping which breaks large favors block-caving. Sub-level caving always occupies a position intermediate between top-slicing and block-caving. Where a choice exists, it usually lies either between top-slicing and sub-level caving, or between sub-level and some form of block-caving; for detailed comparisons, see Art 78, 81.

COMBINED METHODS

83. GENERAL

Term "Combined method" designates here a group of mining methods involving a concurrent and systematic use or combination of two or more of the methods described in Art 29–82. Such methods vary widely and are difficult to classify specifically. They are employed chiefly in mining large bodies of soft or hard ore; in general, they are for large-scale work and aim at a high extraction. The term does not apply to cases in which a minor portion of an orebody is mined by methods other than that applied to the major portion of the orebody, even though the use of 2 or more methods may be systematic.

Combinations used generally involve subdivision of the orebody into a series of alternating pillars and stopes; stopes are usually shrinkage stopes, with various methods for mining pillars (see Table 58). Combinations of shrinkage stopes and block-caving are also known as "Shrinkage Stope and Pillar-caving," or more simply as "Pillar-caving."

Table 58. Combined Methods

Mine	Method of mining		For details see Art

Golden Queen, Cal	Open sq-set	Shrinkage, or cut-and-fill, or sq-set	87

(*a*) With delayed filling, Art 67. (*b*) Not described here, see Bib (604).

South African diamond mines use combined shrinkage stoping and sub-level caving (Art 88), differing entirely in principle from pillar-caving. Methods at Creighton and Beatson mines, Art 68, may also be classed as shrinkage-stope and pillar-caving systems.

84. PRACTICE AT BOSTON CONSOL MINE

General. SHRINKAGE STOPES AND PILLAR-CAVING were used for about 5 years by Boston Consol Co, but were abandoned in 1914 after the property had been acquired by Utah Copper Co, which it adjoins. This company extended its opencut (Art 96) into Boston ground and ceased underground mining there. Early method at Ray (Art 85) was developed directly from the Boston method; its evolution illustrates many essential points in mining large, low-grade orebodies by shrinkage stopes and pillar-caving. There are two variations, based wholly on differences in mode of handling ore: (*a*) HAND-TRAMMING SYSTEM, in which stopes are opened directly over the drift sets on the levels and ore is handled there in small cars to chutes connecting with a haulage level below; (*b*) SUB-LEVEL OR MOTOR-HAULAGE SYSTEM, in which stoping begins from a sub-level above a motor-haulage level and ore is drawn down to latter through chute-raises; the sub-level is a stoping base only. OREBODY is a large, low-grade, disseminated copper deposit, in monzonite porphyry, overlain by leached capping. It was opened by 2 adit levels, 150 ft apart vertically, the upper reaching a max depth of 200 ft below capping (114). Following data are by L. A. Blackner in 1915 (61).

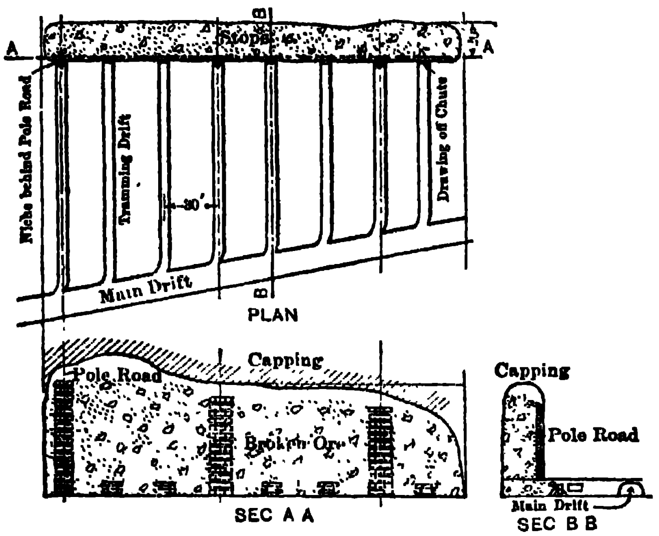

Fig 566. Boston Mine, Hand-tramming System; Chutes at One Side of Stope

Hand-tramming system. In the early stages, the plan shown in Fig 566 was tried. A drift on the center line of the stope nearest the ore boundary was widened to 20 ft. From it was carried up a shrinkage stope, access to which was through "pole roads" (Art 88) at the ends of alternate tramming drifts. At first, excess ore was shoveled at the ends of the drifts; later, chute-gates were erected in each drift to eliminate shoveling. DISADVANTAGES: (*a*) max output was limited to that which could be produced from one stope; (*b*) the broken ore in the stope drew down on one side, making it difficult for machinemen to work; (*c*) as cars had to be loaded at the end instead of the side, they slopped over, and much shoveling was required to clean the tracks; (*d*) the widening of the stope floor on the level wasted time and money, as the space so formed was filled with unrecoverable ore; (*e*) final extraction was low, as ore in rear of stope could not be recovered.

Fig 567 shows a later plan. Chute-gates, 30 ft apart on each side of the stope, made it possible to draw the swell of the broken ore more evenly, and to secure higher final extraction; also several stopes could be worked simultaneously. But, with the chute-gates so arranged, the miners had to work at times in the middle of the stope, where the back was continually sloughing off, and in starting a stope some ore had to be shoveled from the middle to the sides. Ventilation was poor, the pole roads gave trouble, and the other disadvantages of the plan in Fig 566 persisted. Moreover, the large openings caused by placing the crosscuts from the tramming-drifts opposite each other weakened the bases of the pillars, making it difficult to maintain the tramming drifts.

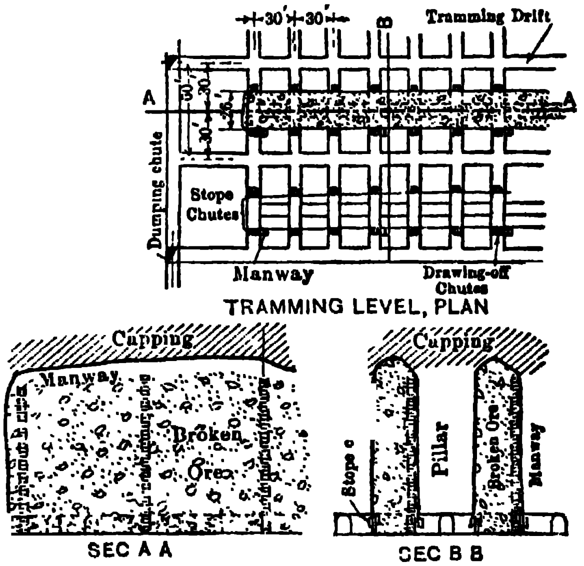

Fig 567. Boston Mine, Hand-tramming System; Chutes on Both Sides of Stope

Fig 568 shows the final stage of the hand-tramming system, before underground mining ceased. The development work was halved by running tramming drifts in alternate pillars only; crosscuts were staggered, reducing the size of opening at their entrance to a minimum. Two chute sets were erected in each crosscut at the stope center, to provide gates under the stope instead of at the sides. The stope floors were above the level and consisted of a series of funnels apexing at the chutes. This important improvement did away with expensive drifting and widening on the stope floor and made it possible to recover all the broken ore. Manway raises were put up in alternate pillars at 60-ft intervals along tramming drifts, small crosscuts from them furnishing access to stopes. This mode of entry was later replaced by manway pillar drifts (Fig 569), because the pillars cracked and the raises became unsafe. Manway drifts were good in hard ground, but in presence of seams and faults they caved; also the drifts and crosscuts on the level required much retimbering. The arrangement of chutes in Fig 568 required a tram uneconomically

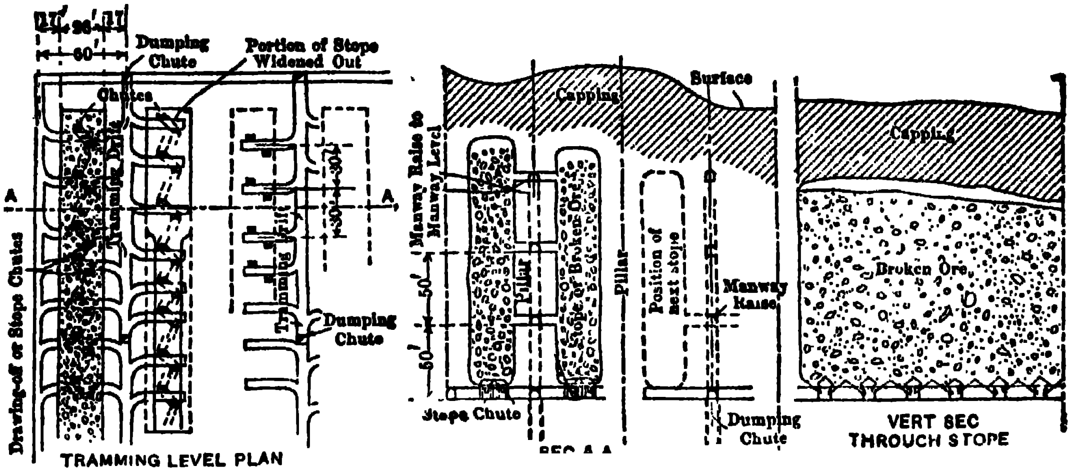

Fig 568. Boston Mine, Hand-tramming System; Chutes in Middle of Stope

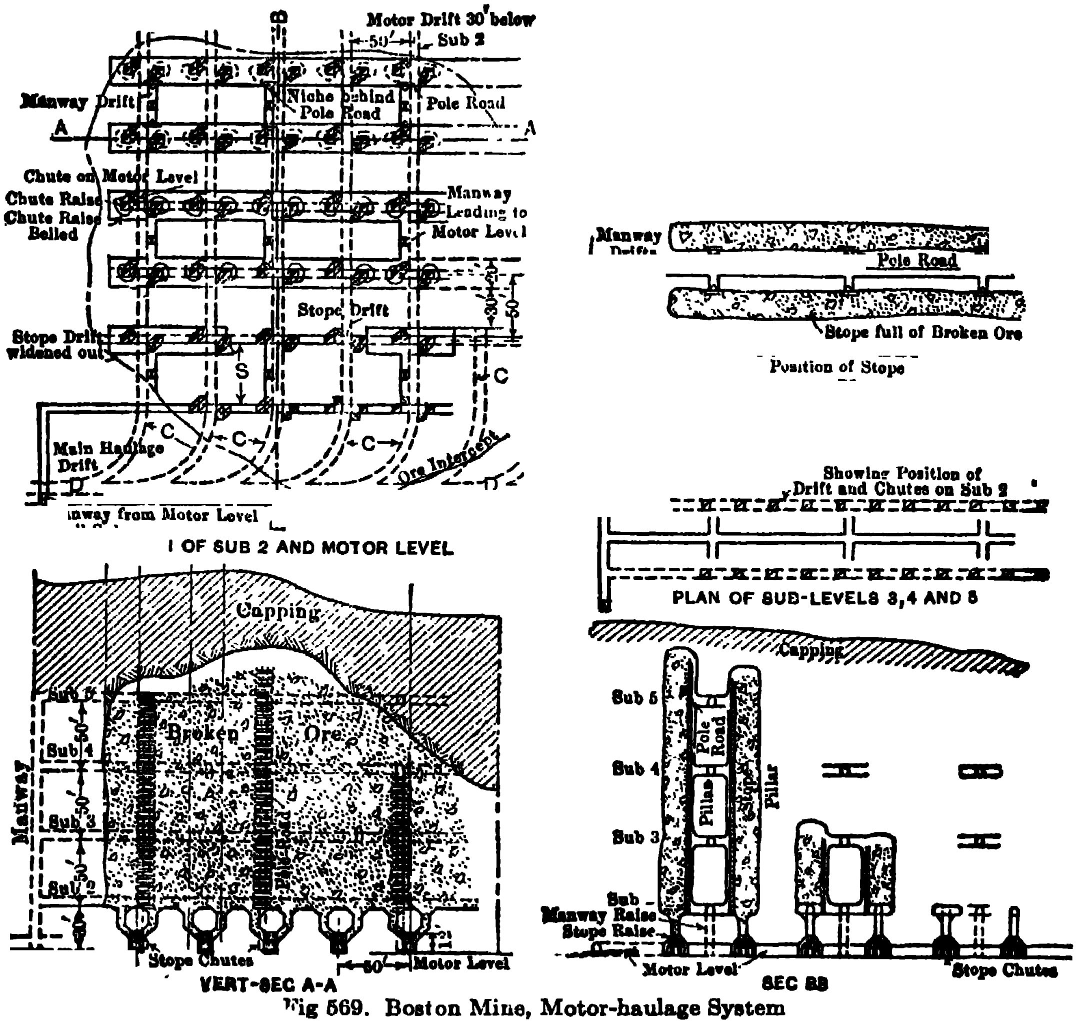

Fig 569. Boston Mine, Motor-haulage System

long for hand work. The detail of caving pillars and drawing ore was not worked out; added drifts would have been needed on the levels to extract the pillar ore.

Sub-level or motor-haulage system (Fig 569). Stopes are at right-angles to the drifts on the motor level and are opened 30 ft above it by widening the stope drifts *S*, which connect the tops of the chute-raises; the latter are spaced 25 ft apart along center lines of stopes. The manway entrances to stopes gave trouble in this as in the hand-tramming system. At first, raises were put up from the motor drifts 100 ft apart along center lines of alternate pillars, with break-throughs at 50-ft vert intervals. The pillars usually faulted or sloughed before the stopes reached the capping, and cut off these entries. Fig 569 shows the next plan tried. Sub-levels, 50 ft apart, were opened by driving manway drifts through alternate pillars, then crosscuts to stope lines at 100-ft intervals along drifts, and a pole road up the stope wall from each crosscut. Manway raises, from motor level to 1st sub were located as in the plan of Sub 2, Fig 569; all subs were connected to a raise outside of orebody. This network of openings gave numerous entries to stopes, but were costly; where pillars cracked, the manway drifts had to be timbered and were expensive to maintain. The pole roads also were troublesome; ore produced in driving them could not be easily handled in Sub 2, and at times their walls broke wide, requiring expensive blocking and timbering to keep them open.

85. PRACTICE AT RAY MINE, ARIZ

General. Present method at Ray is usually classified as block-caving (see Art 80), although some shrinkage stoping is still done in connection with caving operations. L. A. Blackner (61) in 1915 described former shrinkage-stope and pillar-caving, as below, indicating the stages of evolution to the present method. Successive changes have tended to increase the ratio between ore broken by caving and that by drilling and blasting. For data on orebody and development, see Art 80.

Development. Two vert hoisting shafts were required for the large area mined by shrinkage stopes and pillar-caving. There are 3 main motor-haulage levels; drifts are heavily timbered, and are double-tracked near shafts to facilitate handling trains of cars.

Motor-haulage system. EARLY METHOD. Attempts to use stopes and pillars of same size as at Boston mine (Fig 569) failed. To make the 30-ft pillars cave, longitudinal shrinkage stopes 8 or 10 ft wide had to be run through them. Even then, the 10-ft pillars remaining required at their base narrow pillar-stopes, 8 or 10 ft high, to make them crush, which was costly and unsystematic. Vert raises were put up from the motor drifts to the sides of the stope, but the excess ore could not be drawn evenly. The sub-level arrangement of Fig 569 furnished access to stopes. A LATER METHOD involved radical changes. Stopes 15 ft wide were spaced on 25-ft centers, leaving 10-ft pillars. Only 2 sub-levels were driven; one 30 ft above the motor level, and one usually 100 ft higher, near top of orebody, for a manway and ventilation. The sub-level manway drifts were at right-angles to the stope center lines, instead of along the pillars. Manways were provided in the pillars by raises from the lower to the upper sub-level at 100-ft intervals along the stope. Operations comprise 8 stages: STAGE 1: Drifting on motor level. A main drift (*M*, Fig 570), 7 by 8 ft in the clear, is driven along one edge of the orebody. From *M* parallel motor drifts *C*, 50 ft apart, are turned off on 60-ft radius curves and run to a "fringe drift" *F*, near the opposite side of the deposit. At some point outside the orebody, a 2-compt, cribbed raise *R*, the "permanent raise," is put up, and from it sub-levels are opened. STAGE 2: Chute building on motor level. Within the ore limits, drifts *C* are timbered with full sets, surmounted by pony-sets (Fig 572); angle braces and filler blocks are used in heavy ground. Chute-gates (Art 90) are built in the pony sets every 12.5 ft along the drifts, 2 gates being placed opposite each other in each set. Alternate pairs of gates ("stope chutes"), 25 ft apart, serve for drawing ore from stopes; the others ("pillar chutes"), halfway between the stope chutes, are for drawing pillar ore. Outside of the orebody, there are no pony sets in drifts *C*; the drift sets have 12 by 14 caps and 10 by 12 collar braces. STAGE 3: Manway drifts, stope drifts and chute-raises. While driving drifts *C*, the 1st sub-level, 30 ft above, is opened. Manway drifts *K*, Fig 570, are 5 by 7 ft and 100 ft apart; they are 12.5 ft to one side of corresponding drifts *C* below, for connecting with raises *L* (Sec *AA*, Fig 570). Stope drifts *S* are driven 25 ft apart over the entire orebody, and are directly over the stope chutes on the motor level. Chute-raises about 6 ft diam are then put up from the stope chutes, on an incline for 10 ft and then vertically to the stope drifts. On the 2nd sub-level, manway drifts *N* are driven directly over drifts *K*. STAGE 4: Manway raises, belling out chute-raises, widening stope drifts, building manway sets. Manway raises are put up to drifts *N* at 25-ft intervals along drifts *K*; as their centers are 7.5 ft from centers of stope drifts *S*.

they are bisected by the stope wall; chain ladders are hung in these raises. The tops of the chute-raises are funneled while driving manway raises; this is done with stope-drills putting in uppers. Stopes are started by drilling a line of holes slanting into the sides of the stope drift; these holes and those drilled in belling the chute-raises widen the stope drift to 15 ft. Manway sets are erected in the drifts *K*, directly under the manway raises, as soon as the stope drifts are widened; the manway sets consist of drift-sets, standing on 8 by 8-in stringers projecting into the stopes; 3 by 3-ft cribbed manways are built up from these sets through the broken ore as the stopes advance. Stage 5 consists of mining the stopes to the capping. For mode of breaking ground, see Fig 174. The broken ore swells about 33%. The cribbed manways are abandoned when the stope is halfway to the 2nd sub, after which the miners pass through the manway raises. In hard ground, stopes are 15 to 20 ft wide; in soft, sloughing ore, 10 to 15 ft wide. Stage 6: Before drawing the stopes, the pillars are undermined by one of the following methods. Method 1 (Fig 573), used in hard ground where stopes are 15 to 20 ft wide, leaves narrow pillars easily undermined. Pillar raises, run from the pillar chutes (2nd stage), start in the pillar nearest fringe drift *F* (Fig 570). After connecting the raises along a pillar, they are widened, lined with deep holes and blasted. This is repeated in successive pillars, retreating

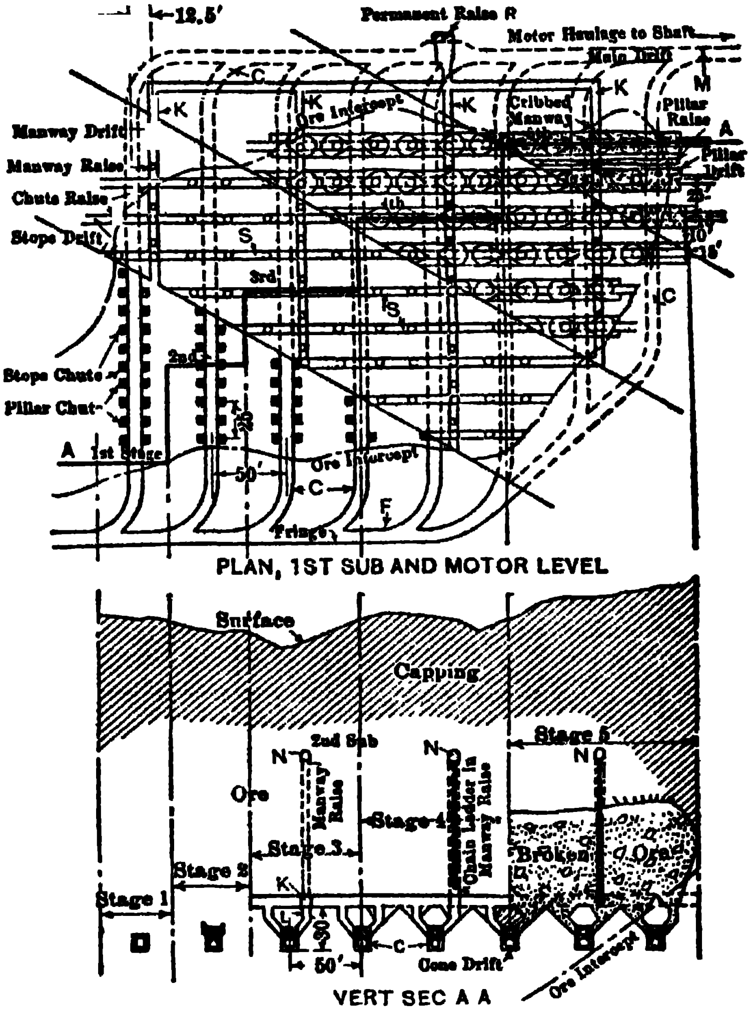

Fig 570. Ray Motor-haulage System (showing 5 stages of work)

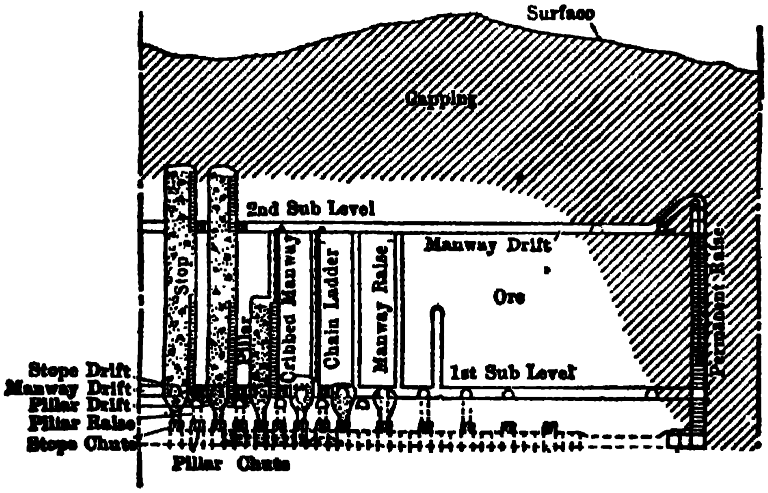

Fig 571. Ray Motor-haulage System

towards main drift *M*. Method 2 (Fig 573) is used in soft ground, where pillars are wide and stopes narrow. Drifts are driven along center lines of pillars, 22 ft above the motor level (Fig 571), and chute-raises are put up to them on flat inclines from the pillar chutes. Raises are funneled at the top and pillar drifts widened as desired. The backs of the drifts are then blasted with deep holes (Fig 573). Method 1 is cheaper and is used wherever pillars are narrow enough to allow it. Stage 7: Drawing ore ("reserve drawing"). Generally the orebody and capping are fractured, so that when the pillars in a stoped area are caved and the ore drawn, the capping breaks to the surface along a nearly vert plane at the edge of the area. In areas where haulage drifts are to be abandoned, the chutes near the fringe drift are drawn faster than the others, so that the capping assumes a slight incline toward this drift; by the time the drifts take weight, all the ore beyond is drawn, which avoids expense for retimbering. Only a few cars of ore are drawn at a time, to induce gradual settling of the capping, with minimum loss and dilution of ore. When drawing chutes, the motorman runs empty cars through the fringe drift into the back ends of drifts *C*, Fig 570, whence they are trammed to the chute. A chute blaster or loader loads the car, and one trammer pushes it toward the main drift while another spots an empty. All drifts have a 0.25% grade in favor of the load. When an 8- or 12-car train is loaded, a motor hauls it through the main drift, returning the empties to the back end of the motor drift. The highest efficiency results when only 2 trammers and 1 loader are used in a drift. In one case 6 trammers, 3 loaders, 2 machinemen (for blasting boulders in chutes), 1 mucker and 1 timberman (for repairing damage to chute-gates by blasting), working in 4 drifts, loaded an aver of 150 tons per 8-hr man-shift. A boss, a timberman on general repair work and a car checker are employed in each reserve-drawing section. (See Hand-tramming system for further detail.) Stage 8: Cone-drifting. After all chutes in a block are drawn to the capping, the ore below the sub-level in the pillars between the motor drifts is recovered. Small, timbered "cone-drifts," parallel to drifts *C*, are driven on the motor level in the centers of the pillars (See *AA*, Fig 570). Chutes are built opposite each other in every set along the drifts. A small shrinkage stope directly over the drift is widened and carried to the sill floor of the 1st sub level. Ore is trammed to a winze at end of drift, and dumped to the motor level. When all the cone-drift chutes are drawn to the capping, the remaining pillars are mined by slicing. Thus, all ore above the motor-haulage floor is eventually recovered.

Hand-tramming system (Fig 574, 575). Development on tramming levels comprises parallel drifts *D*, 25 ft apart and connected with fringe drifts *F*, near edge of the ore

Drifts are timbered as in Fig 576, using angle braces only in heavy ground. Caps are lagged with 4 by 10-in plank; posts with 2 by 8-in, placed as indicated. Stope chutes are 25 ft apart along tramming drifts. A permanent raise *R* is put up as in the motor-haulage system, and a sub-level opened 75 to 100 ft above the tramming level. The sub-level consists of manway or ventilation drifts, 75 ft apart and directly over every 3rd tramming drift *D*; manway drifts are turned off from a drift overlying one of the drifts *F*. Vert raises, with chain ladders, are put up from *D* to the manway drifts, as in the plan, Fig 574, and in Fig 575. Stopes, 15–18 ft wide and 25 ft apart, run at right-angles to *D*, and are started from the stope chutes by driving inclined chute-raises, 2 sets (10 ft) wide, to meet raises from adjacent drifts and form hogbacks in stope floor (Fig 574). Tops of these raises are widened and stope carried up as in motor-haulage system; 3 by 3-ft cribbed manways through broken ore directly under manway raises give access to stopes. Undermining the pillars (Fig 577). Pillar chutes are built in drifts *D*, Fig 574, between the stope chutes. Raises in Fig 577 are driven from the pillar chutes, widened and blasted; remaining ore in the block (about 80% of total) is then ready to be drawn. Some ore packs in cones over the hogbacks between tramming drifts; in the higher-grade ore it is recovered by cone-drifting, as in motor-haulage system; in low-grade ore, cones and hogbacks are caved with the lift below. Dumping chutes, connecting with a motor-haulage level, are built at ends of each drift *D*, Fig 574.

VERT SEC BB OF FIG 574

Fig 575. Ray Hand-tramming System

Drawing ore differs from drawing in the motor-haulage system, because the pillar over drifts *D* is too small to take the weight off them. This difficulty is met as follows: (*a*) If large blocks are drawn evenly over their entire area, great pressure is brought upon the tramming drifts and timber repairs are excessive. Hence a "receding method" of drawing is adopted. The 2 pillars farthest from the permanent raise are caved first, and the chutes farthest from the permanent raise are drawn fastest. As soon as the first row of chutes runs capping, the next pillar is undermined and caved. Thus, no area greater than 50 to 75 ft wide is crushing at one time. A steep slope is maintained between caved ore and waste. (*b*) Rapid drawing is advisable, as it usually allows the ore from an undermined area to be recovered without timber repairs. To secure fast work and low costs, the number of trammers and muckers must be properly proportioned to the non-producers (timbermen and chute-blasters). There should be as many trammers as can work without interference. Chutes at each end of the tramming drifts facilitate rapid handling; other chutes in the middle of each drift weaken the drifts and make them crush. In one section, with chutes as in Fig 575, 8 trammers handled 97 tons aver per 8-hr shift. (*c*) Drawing operations are systematized. Owing to the large number of chutes being drawn at one time, a continuous record must be kept of each, to know constantly the tons remaining and the assay The car checker notifies the boss which chutes are ore and which waste, so that he can place his men advantageously and know when to undermine the next pillar. The boss is responsible for a steady output, the car checker for the assay value of the ore drawn. (*d*) Broken timbers in drift sets are repaired promptly, by rushing the work from each end of a damaged section; neglected repairs mean lost ore. Drifts never collapse suddenly, and those taking weight are generally detected in time to speed up the drawing and recover all the ore before they become impassable; this effects a large saving in timber repairs.

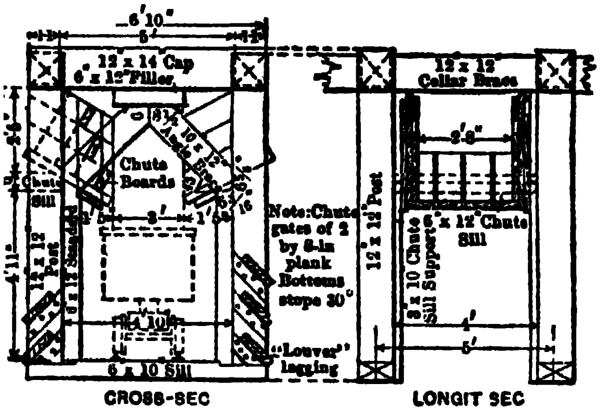

Fig 576. Ray Hand-tramming System, Drift-sets and Chute-gates

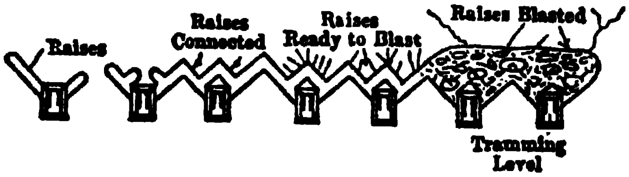

Fig 577. Ray Hand-tramming System, Undermining Pillars

Modifications of Ray system, described by G. J. Young in 1926 (593) follow. Hand tramming. Fig 578 shows procedure in soft ore. Layout of tramming drifts, sublevels and raises is as in Fig 574. Shrinkage stopes *S* are put up to the capping at intervals of 50–75 ft. The block between caved ground and nearest stope is undercut from raises 15 ft c–c along tramming drifts. These blocks are drilled with fan-shaped rounds and blasted successively, starting next to stope and working toward the cave. Drawing chutes are built in each set in the tramming drifts. When a block is completely undercut, drawing retreats from the cave to next block. This plan lessens dilution by waste. Motor-haulage is also modified in soft ground, to increase percentage of ore broken by caving. Every 3rd shrinkage stope reaches the capping; intervening stopes are only 25 ft high, their backs being drilled with fan-shaped rounds to break the 10-ft pillars between them. The pillars are also undermined on 1st sub-level (Stage 6 above). Shrinkage stopes are also carried up on the sides of blocks thus mined, each block being cut loose from surrounding ore on all 4 vert sides.

Fig 578. Modification of Ray Hand-tramming System for Soft Ground. (Perspective view)

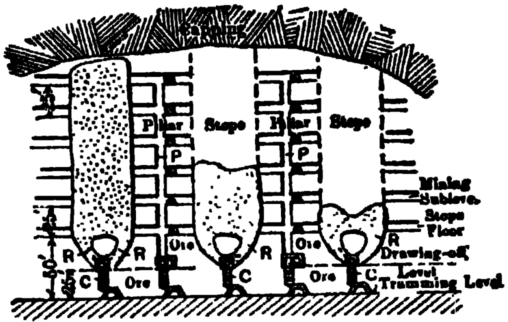
Summary. The Ray systems have been used in both hard and soft ground. Large tonnages are produced per man; as stopes and pillars are mined systematically, the men soon become proficient. Timber consumption is relatively small; the amount of raising and drifting compares favorably with that of other methods in similar orebodies. The systems are flexible as to output; practically any number of men may be used during active operations and a corresponding tonnage produced.

Motor haulage is applicable only to orebodies of large area and of a height exceeding 100 ft; otherwise the cost of driving and timbering the stope laterals and of equipping and maintaining the haulage levels is not justified, and HAND TRAMMING is more economical. ADVANTAGE OF MOTOR HAULAGE: it is suited to large outputs, especially during reserve drawing, when the output is limited only by the efficiency of the haulage and hoisting plants. ADVANTAGES OF HAND TRAMMING in smaller and thinner orebodies: (*a*) lower initial development cost; (*b*) less timber required; (*c*) higher extraction, as chutes can be built in every set in both the original drifts and cone-drifts. With motor haulage, the pillar between the sub and motor level is dangerously weakened if chute-raises are spaced too close; (*d*) blocks of ore can be opened and production started sooner. DISADVANTAGE OF THE RAY SYSTEM is that a large amount of capital is tied up in the broken ore for a considerable time. This is a drawback of all shrinkage-stope and pillar-caving methods (compare with disadvantage *d*, Art 69).

86. PRACTICE AT MIAMI COPPER MINE, ARIZ

Orebody (Art 80). System described below was applied from 1910 to 1916, incl, to a block of relatively hard ground in the western end of the property containing 2 300 000 tons. See Art 72, 80, for methods used in other parts of orebody.

General plan. Shrinkage stopes and pillar-caving were used; stopes, 50 ft wide and 200 to 500 ft long; pillars, 50 ft wide. Originally the pillars were to be mined by sub-level stoping (Art 43), leaving broken ore in the stope, but it was difficult to drill "down" holes, and a shrinkage-stoping and sub-level caving method, similar to that at Kimberley (Art 88), was finally adopted. Ore was drawn simultaneously from both shrinkage and pillar stopes, to make the capping settle evenly. This was called locally the WIDE STOPE AND PILLAR SYSTEM. Following data are from D. B. Scott in 1916 (154).



CROSS-SEC THRO STOPES AND PILLARS

Fig 579. Miami Method

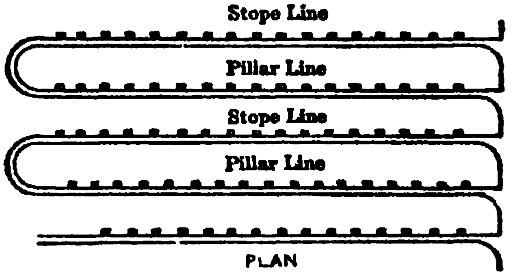


Fig 580. Miami Method, Part of Tramming Level

Development comprised a haulage level, a drawing-off level, the sub-levels for stoping, and raises for handling ore and for access to stopes (Fig 579). Added sub-level drifting was necessary to determine the boundaries of the orebody; its general outline was found by churn drilling (Art 10-b). HAULAGE LEVEL was 50 ft below the stopes. By drifting under the long axes of both stopes and pillars (Fig 580), trains of cars could be loaded along an entire stope without uncoupling; this allowed the rapid drawing of excess ore so desirable during stoping. Also with chutes 25 ft apart, this plan required a minimum amount of development. 10 by 10-in timber was used in haulage drifts, with 9-ft posts and 8-ft caps; sets, 6.25 ft apart (Fig 634, Art 90). DRAWING-OFF LEVEL, a distinctive feature of this method, was 25 ft above the haulage level; it consisted of drifts parallel to those on the haulage level, with a fringe drift at each end for entry and ventilation (Fig 581). Drifts were on center lines of stopes to secure a symmetrical arrangement of raises for drawing ore (Fig 579). For convenience in putting up vert development raises in the pillars, the pillar drifts were 5 ft off the pillar axes; this arrangement was later modified so that symmetrical drawing raises were possible also in the pillars. The drawing-off level drifts were timbered with 10 by 10-in sets 5 ft apart, using 8-ft posts and 7-ft caps. In some drifts, these sets were almost intact after nearly 2 years. Experience showed that a min amount of lagging should be used on these sets, that it should be light (2-in) and spaced 2 or 3 in apart. (For timbering at chutes, see Fig 582, 584). RAISES. Chute-raises *C*, Fig 579 ("pocket chutes"), were 25 ft apart. They were 5 ft square, each holding 15 tons; for cribbing, 8 by 8-in timber proved most economical, a representative group of chutes showing a cribbing life of 12 430 tons each. Grizzlies with 18-in sq openings were placed on the drawing-off level; they were set several inches above the collars of the raises, to permit easy working when the grizzlies blocked. Inclined raises *R*, Fig 579 ("stope raises"), were driven from the drifts to the stope floors at points over the pocket-chutes. Originally, vert raises were run from the back of drift to center line of stope; they proved difficult and awkward to draw. Stope raises (untimbered) were 6 ft sq at the bottom and funneled at the top. Development raises *P*, Fig 579, were 50 ft apart along center lines of pillars. During pillar-mining, intermediate raises reduced the interval to 25 ft. Raises (not shown in Fig 579) similar to the stope raises were put up under the pillars from the drawing-off level. In earlier work they were in the plane of the stope raises (Fig 581); later, in planes halfway between the latter (Fig 583), an arrangement probably more effective in drawing ore. "Pony raises," largely used in drawing pillar ore, and located midway between the regular raises (Fig 581), were put up from "pony sets" (Fig 584). This allowed ore from pony raises to run on slides to the pocket chutes, and doubled the number of openings into the floor of the pillar. The pony sets, of 12 by 12 timbers, were 8 ft high inside, which was found better for both drawing and repairs then 6-ft sets. Sub-levels were opened in the pillars from raises *P*, at vertical intervals of 25 ft (Fig 579). Drifts were driven on the long axes of the pillars to the ore limits, with crosscuts 50 ft apart to the stope boundaries. This plan was selected as best, after trying several others. As originally planned, the Miami method called for continuation of the crosscuts across the stopes, but they were abandoned on finding that they could not be economically used as points of attack. **Development ratio.**

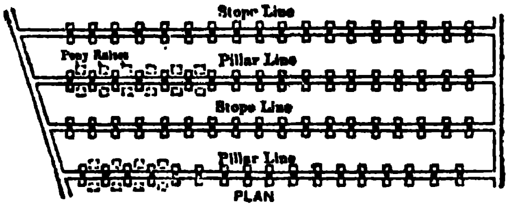

Fig 581. Miami Method, Part of Drawing-off Level, Directly over Fig 580

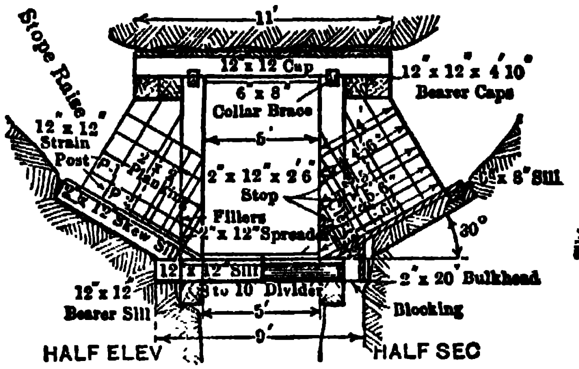

Fig 582. Miami Method, Chute-sets on Drawing-off Level

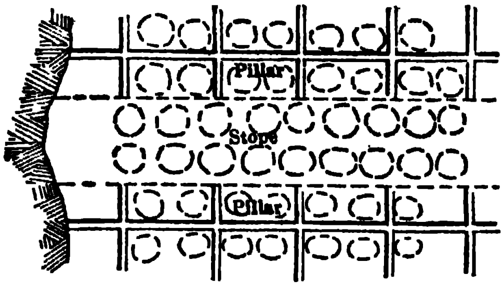

Fig 583. Miami Method, Plan of Stope Floor

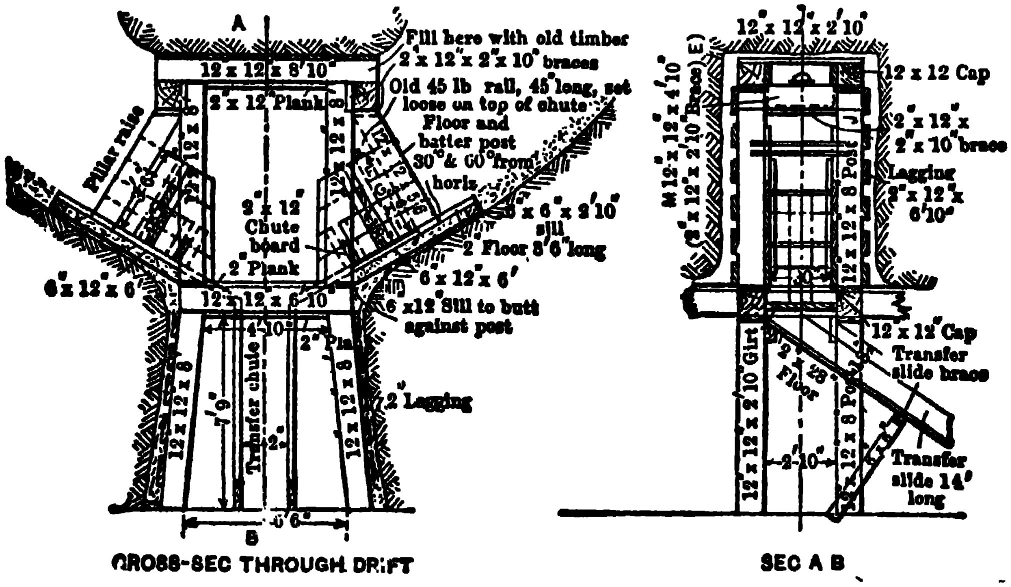

Fig 584. Miami Method, Pony Sets, Chute-gates and Transfer Slides in Pillars

Including all openings in stopes and pillars, 45 tons of ore were developed per ft of drift and crosscut, and 200 tons per ft of raise.

Shrinkage stopes were started by funneling the raises to a top diam of 15 to 20 ft; their rims practically touched over the whole stope (Fig 583). Funneling was done by uppers drilled from a set-up in the raise; down holes around the collar were unsuccessfully tried. The sides of the stope (50 ft wide) were next squared up, and stubs between funnels blasted out. This excavation connected with the pillar crosscuts on the 1st sub-level, which served as entries to the stope. Fig 585 and 586 show steps in the mode of breaking ground. Drilling began along the stope sides, as in Fig 174, Art 28. The swell of broken ore was 39%; enough was drawn to keep a 6 to 8-ft space under the back. Max height of stopes, 125 ft; in most cases, ore was broken to the capping, completed stopes being left full.

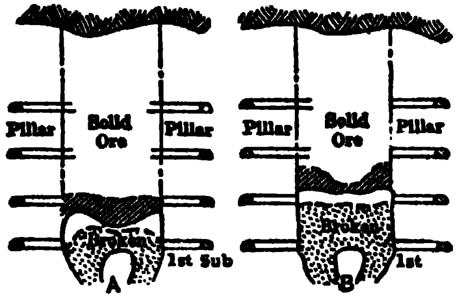

Fig 585. Miami Method, Successive Steps in Breaking Ground

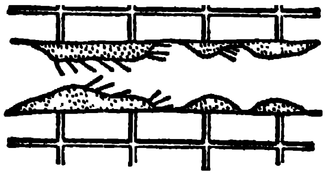

Fig 586. Miami Method, Horiz Sec through Stope, showing Drill Holes

Pillar-mining began at the edge of the ore on the top sub, and progressed downward and along the pillar (Fig 587), to provide a safe exit and insure even settlement of capping (compare Kimberley method, Art 88). As pillars took weight when the capping over them was dislodged, they had to be mined quickly. Hence 3 or 4 sub-levels were attacked simultaneously, the working faces on adjacent subs being kept 100 ft apart. In mining pillars, crosscuts were driven halfway between the original ones, to furnish more drilling faces. After crosscutting was well advanced on the top sub, the end of the pillar was undercut by uppers drilled outward from the faces of the central drift and the end crosscut. Enough shoveling was done for setting up drills on the broken ore, and long holes were put in the back. Usually, no ore was broken on the highest sub nearer than 10 ft to the capping. Similar working faces sloping about 45° (Fig 587) were opened successively at the end of the pillar in lower subs. Fig 588 shows routine of drilling in retreating along a sub. The first round from the drift and crosscuts broke to about 12 ft above the sub; the 2nd round, for which long bits could be used, increased this height to 20 ft. Holes were often drilled to the broken ore above, but the remaining 5-ft arch usually caved. Attempts were made to drill 5-ft holes in the floor of the sub, to assist subsequent caving of this arch, but the ground "raveled" so badly that the collars of these holes had to be cased with 3-in pipe to prevent fitchering. These holes broke poorly and were given up. Excess ore was shoveled to raises *P*, Fig 579, and to intermediate raises in the pillars. Just before each raise was abandoned and covered by broken ore, lagged stulls were placed in it about 5 ft below the sub-level. This is important in pillar-mining; if raises were not covered, the capping would "pipe" down through them and prevent proper breaking. As each raise was reached in mining on the next lower sub, a similar stull platform was built, and the stulls above were blasted out. Mining on the lowest sub, or sill-floor of the pillars, was subject to modifications imposed by the pony raises, which halved the distance between the regular 25-ft drawing raises. All raises were funneled in retreating

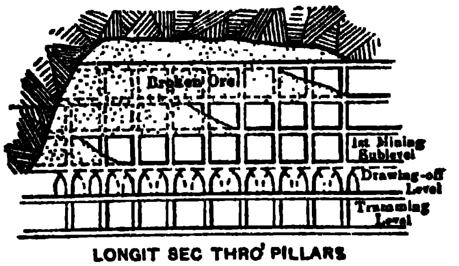

Fig 587. Miami Method, Mining Pillars

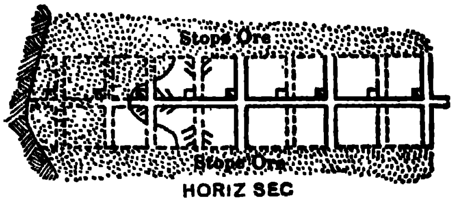

Fig 588. Miami Method, Drill Holes in Pillars

from the end of the pillar. Funneling was not carried more than 25 ft ahead of pillar breaking, because it undercut the entire width of pillar. To protect drillers in case broken ore settled suddenly in the raise, machines for drilling the back were set on 10-in stringers across the funnels.

Drawing broken ore systematically began on completion of about 70% of all stope and pillar-mining; no drawing was permitted within 100 ft of any active mining. Drawing of a stope next to a pillar in process of being broken was tried, and caused the pillar to crush and sway. The weight on the drawing-off level during the drawing period varied greatly at different points; at first, some ground was very heavy, with apparently no weight in other places. Probable causes: (*a*) Combined height of capping and ore in northern part of section mined was 465 ft; in southern part, 350 ft. In the northern section, some drifts required complete retimbering; in the southern, only 20% needed repair. (*b*) In one small section, the pillars could not be broken from top to bottom; drawing-off drifts below unbroken blocks were always heavy, probably due to unequal distribution of the weight. In a large area, where all conditions were good and the pillar breaking most complete, about 70% of the timber on the drawing-off level was still standing after 3 years. (*c*) Weight on drawing-off drifts decreased after drawing on a large scale had progressed over a considerable area, probably due to a wide and even distribution of weight.

Pillars between drawing-off drifts took little weight. The drawing-off level is advantageous in taking pressure off the haulage level, sections of which were intact after 5 years, even beneath badly crushed drawing-level drifts. The max repair cost in any drawing-off drift did not exceed 10¢ per ton of ore drawn on it; the aver was much lower. Drawing operations were conducted so that the surface between broken ore and capping dipped about 15° W. Hence the final stages were reached first at western boundary and retreated eastward. Drawing was planned to cause even settlement of the capping. The ore ran most freely when drawn from a series of chutes in a plane at 90° to the direction of retreat, or crosswise instead of along a stope or pillar. In some stopes, the ore packed tightly in the chutes in the long time elapsing between stoping and drawing. To start such chutes, pony-set raises were sometimes put up from the drawing-off level halfway between the drawing raises. Inclined raises 15 ft long were driven on each side of the drift to broken ore on the stope floor. The tops of the raises were funneled just before they broke into the stope; blasting of funneling rounds loosened the broken ore above and usually that in the adjacent drawing raises. This method had the disadvantage that the pony sets took weight and were expensive to maintain. To start the flow of ore in packed chutes without extra raises, the back of packed ore over the drawing raises was temporarily supported by heavy stulls. Small drifts were then driven in solid ground, parallel to the long axis of the stope and about 15 ft above the drawing-off level. These drifts connected a series of hung-up raises. Starting at the end of the drift, vert and horiz holes were drilled across the stope; these blasted out the legs between the regular raises and left an arch of broken ore which always collapsed, bringing down the stope ore. No accidents occurred in working under the packed ore.

Cost of drawing ore. In 1 yr, the aver rate of drawing about 400 000 tons of ore into pocket chutes was 118 tons per man-shift; monthly averages, 94 to 142 tons. These figures include all labor directly employed in drawing. Under very favorable conditions the tonnage per man for several shifts exceeded 200 tons. Aver cost of drawing this ore into the chutes was 3.7¢ per ton, for labor and explosives. Where chutes hung up, the cost for short periods reached 15¢ per ton. (Costs prior to 1916.)

Extraction was 95% of the total tonnage in a block of 1 700 000 tons. Detailed data showed the recovery from stopes was about 10% greater than from pillars; some pillar ore was undoubtedly drawn through the stope-chutes and *vice-versa*. Extraction and ease of drawing improved with the hardness of the ore; soft ores were more apt to pack. In a few chutes where the ore was tightly packed, drawing removed a cylindrical mass of ore about 14 ft in diam, extending to the capping. This tendency of chutes to "ravel" to the capping without drawing from the sides is greatest in soft ores which are compressed by pressure; raveling may contaminate large tonnages of ore with capping. These facts suggest that many raises per unit of area tend to a higher extraction than fewer with large funneled mouths.

Secondary recovery of ore. After finishing drawing, some broken ore remained in wedges over the drifts and along boundaries of stopes and pillars. Ore above the drawing drifts was recovered by shooting down their backs, retreating from the ends of the drifts. In this work, the output per man-day averaged 40 tons. To recover ore along old pillar lines, intermediate drifts were driven between the original drawing-off drifts. Chute- and supply-raises at 200-ft intervals were put up to these drifts from crosscuts in the tramming level. The drifts were supported by 12 by 12-in sets, 4.16 ft apart. Chute-gates were built in each set. A shrinkage stope 20 ft wide was then carried above the drifts until loose ground was met or caving occurred. The ore was trammed in small cars to the raises, the max tram being 100 ft.

Undercut caving with hand-tramming later replaced above-described method; for details, see Bib (601). For more recent applications of block-caving, see Art 80.

87. MISCELLANEOUS EXAMPLES OF PRACTICE

Braden mine, Sewell, Chile. Data from J. S. Webb and T. W. Skinner (289) in 1932. For geol features and block-caving, see Art 80. SHRINKAGE-STOPE AND PILLAR-CAVING, closely resembling Ray system (Art 85), was used prior to block-caving. Original stopes, normal to strike, were 7 m (22.95 ft) wide, separated by 10-m (32.8-ft) pillars, and were carried to a vert height of 100 m (328 ft). As these pillars tended to arch and failed to cave properly, their thickness was reduced to 5 m, stope width being kept at 7 m. Caving of pillars still proving unsuccessful, their width was reduced to 3 m, and the stope width to 5 m, with satisfactory results. DEVELOPMENT. Stopes and pillars were originally developed by crosscuts *C* (Fig 589), at intervals depending on stope and pillar dimensions. Each crosscut served 1 stope and the pillar in which the crosscut was driven.

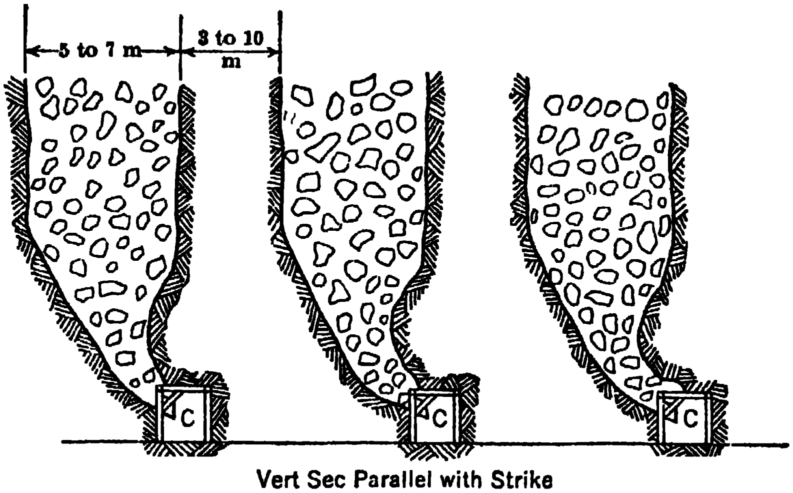

Fig 589. Original Development by Crosscuts, Braden Mine, Sewell, Chile

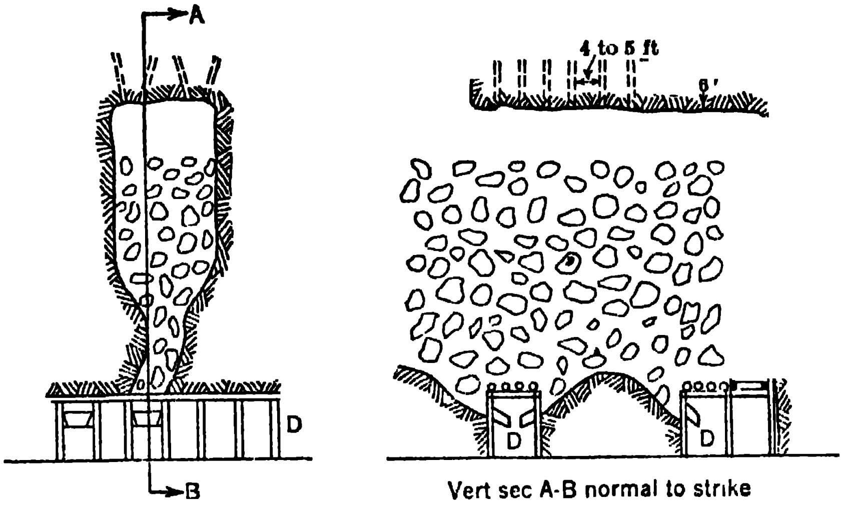

Fig 590. Spacing of Drill Holes in Shrinkage Stope, Braden Mine, Sewell, Chile

Difficulty in maintaining crosscuts during pillar-caving led to replacement of crosscuts by drifts *D* (Fig 590) on 8 or 12-m centers, direction of stopes and pillars remaining normal to strike. SHRINKAGE STOPING. Access was by cribbed manways *M* at each end of stope. In shrinkage operations, miners worked in pairs, drilling per shift a section of back about 10 m long. Stoper-drill holes, 6 ft deep, were spaced 1–1.25 m apart longit, and in sets of 4 (Fig 590), 2 cut and 2 side holes; 15–20 holes were drilled per machine-shift, breaking an aver of 70 tons, of which about 28 tons could be drawn. **Pillar caving** began by driving a 2 by 2-m sub-crosscut *C* (Fig 591) along center line of pillar just above the drift sets. Starting at the hanging wall, the tops and sides of sub-crosscuts were drilled and blasted in 6-m sections until the entire pillar base was weakened. Subsequent drawing caused complete breaking up of the pillar.

Coronado mine, Clifton, Ariz (599); part of Phelps Dodge Corp; work in this property stopped about 1923. Cu ore occurred in a steep fissure. Shrinkage stopes, with intervening pillars which were caved and drawn with the stope ore, were used in one area where ore was siliceous and quite hard. Pillars were 25 ft long; stopes 40–160 ft long; height of lift, 100–150 ft; width of vein, to 40 ft. Branched raises were put up from a haulage level to a drawing-off level 45 ft above; their tops were connected by timbered crosscuts, from which stopes were opened; access to stopes was by manway raises and breakthroughs in the pillars. Before drawing, the pillars were undercut and also cut free on top; pillar ore was drawn at same time as the stopes. Output, about 14.5 tons per man-shift.

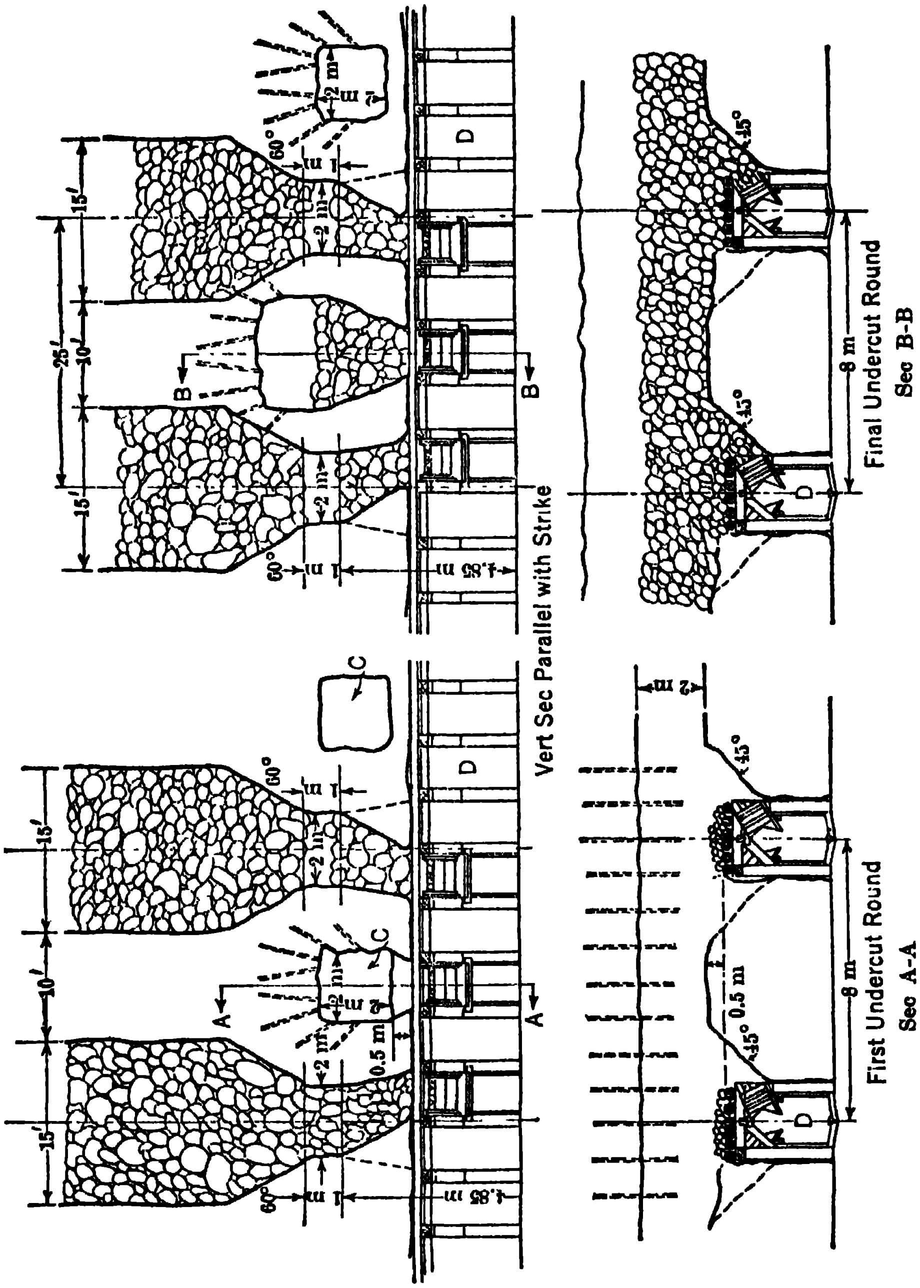

Fig 591. Method of Undercutting Pillars, Braden Mine, Sewell, Chile (289)

Humboldt mine, Phelps Dodge Corp, Morenci, Ariz; operations suspended in 1932. Data from M. Mosier and J. Martin in 1925 (600). Orebody is large and carries about

2% Cu; ground harder than in most "porphyry" mines; Art 73, 80 give details and other methods used. The timbered-slide method (Art 80) was used above the 350-ft level to "base-level" the deposit there. Following method, locally called "Morenci block-caving," used on lower levels, combined shrinkage-stope with pillar-caving, somewhat like the Ray (Art 85) and the Inspiration (Art 80); where ore was weak enough, it was modified to straight block-caving into chutes (Art 79). Development. Levels comprised haulage drifts 56 ft apart. At first, branched raises sloping 60° (Fig 592) were put up from the drifts at 28-ft intervals to a grizzly level 45 ft above; these proved too flat, and caused clogging. Later practice (Fig 593) was satisfactory in reducing total footage of raises 40% and their cost 50%. Two grizzlies, of 50-lb rail with 10-in openings, were placed over each raise, with 2 finger raises from each grizzly to the undercutting level 20 ft above; this spaced the finger raises on the undercutting level on corners of 14-ft squares. Height of lift (Fig 592), 145 ft; later increased to 200 ft. Stopes were in panels or blocks. First step was to put up, on sides of panel, boundary shrinkage stopes, 8 ft wide, to a height 10 ft below top of block. Next, transverse shrinkage stopes, 18 ft wide and at least 70 ft high, were driven successively, leaving 10-ft pillars. These stopes were opened from drifts and crosscuts connecting tops of finger raises. Access to stopes was by small pilot raises to the level above. Undercutting. A pillar was undercut when stopes on both sides were completed. Drawing. See Art 79 for percent extraction and detail of practice in block-caving, which applies also here. Table 59 gives slope of contact between waste and ore in stopes during drawing. In drawing a stope with a high lift, a wedge of broken ore was left on sides of the block next to future stopes; slope of such wedges was steepened to 70°, to minimize amount of ore tied up; wedge was drawn with ore from the later stopes. Fig 594 shows modifications of stope and pillar widths to suit strength of ore; in softer ground, ore would cave if cut loose by boundary stopes and undercut; method then be-

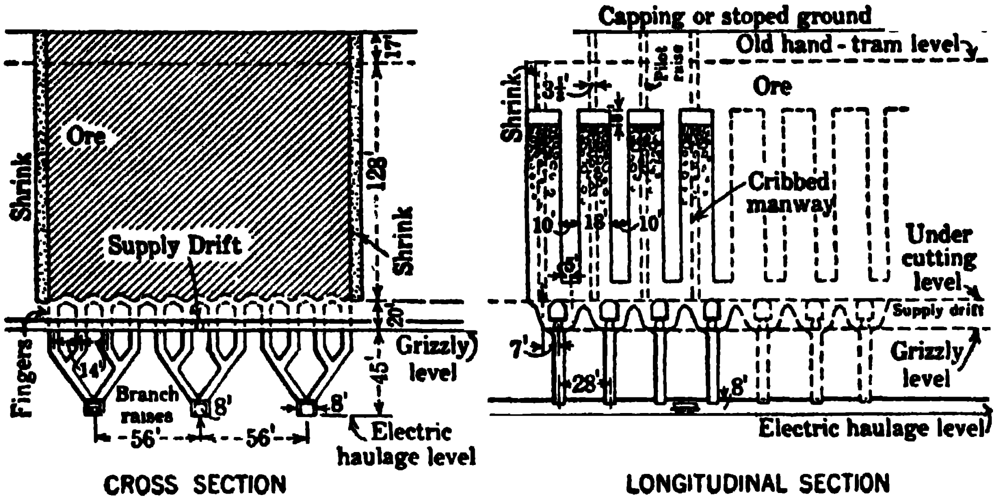

Fig 592. Pillar-caving, Humboldt Mine, Ariz (600)

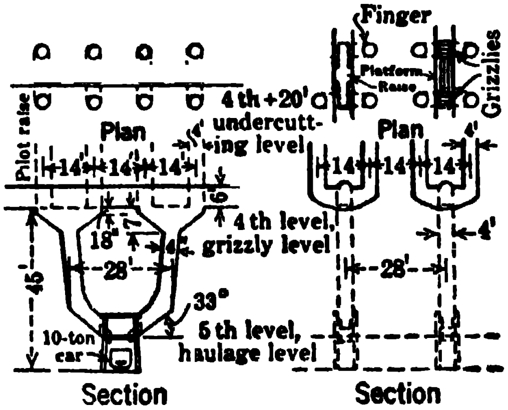

Fig 593. Haulage-level Raises, showing Fingers and Grizzly Stations, Humboldt Mine

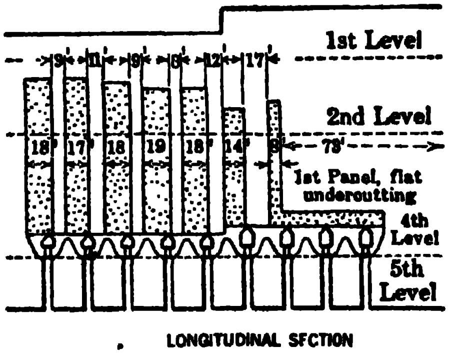

Fig 594. Change from Shrinkage Stopes and Pillar-caving to Straight Block-caving, Humboldt Mine

came straight block-caving. In such cases, horiz undercutting was done by connecting tops of finger raises by drifts and occasional crosscuts, belling tops of finger raises, and shooting pillars simultaneously in areas 56 by 14 ft. Operating data in Table 60. For further details see Bib (99, 600).

Table 59. Slope of Contact Between Caved Ore and Waste During Drawing, Humboldt Mine, Ariz

Number of stope	Height of lift, ft	Character of ore	Method of mining	Drawing time, months	Slope of contact between caved ore and caved capping during drawing (a)		
					Max, deg	Min, deg	Aver, deg
1-48	55	....	*TS*	8	70	47	60
A-38	70–100	*H*	*TS*	10	88	55	72
A-48	55	(*b*)	*MI*	12(*c*)	76	62	69.5

Duluth mine, Cananea, Mex. Data from R. L. Herrick and M. J. Elsing in 1909–10 (282, 284). Orebody (see Art 72) was about 1 100 ft long; width, 60 to 100 ft, aver, 75 ft; it dipped steeply and was overlain by 40 to 150 ft of leached capping. The ore was hard and brittle; ore and capping broke well and stood over large openings. The mine is no longer active. General plan. Top-slicing was used in the eastern part of the orebody, in lenses separated by porphyry horses (Art 72). In the western end, where there were no horses and the ore was fairly uniform, a combined method was employed (Fig 595). Open square-sets (Art 45) were used where possible above level No 1, as the ore near the capping was the richest in the mine Shrinkage stoping and pillar-caving were employed in the larger blocks (Fig 596). On completing the square-set stope over the block, the timbers were removed and the stope left open. Drifts and crosscuts, 5 by 7 ft, 45 ft apart, were driven on level No 2, underneath the block, dividing the ore into 40-ft square pillars. Raises *R* (chute and ladderway), timbered with square-sets 2 sets high, were put up from drifts and crosscuts; one raise was carried to level No 1 for ventilation. From *R*, 16 ft above level No 2, a sub-level was opened by drifts and crosscuts directly over those on the level. These openings, 10 to 15 ft wide, served as floors for shrinkage stopes of the same width, carried up to level No 1. Chutes *C*, over raises *R*, were for entry and for handling the excess ore. Chutes were lined with 3-in plank set on edge, with ends beveled at 45°. These stopes cut the block into 6 pillars *P*, 25 to 30 ft sq and 85 ft high, free at the top and supported on the sides by the broken ore. The tops of raises *R* were funneled (Fig 596) and the ore was drawn. The chute lining came down with the ore; end pieces and dividers and about half the side pieces were recovered. Pillar-caving. The ore often contained small fractures, causing pillars *P* to break and fall into the stopes during drawing. If it were known that the pillars would not break, they were undercut before drawing. Drifts and crosscuts on the sub-level floor divided the base of the pillar into small units. which were blasted out before

drawing began. Broken pillar ore was drawn through inclined raises to the sub-level floor from the openings on level No 2. If a pillar had not been undercut and did not break down during drawing, a drift was run below it on level No 2 and raise *S* was put up (Fig 596). The base of pillar could then be blasted by holes drilled from the raise, or in drifts and crosscuts driven from it. **Advantages** of shrinkage stoping and pillar-caving as practiced in Duluth mine: (*a*) it is cheap, because of the mode of breaking ground and of its small timber consumption; (*b*) ventilation is good; (*c*) it is safe if properly applied. **Requirements** for this application of shrinkage stope and pillar-caving: (*a*) orebodies of large area; (*b*) orebodies with definite boundaries; (*c*) ore that will stand unsupported in the stope backs; (*d*) ore of fairly uniform grade, little sorting being possible underground; (*e*) ore which will not pack; (*f*) capping that will stand unsupported while mining the blocks. These requirements being evidently rigid, the method in this form has a limited application.

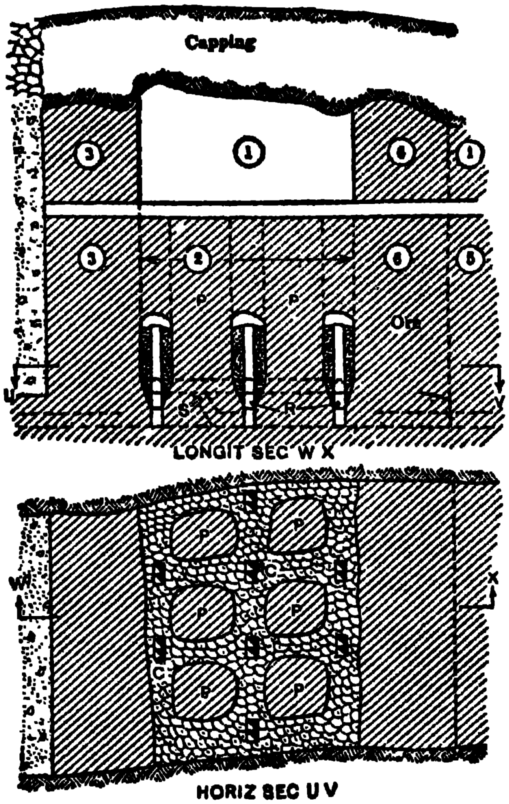

Fig 596. Duluth Mine, Pillar-caving in Block No 2, Fig 595

Magma mine, Ariz. Data from W. C. Browning and F. W. Snow in 1925 (574) and from Snow (77) in 1929. Orebody is a steep-dipping fault-fissure, carrying in places 6% Cu, with some Au and Ag; width, to 45 ft. For some areas requiring close timbering, rill stopes are used; in firmer ground, a combined method (Fig 597), which comprises transverse filled-rill stopes, separated by pillars mined later by a modification of Mitchell slicing (Art 55). **Stopes** are usually 16 ft wide along the strike and separated by 14-ft pillars; but, in vein-widths of 10–15 ft, stopes are longit and distance between pillars reaches 45 ft. Experience indicates that 16 ft is max safe width of open stopes. Level intervals of 100–300 ft have been tried, but 200 ft has proved best. Level development comprises: drift *D* in footwall, with crosscuts to orebody about 150 ft apart; extraction drift *L* in ore along footwall; and crosscuts 30 ft c-c, on center lines of stope sections,

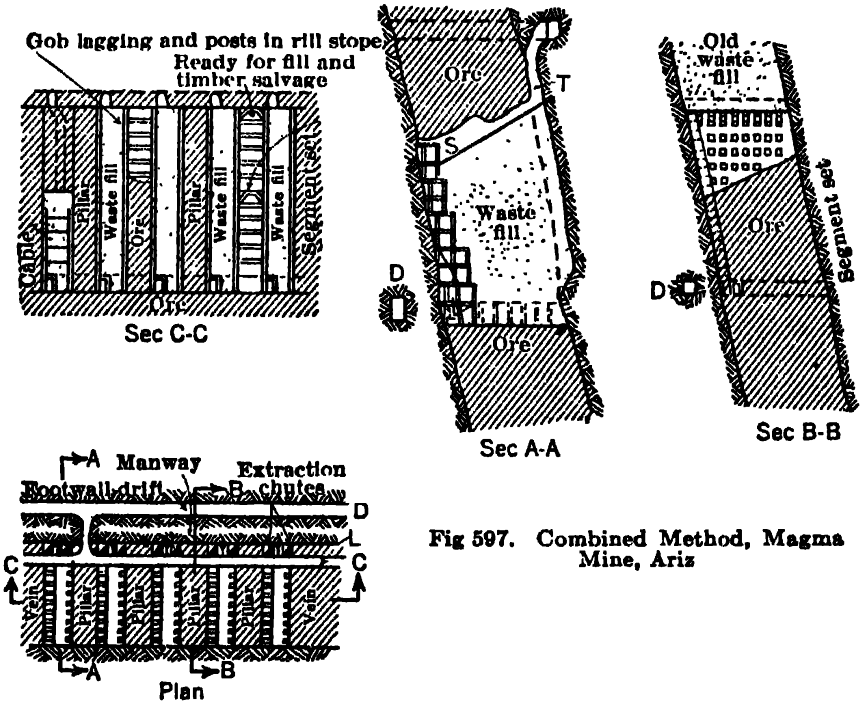

Fig 597. Combined Method, Magma Mine, Ariz

driven to hanging wall. Sill-floor of stope is cut by widening crosscut to 8 ft on each side of center line and raising the back to height of 10–12 ft. Stringers, 10 by 10 in by 16 ft long, are placed on sill-floor, parallel to strike, at 5-ft centers, and covered with a double floor of 2-in plank. Square-set raise *S*, started at footwall and carried up with stope, has 3 compts; outside sets are chutes, the center set a manway. Square-sets are also erected on the sill-floor along one side of stope; square-sets are lagged and held open as a crosscut; 8-ft posts are stood along other side and lagged, to retain waste when adjacent pillar is mined. After sill-floor timbering is placed, a small waste raise *T* is started in hanging wall. Stope is then carried up as a filled-rill stope, taking slices 7 ft thick at a 35° angle. As the stope goes up, a "gob line" is established along each pillar by standing posts on those below and lagging them. Ends of posts are halved into each other; before a layer of filling is run in, a strand of old cable is tied around each joint and to the joint between corresponding posts on opposite side of stope. Stope backs are arched to the hanging wall; when highest point of stope is about 35 ft above sill-floor, raise *T* is holed through to level above; thereafter, waste filling comes from outside sources. Filled square-sets are used to extract ore under the floor timbers of filled stopes on level above. PILLARS ARE MINED by modified Mitchell slicing (Art 55). Segment sets (Fig 597, sec C–C) are placed at top of pillar, under the sill-floor timber of overlying stope, and between the posts set in the gob lines of adjacent filled stopes. Work starts at footwall and stope floor is kept sloping (Fig 597, sec B–B), so that ore will slide to the square-set raises that were used for the stopes on each side of the pillar. Another line of segment sets is put in for safety, 50 ft below top of pillar; if necessary, a floor can be laid at this point and the space above filled with waste. After pillar is mined, the entire space is filled and 75% of the stringers is recovered. Pillar-stope crew includes 2 miners and 1 mucker; good crew will mine 16–25 tons per man-shift.

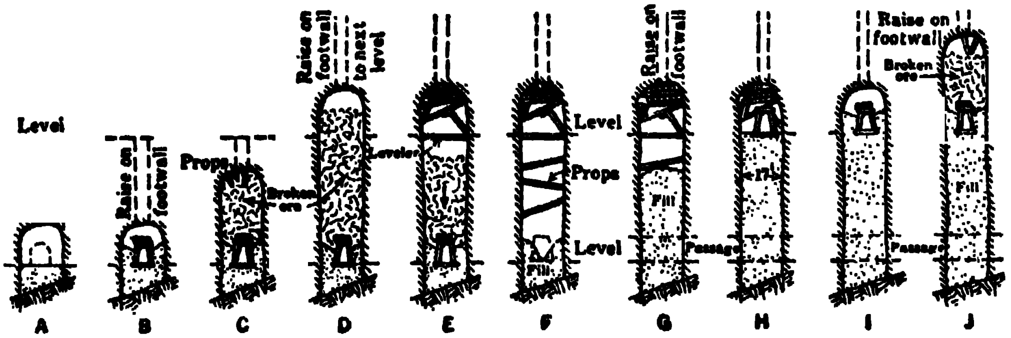
Silver Dyke mine, Neihart, Mont. Data from G. J. Young in 1927 (603). OREBODY is a massive deposit of low-grade Cu, Pb and Zn ore, in altered quartz porphyry and gneiss; roughly elliptical in plan; max length, 600 ft; width, 400 ft; developed depth, 250–300 ft. Mine has been inactive for several years (1938). GENERAL PLAN of mining (Fig 598–600) was to undercut a block from inclined raises, after carrying up and drawing shrinkage stopes around the periphery. Stopes were widened by blasting of churn-drill holes drilled from surface; eventually the whole block caved and was drawn. DEVELOPMENT. Mine was opened by adits. From the lower one drifts were run at 80-ft centers. Two drifts were connected by a loop (Fig 598); others were to be extended as needed. Vert chute-raises were at 25-ft intervals along drifts; chutes were either single or double, well timbered, and contained a small ore pocket under a grizzly for bulldozing. Fig 599 shows rock limits of a double chute. ISOLATING STOPES (Fig 598, 600). From top of each chute raise, two 45° raises connected above the center of drift. Shrinkage stopes, 20 ft wide by 50–60 ft long, were put up from these raises

60 ft above each drift. Stopes were widened to 40 ft by blasting bottoms of the churn-drill holes drilled from surface as shown; ore was drawn after each blast. Narrow pillars between stopes were then broken by churn-drilling, leaving a horseshoe-shaped open stope isolating a central pillar *P* (Fig 598), about 60 ft thick. Undercutting. Drift *D* (Fig 600) was driven about 40 ft above grizzly level, and connected to each chute by inclined raise *R*. Undercutting started at inner sides of open stope, which were drilled and blasted from bottoms of raises *R*; work retreated upward to drift *D*. Complete undercutting produced condition shown in *B*, Fig 600. It was expected that caving would extend to surface, the resulting pit to be enlarged as an open-cut, if desired, by churn-drilling. Aver cost of mining for 8 mos in 1926 was 42¢ per ton, including overhead, plus about 30¢ per ton for development. Production, 700 tons per day.

New Jersey Zinc Co, Franklin, N J. Data from C. M. Haight and B. F. Tillson in 1917 (522) and R. B. Paul in 1938. Orebody is trough-shaped, of franklinite, willemite, zincite and calcite, in crystalline limestone; it has sides of unequal height and pitches at a gentle angle. The ore in the legs of trough is 12 to over 100 ft thick, compact and tough, but not very hard (307, 98). General plan of mining. Entry is by a 1 500-ft inclined hoisting shaft and 2 inclined service shafts. Level interval, 50 ft. In wide parts of deposit, a combination of shrinkage-stoping and top-slicing is employed; ore is high-grade, hence the method is planned to give complete extraction. Shrinkage stopes, 17–18 ft wide, are run from wall to wall, leaving 20–60-ft (aver, 35-ft) pillars. On completing and drawing a 50-ft lift, stopes are filled with waste from surface, and lift above is started.



A. Drift widened, bottom filled. B Sets on fill, footwall raises. C. Stope being carried up. D. Stope finished, 15 ft or more above level. E. Pulling stope, back taken up, levelers placed. F. Stope finished, with props to hold sides. G. Stope being filled, with passage on lower level. H. Stope filled, sets erected, ready to take out timber. I. Fill behind sets, ready for mining. J. Stope going up to repeat cycle.

Fig 602. Transverse Stope, N J Zinc Co, Longit Secs

Fig 601, 602 show mining and filling operations in transverse stopes; novel features are: (*a*) only one cutting-out stope is required, that is, at bottom of the deposit; before ore is drawn, stopes are carried from one level to a height 15–18 ft above next higher level; a timbered gangway is built on the fill to serve the lift above; (*b*) stope backs are timbered prior to drawing, for safety and to support a track on which waste fill is trammed into the stope. Mining of pillars is started from top downward, after the stopes at one end of orebody are completed. Fig 603 shows one method of mining pillars. Crosscut *A* is driven from wall to wall on center line of pillar; entrance raise *R* is put up in footwall; chute-raises *S* are vert except the one at footwall contact; they are 20–30 ft apart, and each has a chute *C* at its bottom; in wide pillars, 2 lines of raises are driven, as in Sec *A–B* (2) of Fig 603. Three 4 by 6-ft sub-level drifts *D* are driven in each 50-ft lift. In opening a slice, "center drift" *E* is advanced to hanging wall, at full height of slice

Slicing to sides of pillar begins at hanging wall, retreating to footwall; stope fill is breasted back with lagging. Except in long pillars, each slice is completed before another begins.

Golden Queen mine, Mojave, Cal. Data from C. E. Julihn and F. W. Horton (309) and C. A. Kumke (310) in 1937. Quartz vein, carrying $10-$12 per ton in Au, is in felsite. Hanging wall, very hard and well defined, dips 50°–70°. Footwall is not well defined; its limits are determined by assays. Width of ore is 10-40 ft. Vein is fractured, but can be mined by ordinary shrinkage where narrow; difficulties met in shrinkage mining, when ore widened unexpectedly, led to a novel method known locally as "slot" system, combining square-setting with shrinkage or cut-and-fill methods. DEVELOPMENT. As topography is steep, entry is by adits at 200-ft vert intervals, with intermediate levels halfway between. Drifts are driven along footwall and sometimes also along hanging. STOPING. In the "slot" system, square-set stopes, 1 set wide and without fill, are

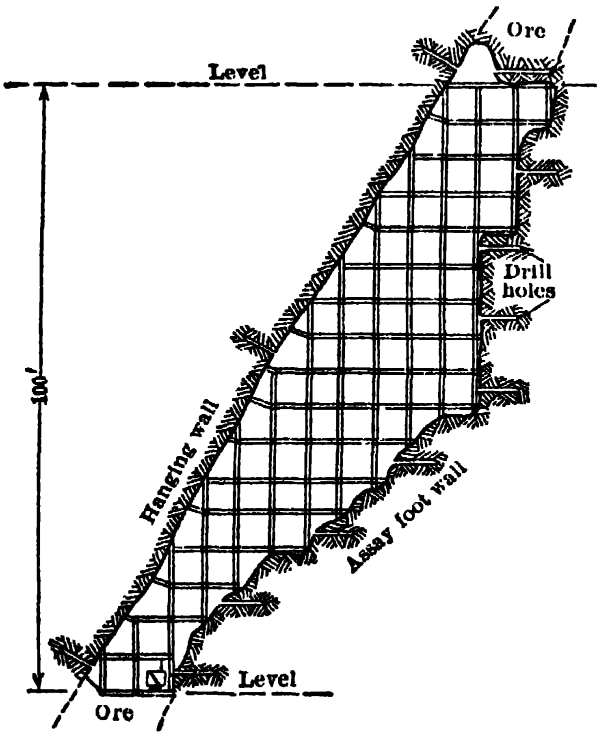

Fig 604. Prospecting Walls by Drill Holes in Mining "Slot," Golden Queen Mine (310)

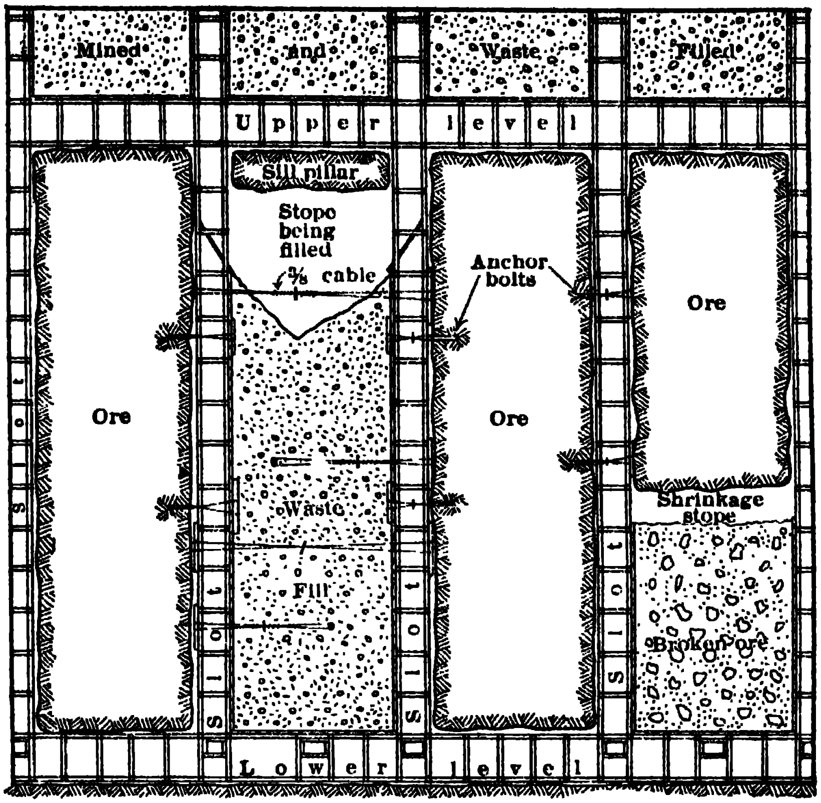

Fig 605. Method of Mining Pillars between Slots, and Tying Slot Timbers, Golden Queen Mine (310)

carried up from level to level, these slots being separated by pillars 25–35 ft long. As the slots advance upward, the footwall is explored by test holes to assure that footwall ore limit has been reached (Fig 604). When 2 adjacent slots have been completed to level above, the intervening pillar is usually mined by shrinkage (Fig 605). If ground becomes bad, the shrinkage stope can be changed readily to horiz cut-and-fill, by drawing out broken ore and filling with waste through adjoining slots. Then the slots are used also for chutes and manways for cut-and-fill operations. To avoid necessity for men to work under bad ground, scrapers distribute the fill, hoists being placed within the square-sets. If, after changing to cut-and-fill, the back gives too much trouble, it is easy to change to straight square-setting. These methods have proved flex-

ible and satisfactory. Outlining of ore limits in carrying up slots permits rapid mining of pillars without danger of leaving ore behind. Slots afford easy access for air and water lines, assure good ventilation, and serve as storage places for machines, drill steel and hose.

Carson Hill mine, Calaveras Co, Cal. Data from J. A. Burgess (297) in 1937. A combination of shrinkage and square-set stoping is applied where prompt support of walls is required and ordinary shrinkage stopes are not applicable. Gold-bearing quartz veins, dipping about 60° and having minable widths of 5–20 ft, occur in a belt of soft, talcy schist. Development is by drifts in ore at 75-ft vert intervals. Stopes, 1–4 sets wide, are mined in sections 4 sets (20 ft) long (Fig 606). Sets, of 8 to 10-in round timber, are 5 by 6.5 ft. Stope is kept full of broken ore until it reaches the level above; ore is then drawn out and replaced with waste, after which an adjacent 4-set section is started. Use of short sections and small lift permits speedy completion of individual stopes and contributes to successful application of this variation of square-set mining by a "block" system (Art 46).

88. PRACTICE AT DE BEERS DIAMOND MINES, KIMBERLEY, SOUTH AFRICA

(Contributed by L. J. Parkinson, Ass't Gen Mgr, and H. T. Dickinson, Tech Dir, 1938.)

General. Diamonds are disseminated in volcanic necks (pipes) of "kimberlite," a serpentine derived from peridotite (307, 252). The pipes are nearly vert, of circular or ellip cross-sec; diam of pipes in the 3 operating mines is approx 800 ft at depth of 1 000 ft and gradually diminishes with depth. The kimberlite is brecciated; locally called "blue ground" or "blue." A typical geol section (Fig 607) of the country rock in which the pipes occur is: surface debris 0–10 ft, dolerite 10–110 ft, shale 110–380 ft, Dwyka conglomerate 380–385 ft. Below the conglomerate is the "hard rock" contact, beneath which are melaphyre, quartzite, and granite.

The Kimberley mine was allowed to flood in 1914, when the bottom level was at 3 650 ft. The De Beers mine has been idle since 1908, though pumping and maintenance work continue. Wesselton, Bultfontein and Dutoitspan mines are now (1938) being exploited. All the pipes were mined as open-cuts (Art 95) to depths of 300–500 ft before underground work became necessary. Underground mining is a combination of shrinkage stoping (Art 67) and sub-level caving (Art 75); methods at the 3 operating mines are standardized. Work is now carried on at moderate depths, the depths, below surface, of top sublevels and bottom, or haulage, levels (1938) being, respectively: Wesselton, 980 and 1 600 ft; Bultfontein, 960 and 1 600 ft; Dutoitspan, 670 and 1 350 ft. The solid blue ground is overlain by several hundred feet of loose or broken rock, composed of a mixture of shales and dolerite which has sloughed off the sides of the open pit, and blue ground which has been abandoned or lost in mining the upper levels. The method utilizes the wt of this overburden to cave approx half of the ground mined.

Mine layout. Each mine is served by two 5-compt shafts in country rock, about 1 000 ft from edge of the pipe. The main hoisting shaft is downcast; 2 compts are for hoisting, 2 for men and material, and the fifth for service lines and ladderway. The second shaft (not shown in Fig 607) is upcast, with an exhaust fan at the collar; it is used as an emergency exit. Two main 17 by 8-ft tunnels, 600 ft apart vert, run from the hoisting shaft to the pipe. The upper one *A* (Fig 607) is a traveling way, waiting place for shift, and for storage of material. The lower *B* is the haulage way, the deepest level of the mine. A 3-compt service shaft ("prospect") *F* is sunk in country rock just off the main tunnels and approx 100 ft from the pipe. From this, stations and connections *T* to the workings are 40 ft vert apart, to serve each sub-level; this shaft is used for distribution of men, explosives and material throughout the mine. Added communication is provided between sub-levels by 2 or 3 sets of 32° "stepways" *G* (Fig 608), in country rock on both sides of the mine. Six or more vert passes *P* (Fig 608), located around the rim of the pipe in country rock, 50–75 ft back from the contact, connect the sub-levels to the haulage level; all ground broken is "tipped" into them and drawn off on the haulage level. A vert air shaft *M* (Fig 608) also connects the sub-levels to the haulage level. Fresh air is drawn down to the haulage level and upcast through this shaft; regulators control vol of air taken by each sub, and the return air is upcast through the stepways to the upcast shaft bottom.

Development. New work consists of deepening the hoisting shaft and "prospect" by 600–1 000 ft, depth varying inversely as cross-sec of pipe. Shaft station and ore handling arrangements are then provided at new bottom level, and a haulage tunnel is driven from the hoisting shaft past "prospect" *F* through approx center line of pipe and beyond. As the " prospect " is sunk, stations are cut 200 ft apart and tunnels driven in country rock to the new vert " tipping " passes. From these points of attack, passes are raised 150 ft and winzed 50 ft until holed. Closed " tip doors " (grizzlies) are installed at each tipping point, to limit size of lumps to 12-in diam. Subs are developed by first driving a single tunnel *T* (Fig 609-*A*) across the pipe from the " prospect," at 0.75% up-grade. Simultaneously, 2 parallel crosscuts *C* are driven in " blue " at right-angles to this, on a line approx $^2/_3$ the distance across the pipe from the prospect. These are 67.5 ft c-c and, by connecting " splits " *S*, 90 ft apart, ventilation is provided. Secondary development consists of cutting subs into blocks *U* which are multiples of 22.5 ft, usually 67.5 by 90 ft (Fig 609 *B* and *C*). This work is done only as the advance of stoping requires it, since the blue ground does not stand well and weathers rapidly on exposure. As stoping (chambering) advances, the blocks are finally reduced to 22.5 by 22.5-ft centers, as at *V* (Fig 609-*C*). Normal section of all "blue" tunnels and crosscuts is 7 by 4.5 ft. Crosscuts on each sub are offset one-half block (11.25 ft) from those of the sub next above, to provide for eventual undercutting of back pillars (Fig 610). In general, little timbering is required, as openings are narrow and only driven as required. Where ground is heavy, 3-piece sets of 10-in round timber are used and lagged with old rails or 3-in plank. If opening must stand a long time, but ground is not heavy, 5 by 4-in lagged steel sets are used to prevent sloughing.

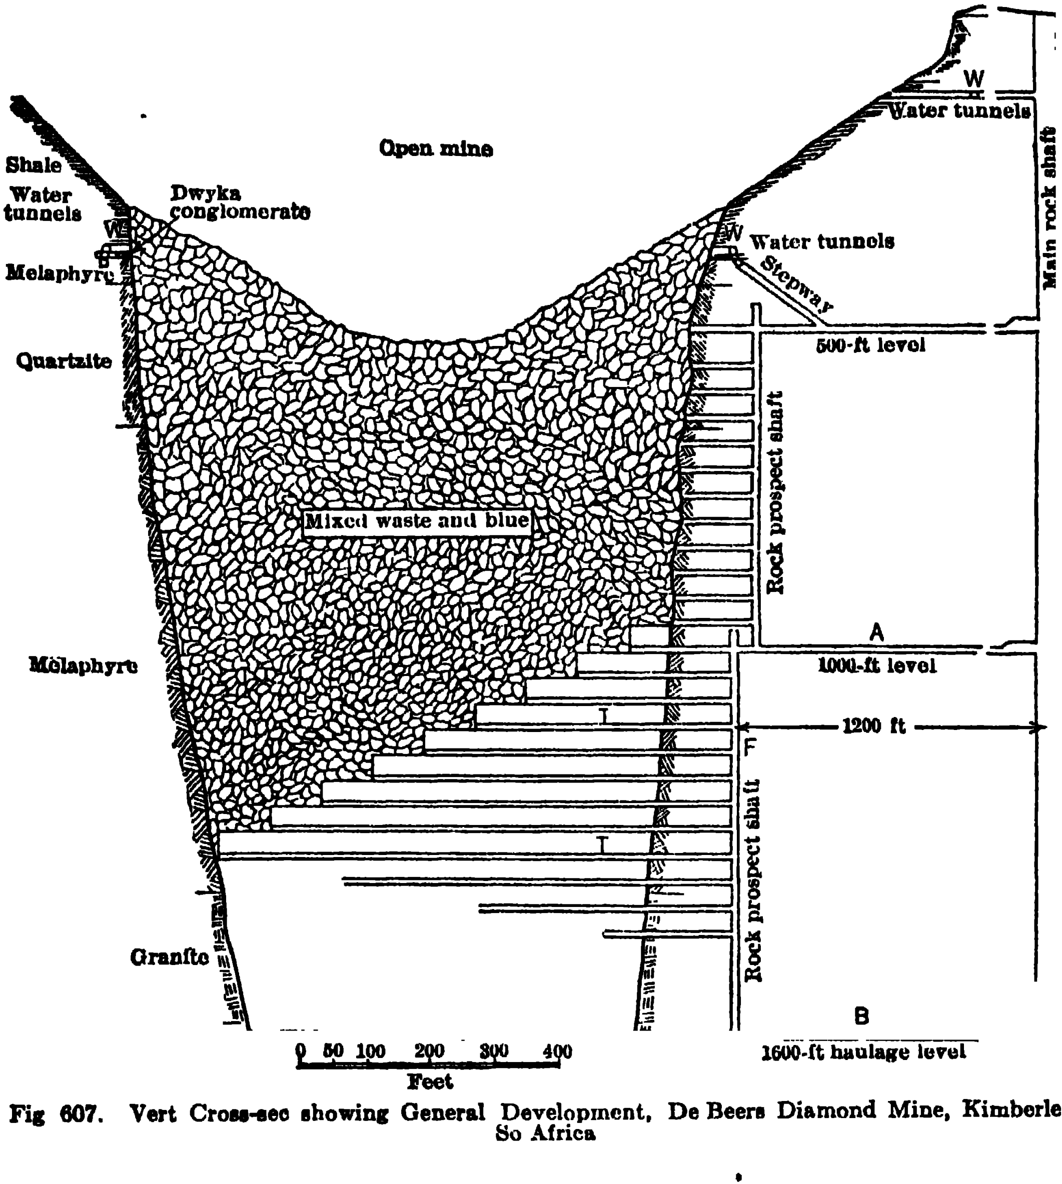

Fig 607. Vert Cross-sec showing General Development, De Beers Diamond Mine, Kimberley, So Africa

Stoping. Approx 50% of the ground is broken in shrinkage stopes; the rest comes from back pillars which are caved. Stoping begins on each sub on side of mine opposite

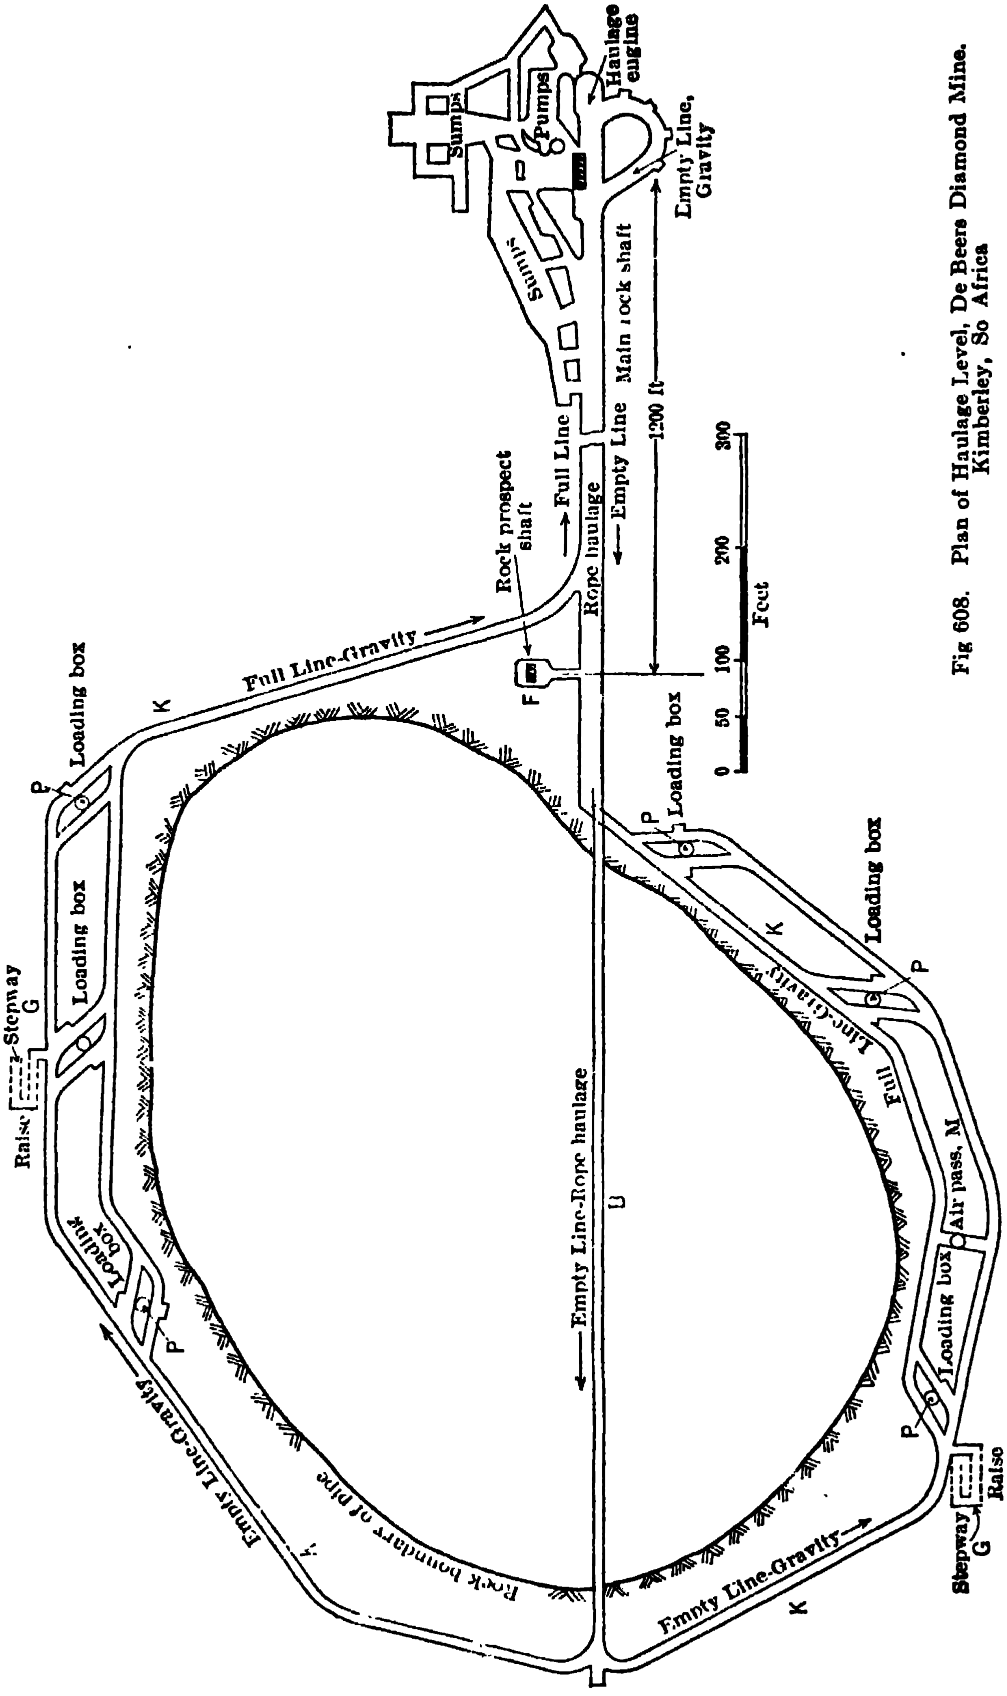

Fig 608. Plan of Haulage Level, De Beers Diamond Mine. Kimberley, So Africa

prospect shaft. From the nearest crosscut, short drifts *D* (Fig 609-*B*) are put through to rim rock. A crosscut *E* is driven along the line on which the stope is to advance. This is widened to 10–12 ft when raising of back begins. Raising is so done that a face lying 25° to the horiz is developed (Fig 611), and extended until the top is holed through into loose ground left on level above. All holes are drilled dry and inclined 20° from the vert. The face is then advanced until it reaches rim rock at the opposite side. On completing the first stope cut, 2 stopes are started on the next cut, on opposite sides of the pipe and advanced until their bottom ends meet, usually near center line of the pipe. The remaining triangular-shaped block of ground is then " squared-up " by shortening the face, and by a succession of horiz slices which advance the face upwards until a final round is drilled and the area holes into the level above. For this concluding stage of a cut, ventilation and access are provided by a poleway and " pass poleway," the latter being cut in solid ground (Fig 611, 612). Stope faces advance along the line of crosscuts and at right-angles to the original blue tunnel *T* (Fig 609-*B*). By a succession of cuts, the face gradually retreats along the line of the tunnel towards the prospect shaft. When the stoping line on any sub has advanced 600–800 ft, 4 stopes may be started on the one sub; 2 begin at opposite contacts and 2 in the center. The stoping line on each sub is 3 or 4 blocks (67.5 or 90 ft)

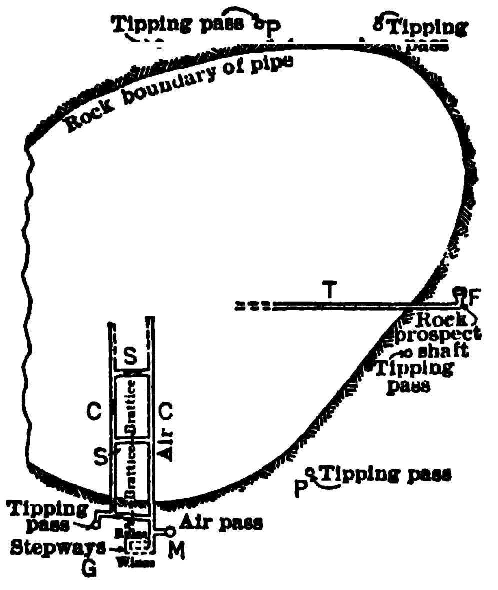

Fig 609A

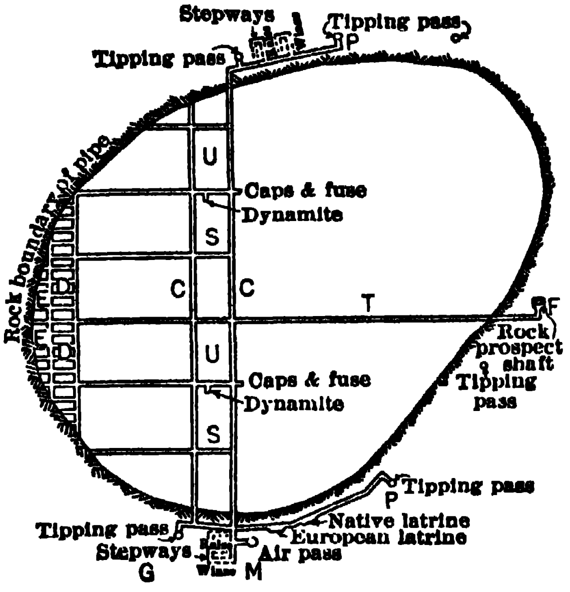

Fig 609B

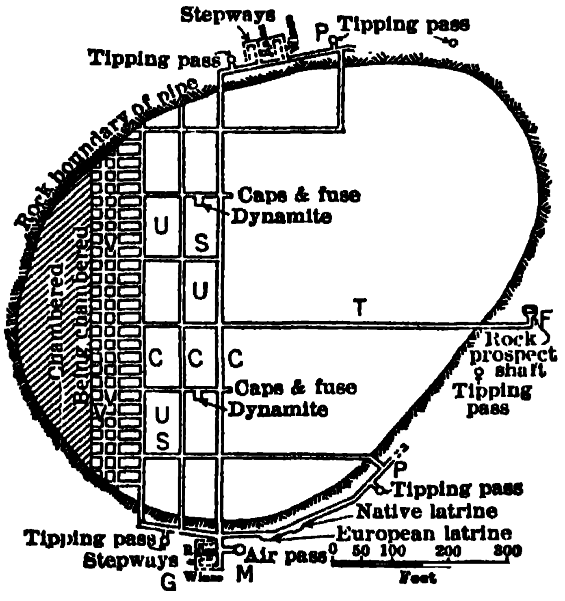

Fig 609C

Fig 609. Plan of Sub-level, showing Steps in Development, De Beers Diamond Mine, Kimberley, So Africa

behind that of the sub above (Fig 610). Standard width of stoping blocks is 22.5 ft, of which a width of 8–12 ft, depending on condition of hanging, is mined by shrinkage. The remainder is left as a " back pillar," which is recovered by caving when undercut later by a stope or chamber on next sub below (Fig 610). Blue ground from shrinkage stopes is removed as required to provide working room at the face, and amounts to 30–35 tons per stope-shift. Ground broken per stope-shift, including back pillar caved, averages 150 tons. Usual access to stopes is from the bottom end; added access and escape ways are provided by "poleways" above every second drift, which also permit through ventilation and entry way for drill hose. Poleway consists of a notch cut in the solid in front side of a stope and covered with poles and old rails to prevent loose ground from filling the cut. When the top end or high-point of a stope has advanced beyond any drift, all ground broken in the stope, plus that from caving of the back pillar above, is loaded out. Two natives hand-load in each sub at an aver of 15 tons per man-shift. Aver life of loading places, 40–45 shifts; added life is often obtained through ground from "other sources," as ground abandoned on higher levels or left behind from old mining methods. When waste rock appears, loading is stopped. The loaded ground is hand-trammed in 16-cu ft trucks to nearest tipping pass. On the aver, ground hoisted is classified according to source, as: development, 3%; broken in stopes and back pillars, 75–80%; other sources, 22–17%, which includes some admixture of waste rock.

Plan

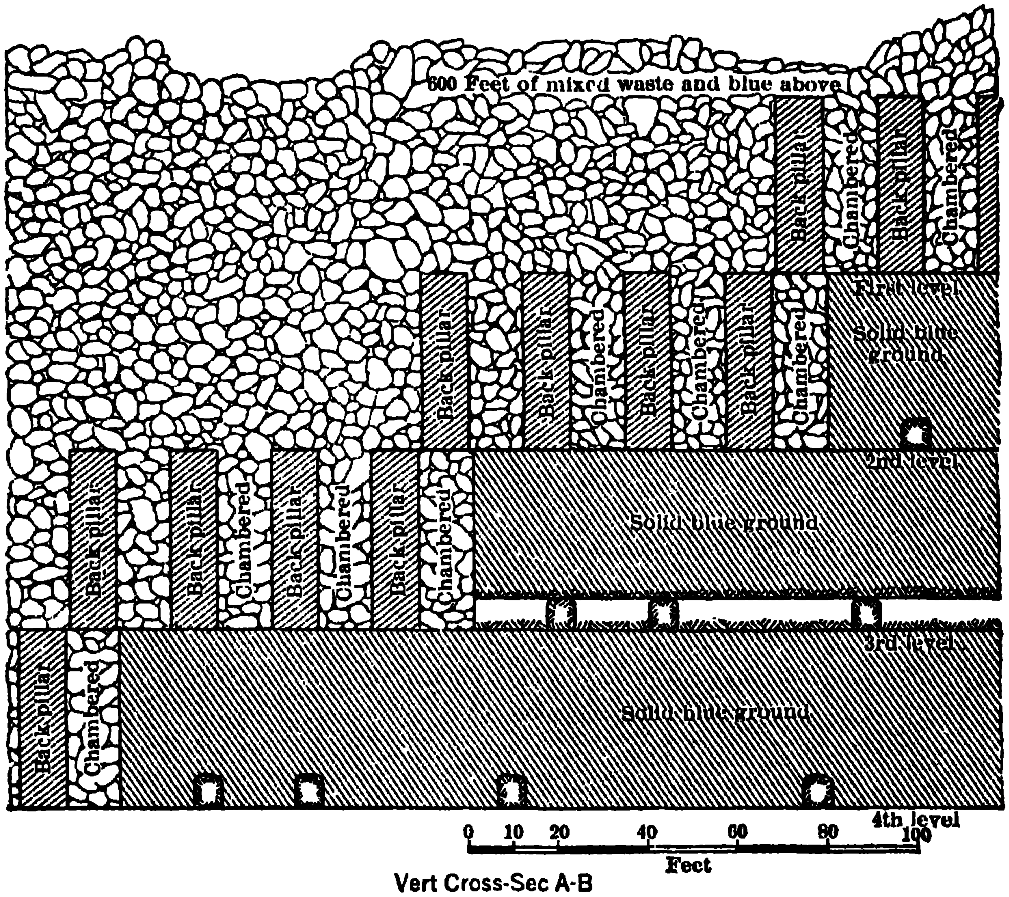

Fig 610. Stoping in De Beers Diamond Mine, Kimberley, So Africa. Showing back pillars left in place, and method of undercutting them from next level below

Eight to 10 subs are worked simultaneously, to give the required 5 000 tons per 8-hr shift. From 1 to 4 stopes are worked on each sub, as a total of 24–26 are required. Present stope back is 40 ft, but 50-ft backs are being introduced. Extraction is difficult to determine, but is estimated under present system to be above 90%.

Haulage. Each mine has an endless-rope haulage on the bottom level (Fig 608). Empty trucks from the shaft are hauled up a grade of 2-4% in tunnel *B* to the opposite side of the pipe. Enough elevation is thus gained to permit the trucks, when taken off the rope, to gravitate either right or left along rock tunnels *K* which encircle the pipe and lead past the loading chutes at bottom of the vert tipping passes. Here they are filled and gravitate to the hook-on point, whence a downgrade of 1.5% leads to the shaft. Side-tipping 20-cu ft trucks are run in trains of 5; rope speed, 3 miles per hr. At the shaft they are disengaged, automatically tipped and righted. There is no storage at the shaft, since that in the passes and full trucks is ample. The trucks discharge into 10-ton measuring pockets. The 10-ton skips are brought to rest on buffer beams just below the pocket, which discharges into the skip by opening an air-operated door; 5 000 tons are hoisted per 8-hr shift.

Mud rushes. The "blue" and most of the waste accumulating in the open-cuts disintegrate rapidly on exposure to air; water transforms it into a fluid mud, which works downward and eventually bursts into the mine. In early years this caused many fatalities and great expense for cleaning out workings. The water comes from the softer formations within 400 ft of the surface. Formerly this seeped into the open-cut, but the problem was solved by driving ring tunnels *W* (Fig 607) around the pipes just below the contact of the shale and melaphyre. A system of raises into the shale and drifts along it trap the water, which is pumped to the surface.

Cost (1938) averages about 55¢ per ton of "blue," including development, mining, hoisting and tipping. Each mine does about 25 000 ft of development in "blue," and 2 000 ft in country rock per annum, the cost of which is included in above cost.

MISCELLANY, UNDERGROUND MINING

89. MISCELLANEOUS METHODS

Exploitation through boreholes is applicable to: soluble minerals, as salt; sulphur which can be melted by hot water, and some kaolin deposits which can be broken by, and taken into suspension in water. In general, the method is used for impure deposits, or those overlain by treacherous cover, or where shaft sinking would be very difficult or costly; it gives low extraction, but permits exploitation of otherwise unworkable deposits of cheap minerals.

Extracting salt through boreholes (311). In U S, salt deposits occur as: (*a*) beds of wide lateral extent, usually nearly horiz and overlain (also frequently interstratified) by shale or gypsum, as in N Y, Mich, and Kan; (*b*) "domes" of almost pure salt, as on Gulf Coast and a few nearby interior points of La and Tex; domes are from 0.5 to over 2 miles in diam and of unknown depth; their walls are nearly vert. Thick deposits under suitable cover, and where shafts can be sunk, are usually mined by room-and-pillar methods (Art 34, 42); otherwise, salt is extracted as an artificially produced brine through boreholes; even in thick and mineable deposits, latter method is preferred by alkali producers, who must work with salt in solution. Methods of casing and sealing boreholes vary with geol and operating conditions. Fresh water may be supplied (*a*) from water-bearing overlying strata, or (*b*) through pipes from surface. Brine is lifted by: (*a*) press applied to inflowing fresh water from surface; (*b*) air-lift; (*c*) deep-well pumps (Sec 44). On starting a new well, fresh water is supplied, and a necessarily weak brine (often wasted) is extracted, at a rapid rate, to enlarge the walls of bottom cavity; thereafter, flow is retarded to yield nearly saturated brine (about 18.5% NaCl in N Y, 23% in Kan) to reduce subsequent cost of evaporation; as the cavity enlarges, rate of delivering saturated brine may be increased, unless a blanket of insoluble impurities on the floor interferes with solution. GULF COAST METHODS (Fig 613, 614), from W. M. Weigel (311). Wells of Morton Salt Co, Grand Saline, Tex (Fig 613), are about 265 ft to top of salt and 400-500 ft in total depth. Casing is sealed above an overlying water-bearing stratum, and brine is lifted by comp air through a 4-in pipe reaching nearly to bottom of well. Fig 614 is typical of the deeper wells on domes worked by alkali producers. Casing is sealed at top of salt, 670-850 ft below surface, and hole continued 600-1 000 ft downward into salt; fresh water is delivered through a pipe nearly to bottom of hole, at a press sufficient to lift brine to surface. CENTRAL N Y METHOD. Salt is interstratified with shale, limestone, and gypsum, in a laminated formation (max thickness, 470 ft) 800-2 250 ft below surface. Starting with 10-in drive pipe to bedrock, a drill hole to bottom of salt is cased with 6-in pipe and sealed at a level below all sources of water. A 3-in pipe is lowered in the casing nearly to bottom. At start, water is pumped down the 3-in pipe, and weak brine rises; after about 6 weeks, direction of flow is reversed (Fig 615-*A*). As explained by E. N. Trump (308), by these means the cavity becomes funnel-shaped because (*a*) fresh water tends to float on brine, and (*b*) rate of solution is faster in water than in brine. Ultimately, the floor of cavity flattens enough to retain a blanket of insoluble residue, and solution is then confined to edges. Caving usually occurs when a cavity reaches 150 ft diam; in a thin bed, this happens about twice a year (perhaps once a year in a thick bed), usually causing abandonment of the hole and drilling a new one. If the roof, usually shale, contains layers of salt, connections may open between adjacent cavities, after which air-lifting or pumping must be adopted. MICHIGAN METHOD (also that of

Kan) is like that at the deeper Gulf Coast wells (Fig 614); water is pumped continuously down the central pipe and brine rises around it. In this case, as shown in Fig 615-*B*, the cavity first assumes a barrel-shape, then approaches a sphere, and finally attains about the same shape as in Fig 615-*A*. According to Trump (308) saturated brine can not be recovered by this procedure in a thin bed, because the fresh water, being lighter and more mobile than brine, tends to rise close alongside the central pipe and dilutes the brine issuing from the cavity; in a bed 150 ft thick or more, the water has better opportunity to diffuse into the brine and assist the dissolving of salt. **TRUMP METHOD** (308) is designed to produce a cavity from which saturated brine can be withdrawn with minimum delay (that is, with least waste of weak brine) after completing the drill hole. As shown in Fig 615-*C*, a bed is dissolved in circular, horiz slices, each about 10 ft thick, beginning with a 5-ft undercut at bottom. At start, action is confined to perimeter of undercut by maintaining a pocket of comp air above the brine; an undercut 4 ft high can be extended to 300-ft diam in 12 mos, delivering 175 gal brine per min. On reducing air press by about 5 lb per sq in, the level of brine rises about 10 ft and begins dissolving the next slice, the entire bottom area of which is now exposed to solution. To provide an equivalent area of spherical surface (that is, to yield same flow of brine of same density) would require dissolving of 13 times as much salt.

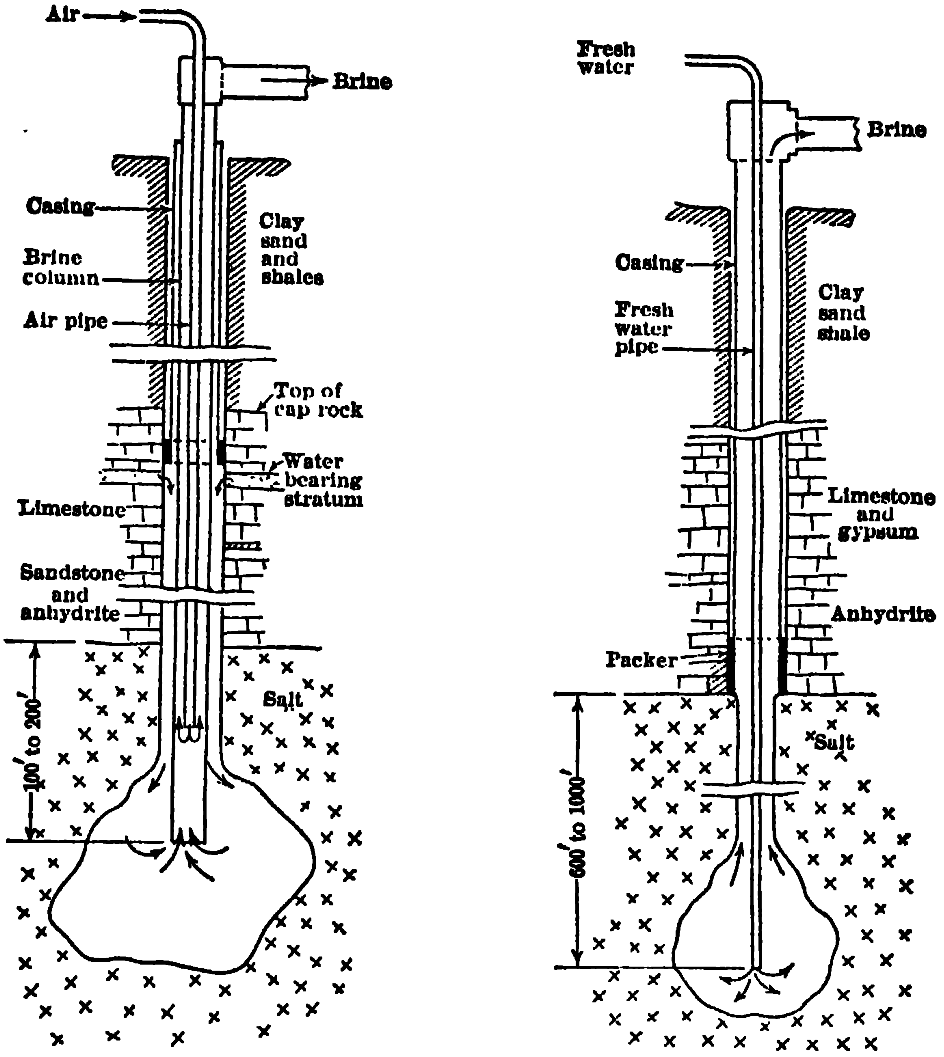

Fig 613 Fig 614

Salt Wells on Gulf Coast Domes (W. M. Weigel)

Leaching copper ore in place. Recovery of "cement" (metallic) copper by precipitation on iron from waters containing $CuSO_4$ is an old practice in many regions, such waters usually being only those naturally met in underground workings, or surface water which has percolated through mine dumps. Application of same principles by artificial distribution of water over ore broken, but still remaining in place, is practicable under certain favorable conditions, of which the most important are: (*a*) presence of iron sulphides (preferably pyrrhotite) in amount sufficient to provide ferric sulphate as solvent for copper; (*b*) geol structure (such as an impervious footwall, Ohio Copper mine, below), permitting the copper-bearing water to be collected without excessive loss, or to be impounded without excessive cost to avoid interfering with mining at lower levels (as at Ray mine, below); (*c*) ore of such physical character that water can penetrate to the copper minerals without causing excessive disintegration or collapse of the ore fragments (a firm, silicеous ore mineralized along seams is most favorable); (*d*) adequate supply of water, and cheap scrap iron. Details of 2 successful operations follow. **Ohio Copper** Co, Bingham, Utah. Orebody is a large tabular deposit of shattered quartzite and monzonite carrying disseminated chalcocite and pyrite and averaging about 0.88% Cu (302). Fig 616 shows the underground development in an unprofitable attempt to mine the ore by block-caving, which left in place about 38 000 000 tons of ore broken to aver size of 4 in. Important feature of orebody is an impervious footwall, dipping about 55°. Entrance was by tunnel from surface, which avoided need of special pumps and water columns. In 1925, water was pumped and distributed over caved surface of orebody, about 1 400 by 600 ft, at 1 200–1 400 gal per min. After percolating through the broken ore, it was caught at the Mascotte tunnel and allowed to flow through 2 wooden launders, one on each side of tunnel track. Launders were 32 by 32 in, and 1 600 ft long, at 0.5% grade, with sectional false bottoms, 17 in above floor, in form of wooden lattice with 0.25-in sq openings, on which detinned iron scrap was distributed. Copper precipitate collecting underneath was removed at intervals of 6–30 days, shoveled into cars, trammed to surface, and shipped to smelter. Water entering launders carried (aver) 0.204% Cu; recovery in precipitate, 97%. Of total precipitate, about $^3/_4$ averaged over 90% Cu, and $^1/_4$ (that from lowest launders) ran over 70% Cu. In 32 mos (1922–1925) output was 17 000 000 lb of copper, at operating cost of 3.846¢, and smelting charge of 2.477¢ per lb. **Ray mines**, of Kennecott Copper Corp, Ariz, began leaching in western portion of its orebody in Jan, 1937, and produced 10 201 364 lb of copper by that method during the following 17 mos (525). In this 10-acre area, the ore was unusually high in pyrite, and averaged about 1% Cu, above it was an unaltered zone 125 ft thick averaging 0.6% Cu surmounted by a leached zone 50 ft thick. Total copper recoverable by leaching in this area down to third level was estimated at 50 000 000 lb. Preparatory work underground included driving drainage drifts, building several concrete dams, and a concrete ditch (500 gal per min), with sump and pump station on third level, to prevent escape of water to lower workings in adjoining areas. Copper-bearing water is pumped to surface by 2 centrifugal pumps made of Duraloy, with combined capac of 500 gal per min, through 8-in lead-lined pipe. Fresh water is pumped by 4-stage centrifugal pump at 340 gal per

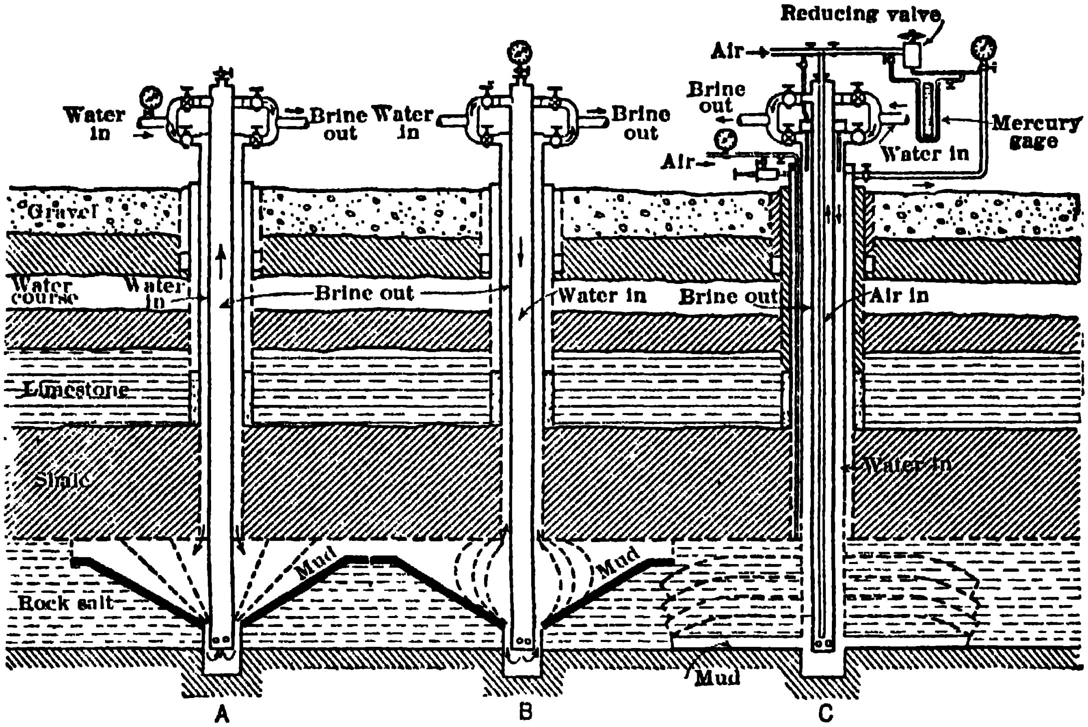

Fig 615. Three Types of Brine Wells. A. N Y Method for thin salt beds. B. Mich method for thick beds. C. Trump system

min, and distributed over surface of leaching area by pipe lines and sprinklers, which are shifted whenever copper content of recovered water drops to 0.4%. On returning the sprays to a previously treated area after an interval of about 2 mos, the percolated water resumes its normal content of nearly 1% Cu. Settlement of caved ground, apparently resulting from the leaching, interfered at times with maintenance of pipe lines and sprinklers; uniformity in distribution of water is essential to good extraction. Occasional shortage of fresh water will be met by utilizing the discharge solution from the precipitation plant, after oxidizing its ferrous sulphate to ferric, and eliminating the objectionable colloidal basic sulphates thereby produced. Precipitation plant, on surface, has 2 units, each of 5 cells, 10 ft-8 in wide by 40 ft long, with 8-in partitions down their middles, thus forming the equivalent of a launder 5 ft wide and 400 ft long for each unit. Preferred form of scrap iron is coarsely shredded detinned cans, from San Francisco; this is charged twice a day, by crane and clamshell bucket, and rests on a wooden grill false bottom, openings $^3/_8$ by 0.5 in. Accumulated precipitate (10–12.5 tons per cell) is periodically washed through the grill (by-passing the flow meanwhile), and flows by gravity through tile pipes to 6 draining cells; there it is handled twice, from cell to cell, by another crane and clamshell bucket, before loading into RR cars; the aver 22.8% moisture in the shipped product could be reduced by added handling. Entire operation is conducted by a crane operator and 2 helpers, working day-shift only. Aver results to July 1, 1938: Cu in leach sol, 0.923%; Cu in tail sol, 0.0079%; indicated recovery, 99.14%; ratio Fe consumed to Cu produced, 1.15; Cu in precipitate (dry), 87.27%. All cells are of concrete; for structural details, see Bib (525). **Phelps Dodge Corp**, Morenci, Ariz, is now (1939) leaching caved areas over old workings by methods similar to those at Ray.

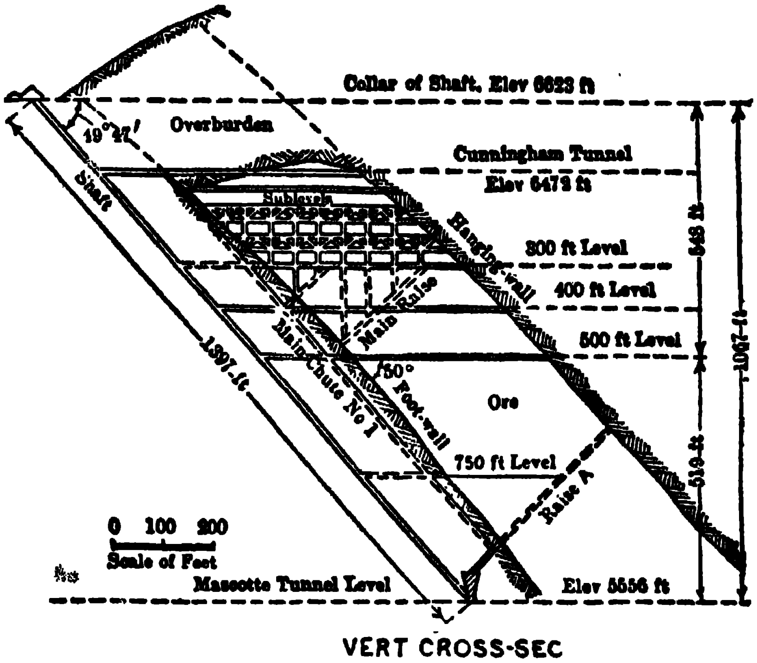

Fig 616. Development Work, Ohio Copper Co

Frasch process for sulphur. Sulphur occurs as disseminations and occasional pocket-masses in beds of porous limestone and gypsum, associated with some salt domes on the Gulf Coast of La and Tex. Of 200 known domes (1935), 9 have produced sulphur commercially, operated by 4 companies, all using improved forms of the original Frasch process. The sulphur-bearing beds lie under 400–2 000 ft of unconsolidated or porous strata carrying large volumes of water impregnated with H_2S, which has defeated all attempts at shaft-sinking. Some deposits, lying under marsh land or open water, have been developed by floating equipment. Some are capped by barren rock, and a bed of anhydrite is usually at bottom of the sulphur horizon. The process consists of sinking and casing drill holes to bottom of sulphur bed, introducing water at 320°–335° F, and recovering molten sulphur by air-lift. Chief difficulty and expense are involved in securing, treating, heating, and distributing suitable water. Modern plants have central stations equipped to heat 5–10 million gal per day to 340° F, distributing it through insulated pipe lines to the several wells. Following data from W. A. Cunningham (312) in 1935 refer to Freeport Sulphur Co's operations at Hoskins Mound, Tex, begun in 1925 and recently enlarged.

Water-heating boiler plant of 12 units develops 16 000–18 000 bhp. Fuel is natural gas, but oil can be substituted in 5 min (unfailing supply of hot water is essential to operations once begun). Of 7 500 000 gal water required daily (from surface reservoir and deep wells), 2 750 000 gal go into boilers and 4 750 000 are heated indirectly for distribution to sulphur wells. Boiler feed-water is softened by lime-soda-sodium aluminate method, settled for 3 days, and filtered; it is then preheated in 2 stages: first in exchangers supplied with "bleeder water" (see below) at 180°–200° F; next by exhaust steam from engines and pumps. Mine water for the sulphur wells is treated cold with soda-lime (also $FeSO_4$, if necessary), sedimented for 3 days, but not filtered. It is heated in 3 stages: first to about 135° F by direct contact with flue-gas, next to about 212° F by exhaust steam and boiler blow-off (amounting to 25–30% of boiler feed), finally to 325°–340° by direct contact with live steam. It is then distributed to wells through insulated 10-in pipe lines. Besides 63 pumps and various power generators, the plant includes 3 low-press and 5 high-press compressors, with combined capac of 4 500 cu ft free air per min to 1 000-lb press, to supply air-lifts at wells. WELL OPERATION. A 10-in casing is sunk through unconsolidated material (1 000–1 600 ft at Hoskins) and seated with cement in the cap rock over the sulphur horizon (Fig 617). Hole for 8-in casing is continued downward with standard rotary oil-well drill to bottom of sulphur and into underlying anhydrite. The 8-in casing, its lower 35 ft perforated, is seated and cemented at bottom of hole. A 4-in pipe rests on a flange welded to inside of the 8-in pipe just above its bottom. A 1.25-in air line inside the 4-in pipe ends about 200 ft above bottom of hole. At start, hot water is pumped down the 8-in and 4-in pipes; molten sulphur accumulates until (upon stopping flow down the 4-in pipe) it will rise, under hydrostatic press in the 8-in pipe, to bottom of the air line; the well is then said to be "sealed." Air is then admitted, slowly at first, increasing gradually to equalize the rates of melting and lifting. Temp of water is held as closely as possible at 320°–335° F, adding "tempering" water at 210° if necessary; if water is too hot, the sulphur becomes viscous; if not hot enough to prevent freezing at any point, the well may be lost, since a solid cake of sulphur is difficult or impossible to remelt with hot water. A normal well extracts sulphur from an area of about 0.5 acre. "Bleeder" wells are distributed among a group of producing wells to relieve the press required to force large volumes of water into the ground. Water returning from them at 180°–200° F is so impure as to be useless for any purpose except initial preheating of boiler feed, by exchangers; no satisfactory method for purifying "bleeder" water has been devised. PURIFICATION AND SHIPMENT OF SULPHUR. Molten sulphur from a group of wells is pumped by air through insulated and steam-heated pipes to a central "relay" station, where subsequent manipulation includes: (*a*) elimination of air and other gases in steam-jacketed separator; (*b*) collection in a steam-heated, constant-level, flow tank; (*c*) delivery through orifice meter into steam-heated, cast-iron "relay" pit; (*d*) transfer from a full pit, by submerged centrifugal pump, to final storage vat. Latter is a rectangular wooden enclosure 800–1 000 ft long, 200 ft wide, with walls erected only 3–4 ft above rising level of sulphur, until final height reaches 40–60 ft; such a block contains 400 000 to 750 000 tons of sulphur, analyzing 99.5–99.95% S. After 6–12 mo for cooling, the walls are removed, standard-gage tracks laid alongside, and face of block is bored with mechanical augers and blasted with dynamite to lumps which can be loaded by clamshell bucket or steam shovel.

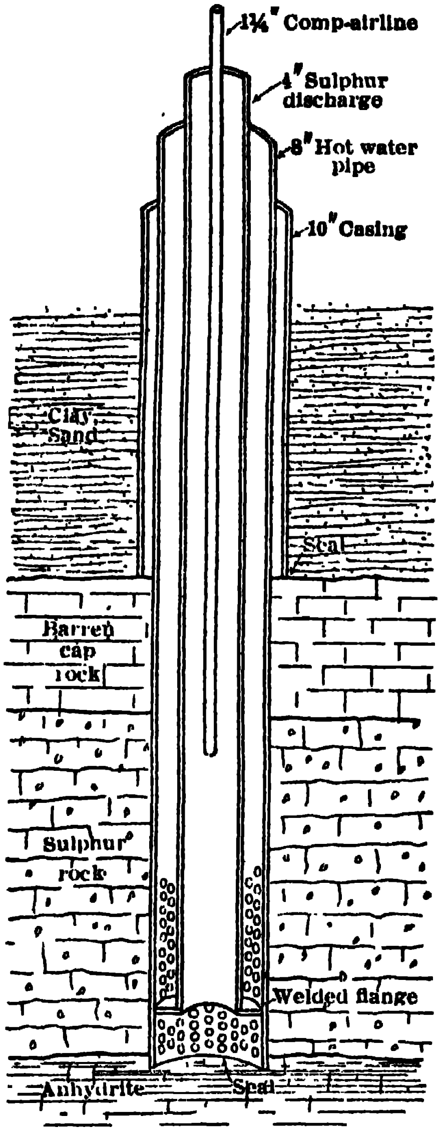

Fig 617. Arrangement at Bottom of Frasch Sulphur Well. (Diagrammatic sec, not to scale)

Mining kaolin through boreholes, West Cornwall, Conn (313). Kaolin occurs in vein-like residual deposits, dipping 50° and intercalated with seams of broken quartz, feldspar, and mica. As the mixed material could not be mined by ordinary methods and the kaolin washed out at a profit, boreholes were used. Holes were cased with 4-in pipe to within a few ft of the footwall of the deposit. Inside the 4-in pipe was placed a 2-in pipe, terminating in a cap with several nozzle-like openings. Water under 40 to 60 lb pressure was forced down the 2-in pipe, the bottom of which was allowed to sink to the footwall as the surrounding material was broken by the jets and washed up the annular space between the pipes. Depth of wells, 50 to 198 ft. The vein matter contained 20% kaolin; the overflow of the wells carried 5 to 10% solids, averaging 60 to 75% kaolin. The percentage of pure kaolin in the solids was inversely proportional to the velocity of the water current.

Mining gilsonite. When heated to a certain temperature, gilsonite flakes off without melting, a property utilized for mining this mineral in overhand stopes. Steam or hot air jets are turned against the face under attack, and, as the gilsonite flakes off, it is caught in a hopper and loaded by gravity to cars below (U S Patent 950 363, Feb 22, 1910).

90. CHUTES AND CHUTE-GATES

Chutes (mills, mill-holes, ore-chutes or ore-passes) are used chiefly in filled and shrinkage stopes, Art 59, 67; also in square-set stopes, Art 47. They are vert or inclined passages through the stopes, for handling ore or waste. The term also designates chute-raises (Art 67), chute-compartments of raises, and chute-gates.

Requisites of a chute: (*a*) a life at least equal to that of the stope it serves; (*b*) minimum tendency to clog; (*c*) a cost small in proportion to total tonnage passed; (*d*) low maintenance cost; (*e*) suitability to the stoping conditions. Details of construction are important as they affect the life of the chute, which often limits the max allowable level interval. The chute's life depends on the amount and character of ore passing through it, and the pressure due to the stope filling. The tonnage passed is a function of the stope width, interval between chutes, and distance between levels. Spacing of chutes is affected by the cost of handling ore in stopes and the development work required for a given spacing (Art 47, 60–66; also Raises, Art 70). These factors should be considered in connection with the initial and maintenance costs of chutes for a given stope.

Vertical *vs* inclined chutes. The former are preferable, as they are easier to construct and maintain, and will pass a larger tonnage for a given amount of wear. Inclined chutes are necessary in narrow, pitching veins, or near an inclined hanging wall in wide deposits; if provided with a ladderway, they are easier to climb.

Types. The commonest chute has a rectangular cross-sec, and is built of cribbing or plank; it often has a ladderway, and sometimes a slide for hoisting timbers, drills and steel. In veins less than 6 ft wide, chutes are sometimes built by lagging vert rows of stulls. Circular chutes of dry stone walls are used at the Baltic mine, Mich (Art 63); circular wooden and steel chutes have been used at Broken Hill, Australia, and circular chutes walled with pre-cast concrete segments, at Ashanti, W Africa.

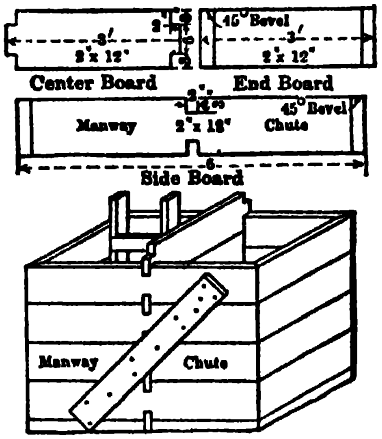

Fig 618. Two-compt Chute, Nevada Wonder Mine

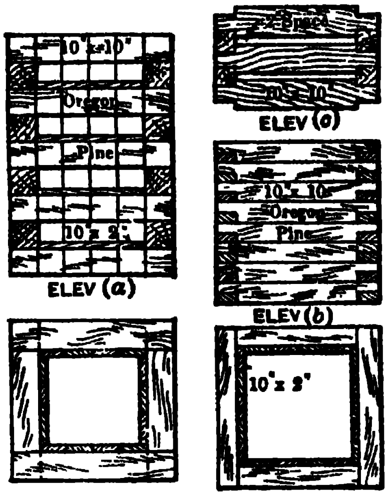

Fig 619. Cribbed Chutes

Size. To prevent clogging by the arching of broken ore, the min cross-sectional dimension should be at least 3 × max diam of the largest piece of ore, and preferably more. Single-compt chutes are usually 4 by 4 ft to 5 by 5 ft. The min width for a ladderway is about 2 ft; better, 2.5 ft. In mines having a large level interval, the chute and ladderway should be of equal size, so that the compartments can be interchanged when the chute is worn out. In filled stopes, manways are usually provided only in every 2nd or 3rd chute. Manways are advantageous for ready access to chutes when they clog or need repairs. See below and Art 63 for sizes of circular chutes.

Rectangular plank chutes cost less than others; the type form is shown in Fig 618 (see also Art 60); the ladderway is sometimes omitted. The first few cribs above the stulls at the level are of 3-in plank. The edges of the planks are toe-nailed together. While filling is being placed around them, the planks are held in position by diagonal cleats, as shown. The planks are cut, notched and beveled by a swinging circular saw (234). Corners, instead of being mitered as in Fig 618, are often notched and dovetailed, end and center boards then being interchangeable. Planks can be spaced close or semi-open by adjusting depth of notches. Plank chutes serve for small tonnages, as in narrow veins, or where ore is sorted and only a small amount is saved; they will not withstand heavy pressures from filling in stopes with weak walls.

Cribbed chutes are in general use in the U S for large tonnages, and for supporting heavy pressures in filled stopes. Fig 619 (*a*) shows open cribbing; 2-in spreaders hold the timbers in place; the lining is of vert plank. Fig 619 (*b*) and (*c*) show close and semi-open cribbing, which may or may not be lined. Timbers with grain at right-angles to the direction of falling ore wear faster than when the grain is parallel to the flow. Unlined chutes must be heavy enough to last as long as the chute is needed, because they are difficult to repair or replace. Fig 620 shows round cribbing, for chutes 5.33 ft sq, either single or double compartment. Crib timbers are 10 to 18-in diam, and have an aver life of 3 months, on 2-shift work, 6 days a week; hemlock is preferred, because of its toughness. The lower 20 ft of worn chutes are lined with 0.25-in steel plate; above that, with 3-in plank (209). Though round timber is cheaper, chutes built of it are harder to erect and to line tightly.

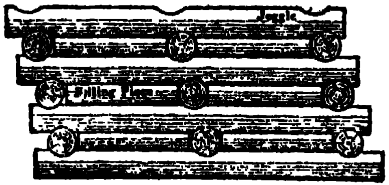

Fig 620. Round-timber Cribbed Chute, Sec 16 Mine, Ishpeming, Mich

Square-set chutes. In square-set stopes, chutes and manways may be made by lagging vert rows of sets. Fig 621 shows a SORTING CHUTE in filled rill stopes at Butte, Mont (see Art 65). For a height of 5 sets above sill floor, the chute is 3 sets long by 2 sets wide; above that, 1 set wide. Middle sets form a manway; outer ones are ore pockets above the level. Gates and grizzlies are placed over the pockets. While ore is drawn from upper chute No 1, waste is sorted on the grizzly and thrown into lower chute No 2, and *vice-versa*.

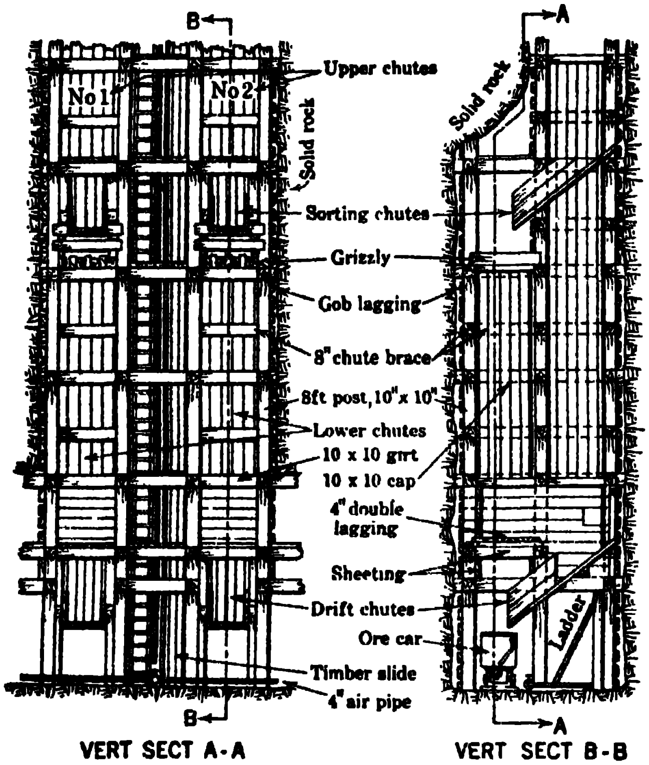

Fig 621. Square-set Chute with Sorting Grizzlies, Butte, Mont

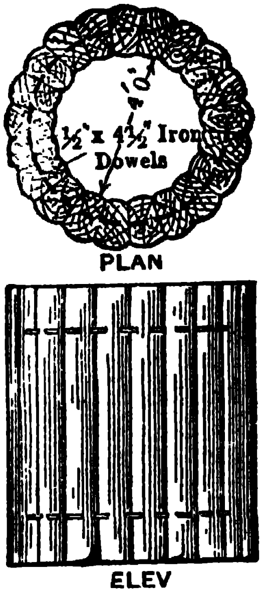

Fig 622. Cylindrical Wood-stave Chute

Cylindrical wood-stave chutes (Fig 622) are preferred to cribbed chutes in large filled stopes at Broken Hill South mine, N S W (314). The level interval is 150 ft. In cribbed chutes (Fig 619), the lining cut out rapidly; the spikes holding it also failed and the planks ripped off. Repairs were excessive and even 4-in lining was inadequate. Cylindrical chutes worked better. They are built in 4-ft sections, of beveled staves. Since the grain of the staves is vert, the cutting action of falling ore is minimized. The staves are bound with wire hoops while filling is being placed around them.

There are 4 types of chute in this mine: (*a*) chute of 4-ft internal diam, with 10-in staves; (*b*) 3-ft chute with 10-in staves; (*c*) 3-ft chute with 6-in staves; (*d*) 3-ft chute with 5-in staves; 5-in thickness is the minimum for sufficient bearing between staves and for resistance to collapse. Type (*a*) is used for the lower 35 ft of both vert and inclined

chutes (its large diam minimises clogging); type (*b*) is for vert chutes, for the sections from 35 to 70 ft, when the lift is 150 ft; type (*c*) is used from 70 to 120 ft on 150-ft lifts, and from 35 to 70 ft on 100-ft lifts; type (*d*) is for repairing rectangular chutes which have failed. The upper 30 ft of these stopes is mined by underhand square-setting (Art 46), and hence chutes are not required. Staves are of eucalyptus, sawed from round or square timbers. At first, dowels, as in Fig 622, were used to hold the staves together until they could be wired, but as this construction was too slow small dogs (cramps), of 0.5-in iron, were employed. Successive lengths of chute are simply stood one upon another, as they do not tend to move laterally after being enclosed with filling. Fig 623 shows an inclined stave chute. Fig 624 shows a connection between vert and inclined chutes; the loosely hanging rails yield to every blow and take wear at the turn.

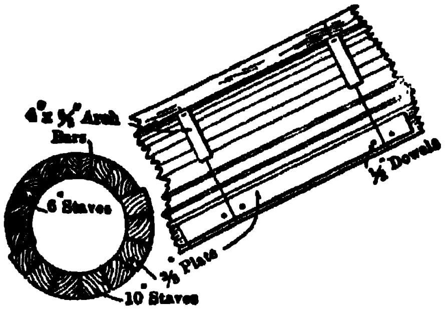

Fig 623. Inclined Cylindrical Chute

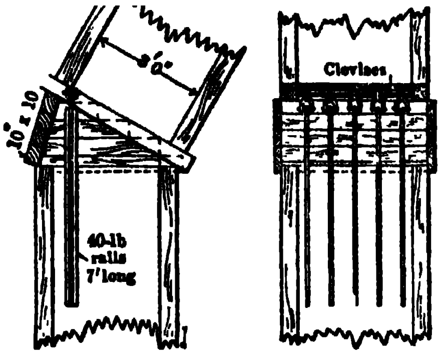

Fig 624

Stave chutes are marked by low first cost and good wearing qualities; they may be withdrawn on finishing a stope. They are serviceable for lining raises and passes for handling filling. E. J. Horwood stated in 1916 that an essential condition for their satisfactory use is that the pressure be approx equal on all sides; hence they are not applicable in stopes having a heavy hanging wall (242). Table 61 shows relative costs of stave and rectangular cribbed chutes at Broken Hill South mine. Eucalyptus costs $56.40 per M bd ft; 10 by 10-in Oregon pine, $45.60; 2 by 10-in Oregon pine, $48 per M. See Bib (314) for details.

Table 61. Cost of Chutes, Broken Hill South Mine, Australia

Type of Chute	Cost per linear foot			
	Material	Labor	Total	
4-ft chute, 10-in staves	$9.35	$0.75	$10.10	
3-ft chute, 10-in staves	7.35	0.75	8.10	
3-ft chute, 6-in staves	4.40	0.35	4.75	
3-ft chute, 5-in staves	3.70	0.35	4.05	*OP* = Oregon pine
3-ft inclined chute, Fig 623	8.60	1.00	9.60	*SB* = Eucalyptus
Close-cribbed chute (Fig 619*b*) 10 by 10-in *OP*	11.80	0.20	12.00	("Stringy Bark")
Cribbed chute (Fig 619) 10 by 10-in *OP*, 2 by 10-in *OP* spreaders, 2-in *SB* lining	10.00	1.00	11.00	
Cribbed chute (Fig 619*c*) 10 by 10-in *OP*	9.50	0.20	9.70	

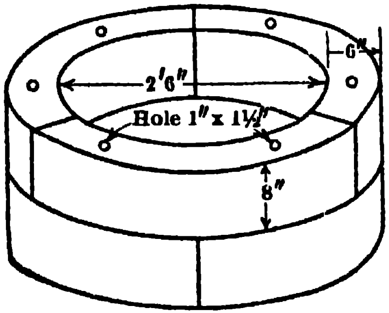

Fig 625. Concrete Chute Wall, Ashanti Goldfields

Cylindrical concrete chutes. Ashanti Goldfields, W Africa, in working exceptionally loose and slippery ore of Obuasi reef by flat-back, square-set and closely filled stopes, has found pre-cast concrete segments cheaper than timber for walling single-compt ore passes (537). Segments, 3 to a ring, are 8 in high, 6 in thick, with inside radius of 1.25 ft (Fig 625). Each segment has 2 holes, top and bottom, 1-in diam and 1.5 in deep, for inserting iron pegs, 6 per ring, equidistantly spaced to allow staggering of vert joints.

Cylindrical steel chutes were successful at the South Blocks mine, Broken Hill, Australia (315). A diam of 30 in is the minimum size to prevent frequent clogging.

Joints with rivet heads projecting inside were a source of weakness, as the heads wore off; this led to the construction in Fig 626. Chutes are of $^3/_8$-in plate for the first 60 ft above the level, $^5/_{16}$-in for the next 50 ft and $^1/_4$-in for the remainder. Some chutes, carried to 140 ft above the level, have passed 15 000 tons without repairs. Repairs were difficult, but unnecessary if sharp bends were avoided, if chutes were properly spaced, and if blasting in clogged chutes was prohibited. Clogged chutes were loosened by a "cannon," made by boring a 2-in hole in a piece of 5-in shafting and using gunpowder to fire a projectile at the hung-up ore. ADVANTAGES of cylindrical chutes: (*a*) moderate first cost and excellent wearing qualities; (*b*) small size permissible without undue tendency to clog, thus lessening the chance that men may fall into them; (*c*) adaptability to stoping conditions, as no special care is needed when blasting ground above them; (*d*) their impervious structure, which prevents loss of rich ore and keeps out sand filling (a difficult matter in wet mines); (*e*) ease and cheapness of erection, each section fitting the one below. At this mine the steel chute worked as well as any timber chute; its adoption in any case depends largely on the relative cost of steel and timber.

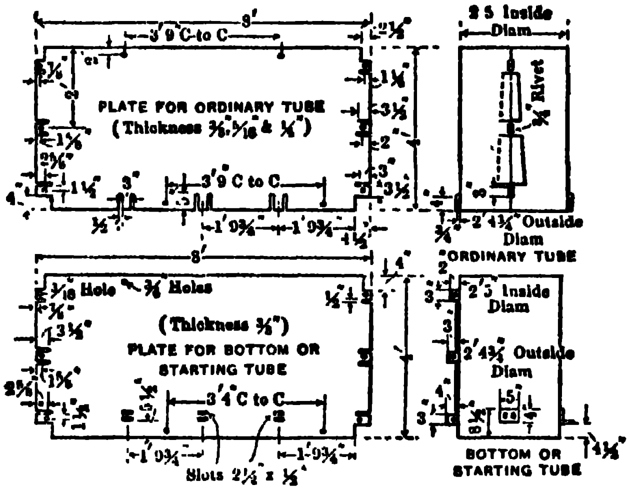

Fig 626. Cylindrical Steel Chute

Rectangular steel chutes (14 by 14.5 in) have been used in filled square-set stopes at Centennial Eureka mine, Utah, for handling high-grade ore without loss of fines. They are of $^3/_{16}$-in plate, bolted to 1.5 by 1.5 by 0.25-in angles at the corners and on the outside.

Clogged chutes may be started: (*a*) by climbing up the chute and placing a light shot to unkey the clog (dangerous work, which should be prohibited); (*b*) if there is a manway, by breaking into the chute; (*c*) by using a " cannon " (see Steel chutes); not always effective and causes delay; (*a*) by exploding " bombs " of 2–7 dynamite cartridges against the hanging ore. At Miami mine, bombs are tied to 1 by 1-in Douglas fir rods (blasting sticks) 10 ft long; if one stick will not reach the clogged point, others are added, to lengths of 50–60 ft. Miami uses electric detonators for firing, experience showing large decrease in chute-blasting accidents compared with fuse and cap blasting. To lessen fire risk, elec detonators are also desirable in blasting timbered chutes. See Bib (619) for details of blasting clogged chutes in southwestern U S. Fig 627 shows a similar device, of a 1 by

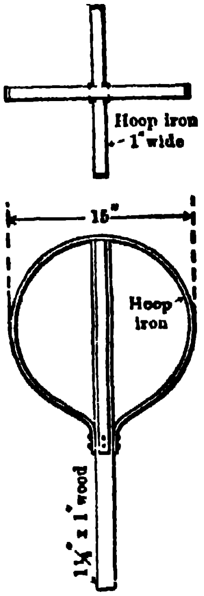

Fig 627

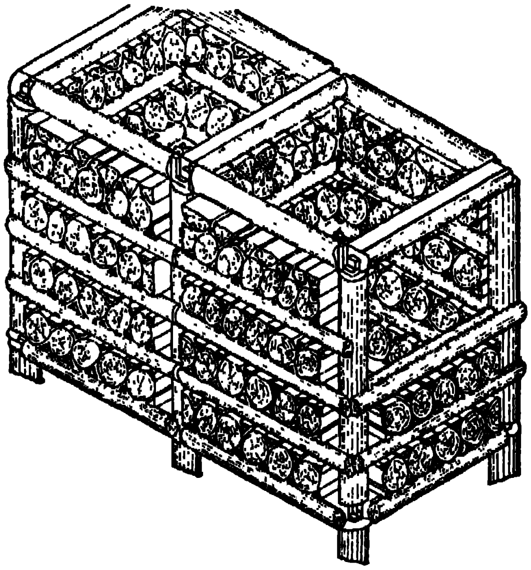

Fig 628. "Bricked" Chute at Black Rock Mine (557)

1.25-in hardwood rod, with flat iron hoops on one end. Extra lengths of rod are lashed on as required. The hoops prevent the rod from catching. The hanging ore is poked until it falls, or a stick of dynamite is fastened to the rod and exploded at the clogged point. This device can be used to a height of 100 ft (316).

Wear. Ore falling freely in a high empty chute is very destructive. Chutes should always be kept nearly full; the wear on the lining then depends on the velocity with which the ore moves and hence varies with the cross-sec. Long chutes may be constructed in segments of convenient height (usually not exceeding 50 ft), offset from one another; a gate may be inserted at bottom of each segment to retard or control flow of ore. Wear on chute lining in square-set stopes can be reduced by substituting short wooden blocks, laid horiz, for the customary vert planking. Fig 628 shows this method of "bricking" at Black Rock mine, Butte (557); blocks are 20 in long and held in place by round poles spiked to outside of posts. Similar method, but using blocks of squared timber, is used at Frood mine (Art 46, Fig 295). Such blocking has additional advantage of stiffening the square-sets.

Chute-gates, at bottoms of chutes, raises, etc, control the flow of ore in loading into cars. Their design and details vary widely. Following general points are important: (*a*) The cheapest chute-gate that will do the work without undue maintenance cost and delays due to clogging is the best. First cost should be considered in connection with the total tonnage passed; elaborate designs are warranted only by large tonnages. (*b*) Gates must be suited to the size of the ore. Simple board gates serve for fine ore; other forms are necessary for handling large lumps. (*c*) For rapid loading, mechanically operated gates are sometimes required. (*d*) Strength is essential, as wear is heavy and gates must often withstand blasting of boulders in or above them. (*e*) Clearances must be ample, to provide room for barring, to allow for settlement of supporting timbers, and to prevent men from being injured by getting pinched between chutes and cars. Following examples are of types found good under different conditions; see also Bib (317).

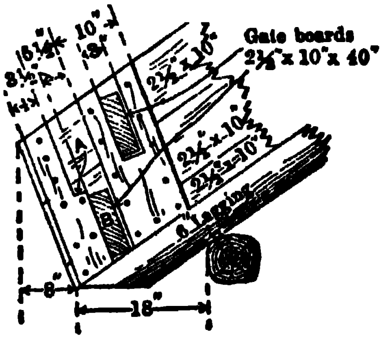

Fig 629. Chute-gate, Homestake Mine

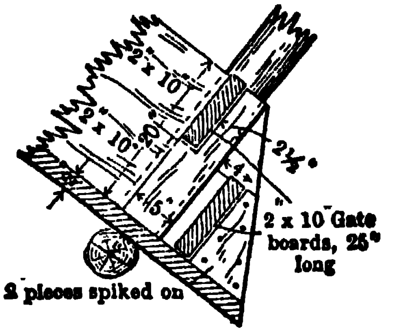

Fig 630. Chute-gate, Dives Pelican Mine, Colo

Simple chute-gates (Fig 629). The gate-boards are held by side cleats; small chutes may have only 1 board, but 2 give better control of the flow of ore and facilitate removal of large lumps (Fig 576, Art 85, shows a larger chute with 3 boards). For small-size material the lower board *B*, Fig 629, is pried up with a pinch-bar; notch *A* is a convenient resting place for board *B* when the chute is running freely. Instead of inside cleats, brackets of round or strap iron or rails may be used to hold gate-boards (Fig 632); these, being outside of chute, do not obstruct flow of ore and are not damaged by it. Modes of attaching such brackets, other than that in Fig 632, are obvious; as brackets of bent angle-iron, used at Noranda (Fig 633); the drop boards are 2 by 10-in; inside width of chute, 4 ft. Fig 630 shows a simple chute supported on stulls, under a narrow shrinkage stope; chutes for mill holes in filled stopes are similarly supported. Fig 631 is a chute for square-set stopes (66). The bottom of such chutes is cut out rapidly, especially by hard siliceous ore, when the chute is not kept full. Linings of plank, old rails or steel plate, are useful. Wear is

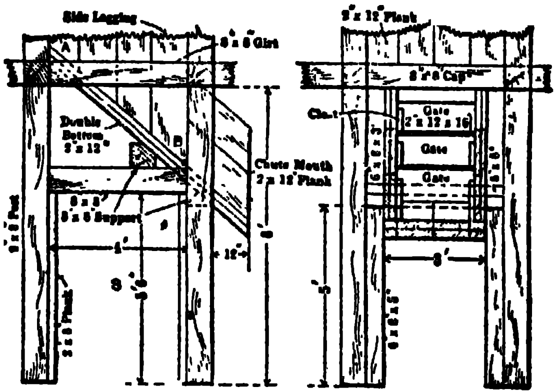

Fig 631. Chute-gate in Square-sets, Bingham, Utah

reduced by offsetting chute (Fig 634), so that solid rock forms chute bottom. In square-sets same result is obtainable by lagging chute sets on level and omitting bottom boards *AB*, Fig 631; space *S* then fills with broken ore, which stands at its angle of repose above chute lip and takes the wear.

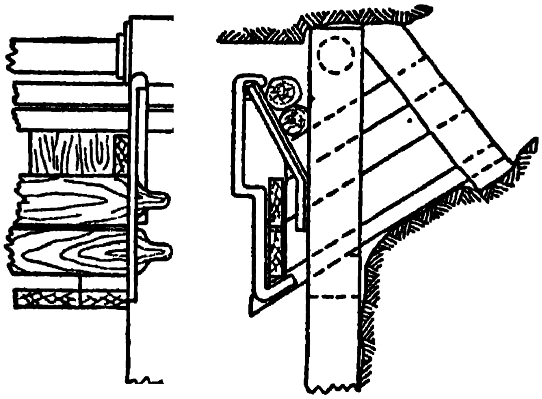

Fig 632. Bracketed Board Gate

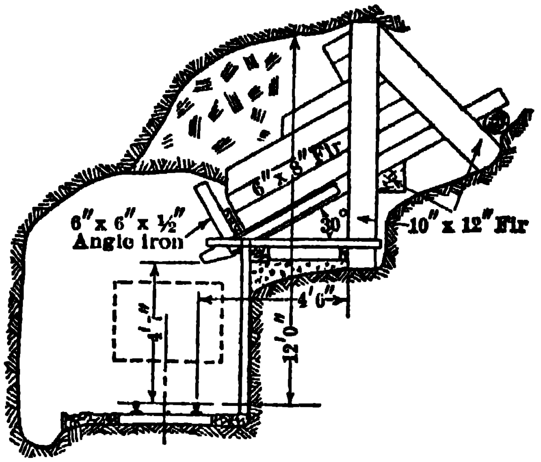

Fig 633. Bracketed Board Gate, Noranda, Quebec

All the above chutes are designed for loading fine ore into small cars, as in hand tramming. Board gates for large cars on motor-haulage levels may be similarly supported, but drift sets of excessive height are required for headroom and for clearance between the chute lip and top of car. For such conditions practice favors pony-sets for supporting chutes (see Fig 634; also Fig 584, Art 86, and Fig 572, Art 85).

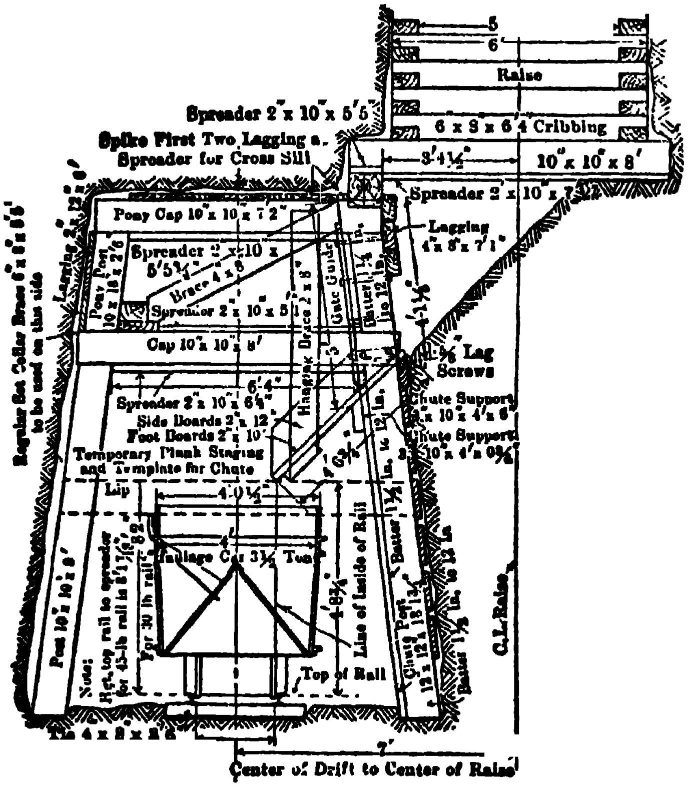

Fig 634. Chute-gate, Miami Copper Co, Aris

Sliding steel gate. Fig 634 shows chute equipped with such gate in the Miami mine on motor-haulage levels for pocket chutes *C*, Fig 579, Art 86. The gate ("guillotine" type) is a steel plate, sliding nearly vertically in guides bolted to the pony-set posts, and operated by a hand lever. The ore is rarely as large as 10-in diam; fine ore is quickly loaded (154). Gates of guillotine type are best adapted to fine or medium-coarse ore, and require mountings free from distortion. They may be operated by levers, rack and pinion, or by direct connection to air or hydraulic cylinders.

Chinaman chutes (Fig 635) are for shrinkage stopes in narrow veins. By omitting lagging between adjacent stulls over the level, an opening is left from wall to wall and of width equal to the interval between stulls. Under this is a platform, 20 to 30 ft long, of horiz stulls in hitches about 5 ft above the track. The stulls are lagged, leaving an open space about 15 in wide over the track for the whole length of the platform. Short 2-in planks *A*, placed across the open space, serve as gates. Broken ore from the stope runs down in a wedge-shaped pile on the platform. For loading cars, a few of the boards *A* close to toe of pile, at either or both ends, are removed; ore from the sides is shoveled to the central opening. **Advantages**: (*a*) the wide opening between stulls prevents clogging; (*b*) large pieces may be sledged or blasted on the platform without damaging timbers; (*c*) the ore settles evenly, as it is drawn over the whole width of the stope instead of from one side; (*d*) rapid drawing is possible, as several cars may be filled simultaneously. **Disadvantages**: (*a*) higher cost; (*b*) the platform is only 5 ft above the rails, thus reducing headroom for trammers; (*c*) level timbering must be higher above the track, which involves more shoveling in opening a stope.

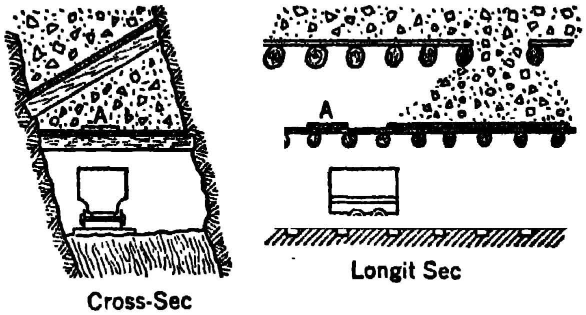

Fig 635. Simple Form of Chinaman Chute

Fig 636 shows a Chinaman chute-gate, with a bulldozing chamber in rock, used by Tennessee Copper Co (data from L. Bregy). This gate is cheaper and requires less dead work in the pillar above main haulage levels than other types of bulldozing chute used there. The 4 20-in sq grizzly openings (double hatched) are protected by 2 angles over inner edges of stringers *S*, and by U-shape steel plates dropped over filler pieces *V*, and bolted below caps *T*. Grizzlies not in use are covered by planks. Loaders enter chamber by ladder at *E*. Large pieces are blockholed on the grizzly. Except the grizzly openings and entrance, floor of chamber is lagged. One or more chute-gates, with raises 30 ft or more apart, are built on a turnout.

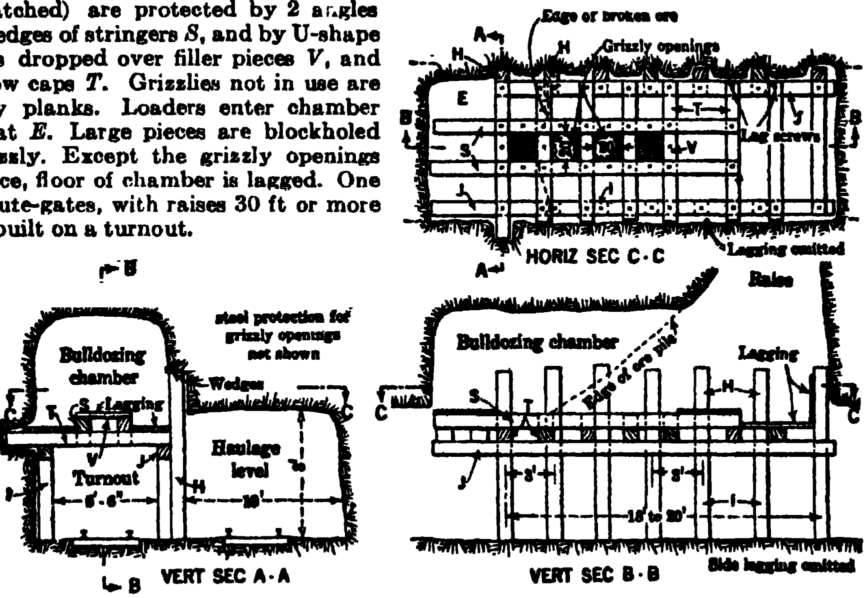

Fig 636. Chinaman Chute with Bulldozing Chamber, Tenn Copper Co

"Bulldozing" chutes and chambers are used for large-scale shrinkage stopes (Art 68), where blockholing can not be done in the stopes and where large slabs would clog the gates. For examples, see Alaska Gastineau, Beatson, and Alaska Juneau mines (Art 68). Bulldozing is also a necessary step at some mines using block-caving (Art 80). For other details of a few installations, see Bib (562).

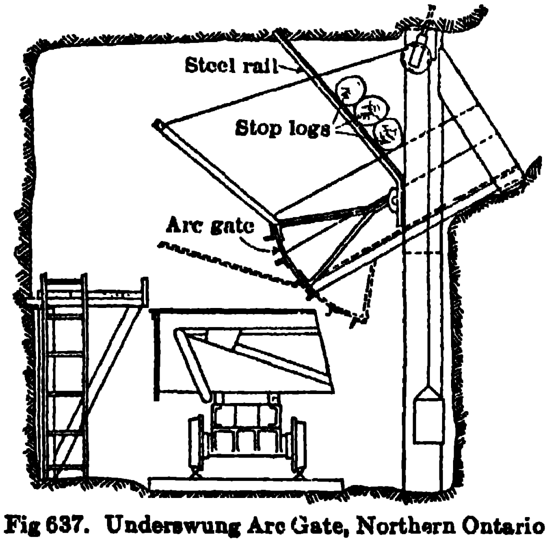

Fig 637. Underswung Arc Gate, Northern Ontario

Arc gates, often used for moderately fine ore, may be operated by hand levers, or compressed-air cylinders; cost not justified by small tonnages. Underswung gate (Fig 637), closed by lifting through the stream of ore, is generally preferable to those which cut down through the ore; it is more easily controlled and less apt to jam or allow sudden rushes into the drift. Overhung arc gate (Fig 638) is not well adapted to coarse ore, due to difficulty of closing it quickly and tightly in presence of large lumps. If the axis of rotation is placed slightly lower than the level at which edge of arc meets bottom of chute, the gate can be operated with less effort.

Fig 639 shows an "overcut" gate made of a flat steel plate, reinforced by a strap of which the ends are bent back to form arms hinged to posts at both sides of chute. This gate is popular in Southwestern copper mines (also used at Frood mine), having advantages of cheapness and simplicity; best adapted to moderately coarse ore. On small gates, the handle may be omitted.

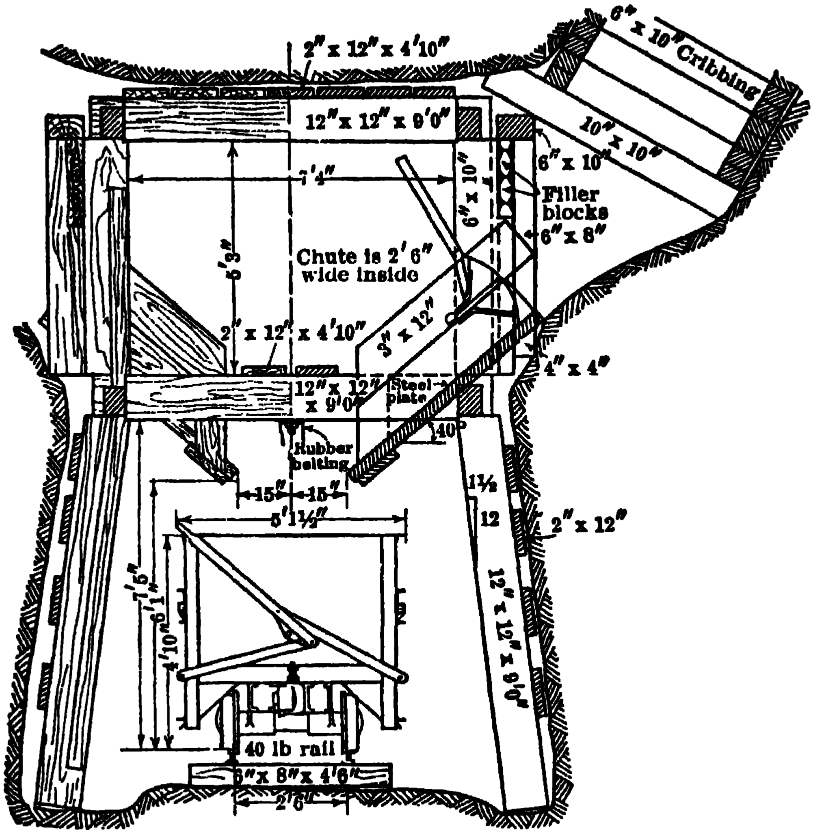

Fig 638. Overhung Arc Gate, Inspiration Mine

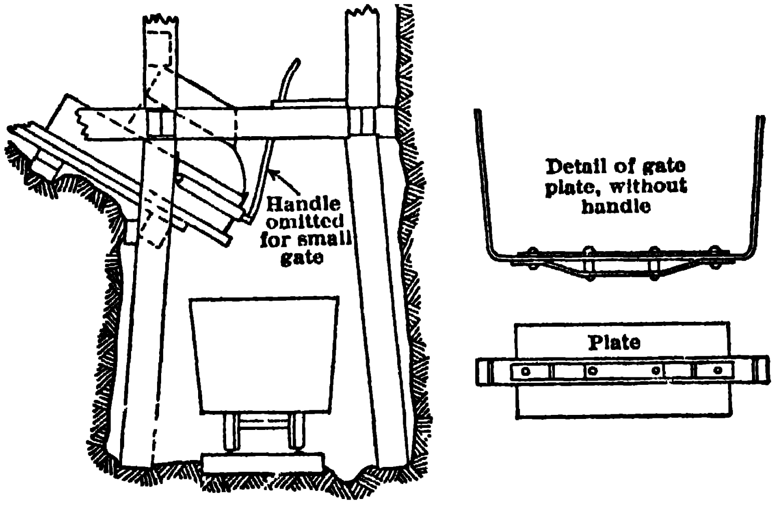
Butterfly gate (Fig 640), originating in So Africa, used widely in Europe and at some Lake Superior iron mines, is simple and easily operated, but not well adapted to coarse ore. A flat steel plate is hinged along its center line so as to rotate on a horis bar *h*, of which the ends are supported on sides of chute. A pin *p*, inserted from outside through a hole in side of chute, holds the gate shut; on withdrawing pin, pressure of ore opens the



Handle omitted for small gate
Detail of gate plate, without handle
Plate

Fig 639. Flat-plate Overcut Gate

gate. Flow is stopped by inserting pin and raising lower edge of plate until upper edge digs into the ore stream, thus rotating and closing the gate.

Finger chutes. Fig 641 shows a chute (105) for handling large amounts of relatively coarse, dry ore. The fingers, held in place by the weight of an arm *B*, are separately hung from rod *CC* so that they move independently. Short ropes from the arms join a main rope, passing over a roller to a small windlass. To draw ore, the fingers are raised high enough for it to pass; when drawing is completed the fingers fall by gravity. If a large piece catches on the lip, it holds up only 1 or 2 fingers, the others dropping to normal position. To prevent leakage when chute is not in use, a tail board is placed across the lip in angle irons *D*. Advantages of finger chutes: quick loading, freedom from clogging and from spilling ore on tracks. Their cost is prohibitive except for large tonnages; in two Alaska Treadwell mines, they were replaced by simple chute-gates. Fingers made of bent rails have been found satisfactory by Tenn Copper Co (317) and several other mines.

Ball-and-chain, or curtain gate (Fig 642) a patented device invented by D. L. Cramp, and used at Lake Shore Gold Mines and elsewhere, is well adapted for chutes passing ore of widely divergent mixed sizes (597), since large lumps can be barred through without causing a run of fines. It acts to hold stationary the upper layer of a bank of ore standing only slightly steeper than its natural angle of repose. Size and wt of balls and chains are proportioned to sizes of ore and chute; a chute 32 in wide would need 5 6-in balls. Each ball is connected by a short, light-weight chain to a bridle bar, which is raised and lowered by rope, pulley, and windlass.

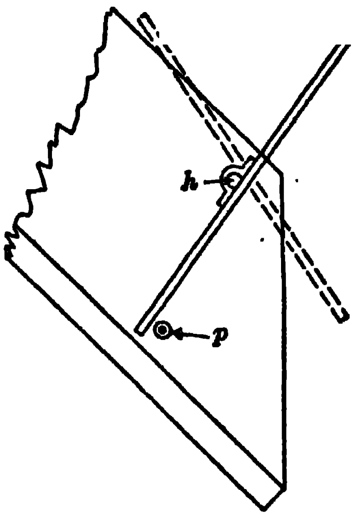


Fig 640. Butterfly Gate

Keating chute (Fig 643) was adopted at Creighton mine, Sudbury, Ont, for heavy ore from shrinkage stopes, after trying numerous other forms. The ore contained many boulders, requiring blasting in the chutes. The gate consists of round lagging *A*, held in place by 2 bent rails. The I-beams across the tops of the posts protect the miner when working at a blocked chute; the inside I-beam may be omitted without danger (317).

Baltic gate. Fig 644 shows gate used at the bottom of dry-wall mill holes in upper parts of the Champion mine, Mich. It is operated by lever *A*, and rests on the edge of the car when loading. It is inexpensive and well adapted to the Baltic method of mining (Art 63), because, as mill holes are used alternately as chutes and ladderways, the gates must be dismantled or installed when the change is made. Same type of gate has been retained under different mining system for loading 5-ton cars on lower levels; lever bar is sometimes placed on opposite side of drift, and connected to pan by rope passing over 2 overhead pulleys.

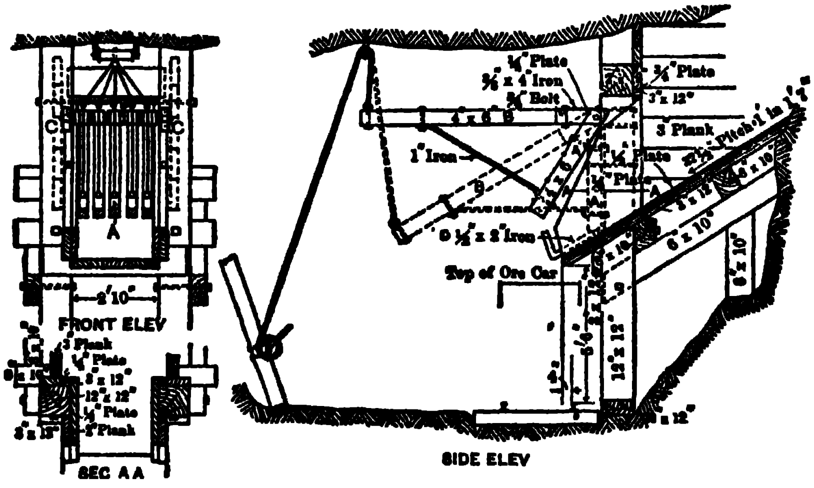

Fig 641. Finger Chute, Alaska Treadwell Mine

Hanging chutes (Fig 645) are used on Mesabi Range while mining the lowest sub-level in top-slicing (Art 70, 71). They have the advantage of holding several cars of ore in a short vert distance, and so avoid interference between miners on the sub and trammers on the main level. The sub-level track is carried on short drift-sets, which also support the chute sides; the bottom, of loose boards, rests on 30-lb rails, which run lengthwise of the chute and carry most of the weight; the rails hang from the caps of small sets just high enough to clear the cars on the main level. The chutes are sometimes 20 ft or more long, 1 or more cars being filled at a time by removing some of the bottom boards (35).

91. MECHANICAL HANDLING IN STOPES (See also Sec 27)

General. Mechanical devices may be used in stopes solely for transport or solely for loading, or for a combination of these purposes. Herein is first described the use of certain equipment for transport; then misc examples of mechanical loading or transport or both. Other examples of mechanical handling are given under open stopes (Art 31–34), top-slicing (Art 71, 72), and sub-level caving (Art 76, 77); for use of scrapers for distributing filling in stopes, see Art 62; for scrapers and loaders in headings, see Art 20. For construction and operation of the numerous machines in use for underground loading and handling, see Sec 27. Development of these machines has been rapid during recent years, with a corresponding increase in their application. In many mines, former stoping methods have been modified to allow the use or increase the effic of mechanical handling; in other more recent ones, the development of stopes has been planned for such equipment as an essential feature. In general, mechanical handling is most advantageous for fairly large-scale operations, where the savings effected apply to sufficient tonnages to warrant the first cost and maintenance of the equipment.

Besides savings in direct cost of loading and transport, there are often collateral or indirect economies connected with mechanical handling: (*a*) increased rate of output from a given area, of special importance under a weak or heavy roof; (*b*) reduction in footage of narrow work required to develop given stoping areas; (*c*) employment of more skilled and semi-skilled labor and less dependence on lower-grade labor (though natives of So Africa and Nor Rhodesia have proved quickly adaptable as scraper operators); (*d*) in flat or slightly dipping stopes, a saving in installation, maintenance, and moving of stope trackage; (*e*) under treacherous roof, or while drawing pillars, scrapers reduce danger to workers by making it unnecessary for them to remain continuously in the stope.

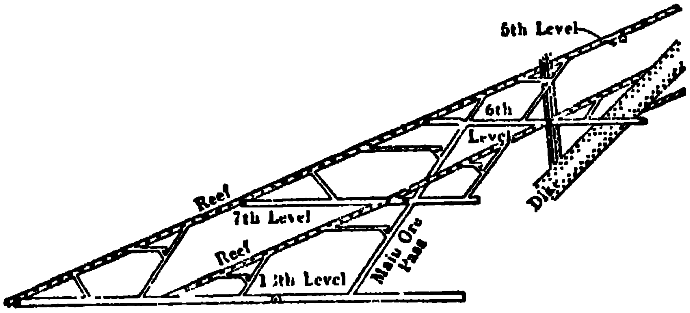

Fig 646. Development at Crown Mines, Transvaal (*E & M Jl*)

Transport in stopes on flat dips. Deposits dipping 10°–35° present a problem of obtaining cheap transport from stope faces to levels. On steeper dips, ore slides to the levels. Minimum dip for sliding by gravity is 33°–45°, depending on character of ore and footwall; on dips flatter than 10°, cars may run directly to stope faces. On intermediate dips, ore must be transported to the levels. Some form of scraper is usually the best and simplest means of stope transport, if scale of work and other conditions justify its installation (see Sec 27, and below, under Scrapers).

Other methods of stope transport, used prior to modern scraping methods, and still used alone or as auxiliaries to scraping are: (*a*) By costly shoveling along footwall. Ore from upper parts of a lift may require several handlings before reaching the level; this limits the level interval (Art 19) and increases development costs. In general, it is justified only for small work in high-grade ores. (*b*) By intermediate levels and raises, to which ore is shoveled or scraped. Lateral transport on intermediate levels may be in barrows, cars, or scrapers. Fig 646 shows an elaborate system at Crown Mines, Ltd, Transvaal, for hand shoveling in stopes (73). Main haulage levels were about 300 ft apart; chute-raises (ore-passes) sloped 55°, and were arranged for a max shoveling distance of 100 ft; 20-cu ft cars trammed to chute-raises; their tracks were on footwall parallel to strike, and level with collars of raises. Such systems, of which many variations are possible, are expensive in non-productive development; they do not eliminate shoveling and wheelbarrow work, but reduce its distance. Hoover (20), in discussing this general method, says: "In some flat deposits, crosscuts into the walls or even levels under the orebody are justifiable. The more numerous the ore-passes, the less the lateral shoveling, but as passes cost money for construction and for repairs, there is a nice economic balance in their frequency." Obviously, scrapers may be used in similar systems of intermediate levels and raises (compare development for top-slicing, Art 70, 71). (*c*) By tracks laid on footwall at an angle to the dip, so that cars can be run to stope faces (Fig 202, Art 34).

This is feasible in deposits of large area, with regular footwall, and dip less than 10°, but not in short, irregular oreshoots. (*d*) By breast stoping to the dip (Art 31). (*e*) By gravity planes, stationary or shaking chutes, or other stope conveyers described below. These aids to stope transport are limited to open stopes in regular deposits; not applicable where hanging wall is heavy, requiring close support, nor to deposits of very irregular shape and dip.

Self-acting (gravity) planes, Empire mine, Grass Valley, Cal. Ore occurrence resembles that at North Star mine (see below); dip is about 30°.

From a raise *R* (Fig 647), near middle of oreshoot, intermediate drifts are driven 75 to 100 ft apart. At *A*, just above the highest drift, are placed 2 drums with a brake. One drum has a friction clutch for regulating the length of rope to suit the different levels. The raise is double-tracked, with turnsheets at the intersections with drifts. Cars lowered from the turnsheets by gravity dump automatically into chutes at the main level (336). To give room for loading, there must be a minimum clearance of 18 in between top of car and hanging wall; hence planes are not applicable in veins less than say 4.5 ft thick. For details of gravity planes, see Sec 11. For use of planes operated by hoists, see Rand practice, Art 33.

"Go-devil" planes, North Star mine, Cal. Aver dip of vein, 23°. L. O. Kellogg (337) gives following data. Main levels are 333 ft apart; from them, stopes are opened in a series of lifts (Fig 648, 649, and Art 39). Beginning at a level, the first stope is carried toward the raise and to the limit of the oreshoot, the ore being shot down on plats laid over the level track. After making 2 or 3 cuts, a shoveling plat is built, at least as high as a car. If the dip is steep enough, chutes are put in to load cars by gravity. When the stope face has advanced about 30 ft, it is drilled throughout its full length. Then the pillars next to chute are blasted out, and a row of stulls is set about 5 ft from the face. These are lagged to retain the broken ore. When space is made, the first intermediate track is laid (Fig 649) and the 2nd lift begun. (Fig 648 shows work at the 6th lift.)

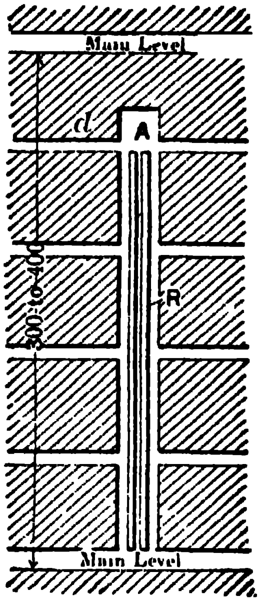

Fig 647. Gravity Plane, Empire Mine

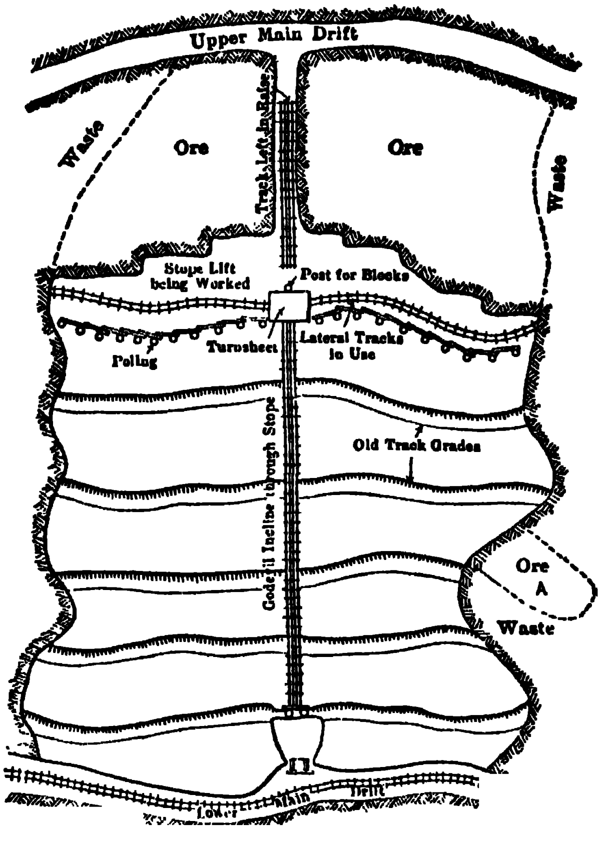

Fig 648. North Star Mine (Stope showing successive lifts)

The ore, stoped in successive lifts, is lowered to the main level by double-track planes ("go-devils"). The headblock (Fig 650) comprises 3 sheaves, with a triangular brake block between them, applied by the lever to all three sheaves. The headblock is suspended at the top of the plane by a bolt through a post. A ⅝-in rope is used for 16-cu ft cars. The trammer fills a car on a lateral track, trams it to a turnsheet at the intersection with the plane, hooks on the rope, pushes the car over the edge of the turnsheet on to the go-devil track, and grasps the brake lever. The descending loaded car pulls up the empty. The track is 20-in gage, of 12-lb rails on 4 by 6-in ties. Three cars in a stope handle the product of 4 or 5 drills, from 10 to 15 go-devils supplying a daily production of 350 tons.

Stationary chutes are open steel-plate troughs, of curved or rectangular cross-sec, laid on the stope floor, or on waste rock or small timber bents. Ore is shoveled into the chutes at the face, or wheeled to them in barrows. On the Rand (Art 33) semi-circular chutes convey dry ore on dips over 30°, which is about the minimum angle at which ore will slide. Flatter dips are possible if the ore is thrown or dumped into the chute, thus having an initial momentum. These chutes are in 10-ft sections, 18 in wide, of ⅛-in plate. Rectangular chutes, 20 in wide by 5 in deep, and pitching 31° to 34°, were used at Golden Cross mine, Cal, for dips of about 30°. Similar chutes have been used for cleaning up stopes at Mohawk copper mine, Mich (Art 41). Stationary chutes are cheapest and simplest. During blasting they may be protected by piling ore on each side. In a few cases on the Rand, a small stream of water has been used to assist movement of ore, when chutes are nearly at the critical angle.

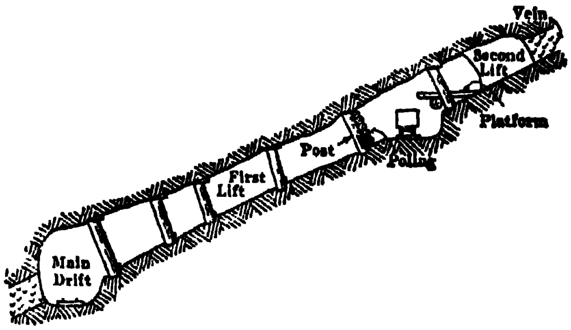

Fig 649. North Star Mine (Sec through stope, showing 1st track)

Shaking chutes have been used widely in flat stopes on the Rand, though lately often replaced by scrapers. They are shallow, sheet-iron troughs, of curved cross sec, hung by chains from eyebolts in holes in the hanging-wall, or better from a taut wire rope and turnbuckle (Fig 651). The chute is suspended in an inclined position, and the ore shoveled into it while it is swung longitudinally by one or more Kafirs. At each backward swing the ore moves by its inertia down the chute a few inches to a foot or so, and discharges almost continuously. In large, flat stopes, ore is thus conveyed considerable distances by two or more chutes in series; also, the successive lengths may be placed at angles to one another. These chutes are inexpensive, with large capacity and low operating cost. Disadvantages of suspending chutes from eyebolts: (*a*) difficulty, with irregular hanging-wall, of drilling holes in line and at proper intervals, and adjusting the chains so that chute swings freely and some chains do not work against others; (*b*) new holes must be drilled each time chute is moved. If hung from a rope (Fig 651), the chains are easily shifted. The rope supports may be 30 ft or more apart; closer, in narrow stopes. Clips are fastened on the rope at intervals equal to the chute lengths. As the rope remains in place during blasting, the chute is readily shifted. A few holes can be drilled on a new line, the upper end of the rope moved over and the rope tautened. Chutes deliver directly into the pocket or car (187). On the Rand, chute segments are 8 ft long by 18 in wide, of ⅛-in plate. Lower end of any segment slips into upper end of the next one, and is fastened by 2 bolts fitting loosely in slots, to allow flexibility. As the stope face advances, the chute is lengthened, to keep within shoveling distance. Fig 652 shows a chute of ¼-in plate, reinforced by straps. On slopes less than 8° or 10°, ore will not move forward efficiently. It is advantageous to have stope faces parallel to the dip, so that chutes may be set at the max possible slope. Long chutes

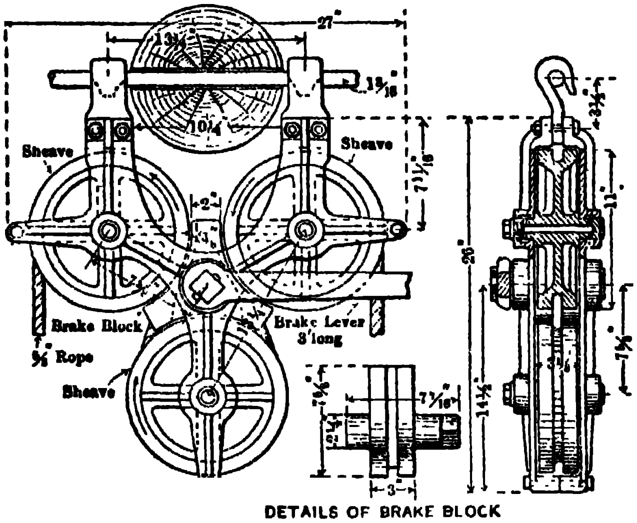

Fig 650. "Go-devil" Sheaves

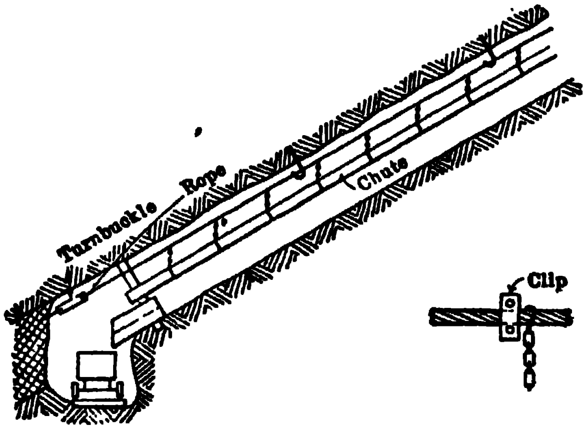

Fig 651. Mode of Support for Shaking Chutes

may be swung by air or electric motor mounted on a drill column and provided with reciprocating mechanism. For data on shaking chutes in Randfontein Estates, see paper by H. Clark (556).

L. Jacob, in 1935 (547) describes use of shaking chutes at Ottange 2 mine, Moselle, France. A nearly level bed of iron ore 1.5–1.7 m thick is worked by room-and-pillar methods, followed by extraction of pillars and caving of overlying strata; immediate roof is a bed of blue marl 0.75 m thick, requiring some support by props and cribs. Ore is wet and contains about 50% of fines with strong tendency to agglomerate; it is broken to room width of 14 m by L O X explosive in slabbing rounds, retreating on both sides of a previously advanced heading 4 m wide. The conveyer comprises 3 sections: (1) discharge end, 12.5 m long, sloping upward from floor to load into a car 1.4 m high, standing on haulage entry outside of room; (2) main horiz section, to max length of 30 m, dividing at its inner end into a short Y; (3) 2 inner extensions, max length 30 m, each joined to a branch of the Y by adjustable connections permitting the extensions to be spread apart at any angle to max of 30°. Troughs are of 3- and 4-mm Mn-steel plate; rectangular sec area of main trough is 750 sq cm; of branch troughs, 530 sq cm. All sections are rigidly joined, mounted on roller bearings resting on floor, and oscillated (with accelerating forward stroke and quick return) by mechanism placed under discharge end and driven by a 19-kw, squirrel-cage motor; strokes about 175 mm long, 82 per min. Aver rate of travel with this ore, 13.5 m per min on main section; slower on branches, and faster on upward-sloping discharge end. With 8 men shoveling into 2 branches, 18 m long and parallel to main line, aver output was 36 tons per hr (6 men, 28 tons); spreading the same branches to 30° apart reduced output of 8 men to 27 tons per hr (6 men, 22 tons). It was found advisable (to maintain speed) for branches not to exceed the length of main section, limiting over-all length of room to about 70 m, reduced to 55 m when ore was very wet.

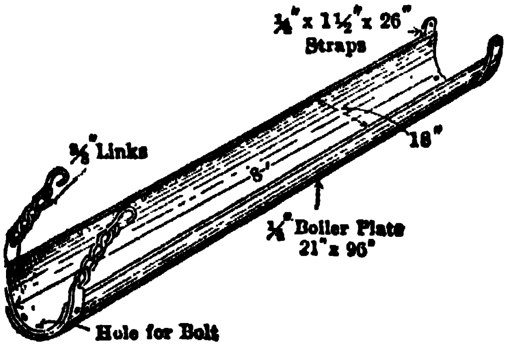

Fig 652. Shaking Chute

For another example of shaking chutes, see Boleo, below.

Aerial ropeways (see Sec 26). One (Henderson-Tucker) gave good service in the Geldenhuis mine (Rand), in stopes averaging 7 ft wide, on dips of 5° to 10°.

The standing rope terminated over a small pocket, for loading cars on the level; upper end was fastened to a drill column at any desired point in the stope, and the rope was tautened by a turnbuckle. The trolley and bucket descended by gravity, and were pulled back by a small air or electric hoist on the drill column. This device was suitable for stopes of any length, but, for spans exceeding 100 ft, the rope had to be supported at an intermediate point by a clamp attached to the arm of a drill column. The bucket dumped automatically. The rig could be dismantled in 15 to 20 min, and erected in about 30 min, irrespective of the length. Moving the column at the upper end took 10 to 15 min. During blasting the bucket was removed and rope slackened (256). Two track-cables were sometimes used, for working in balance. The winch then had separate clutched drums, otherwise buckets could load at one place only. Fig 653 shows a simple device to overcome this difficulty, invented at New Kleinfontein mine. *X* and *Y* were the main ropes; *Z* was a swinging stop, to take up shocks. *M* and *N* were side-tipping trucks, holding 4 to 10 cu ft. Haulage rope *O* passed around 2 grooved wheels *W* and over pulley *A*, which traversed rope *BC* and so varied working length of *O*. This conveyer would work in a reef 45 in wide, and on dips of 15°–35° (546).

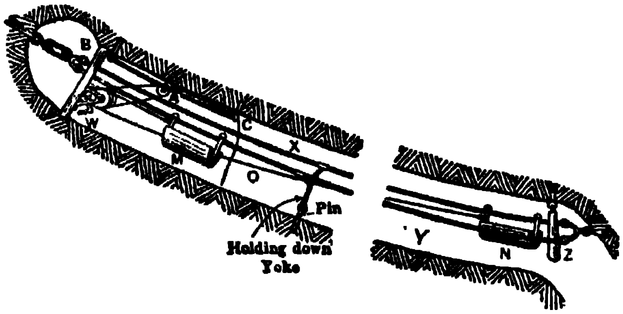

Fig 653. Aerial Ropeway for Stope Transport

Monorails and trucks. The Wager Bradford elevated system, proposed for levels and very flat stopes on the Rand, has not been successful. Difficulties in supporting the rail and cost of installation offset the advantages due to decreased friction. Barrows with grooved wheels on monorails (554). For thin veins at dips to 25°, E. M. Weston used a 2-cu ft wooden Cornish barrow, with grooved wheel running on a wooden rail; or for regular dips to 18°, a 3-cu ft steel barrow on steel rail. Under rear end of the body is a grooved block, for guiding the barrow in sliding on the rail. Wheel is a hardwood disk, with slightly larger 1/8-in steel disks on each side, forming a groove to fit the rail. It will run on the stope floor, if fairly smooth. Several barrows may operate on 1 rail, an empty being tipped off the rail on meeting a loaded barrow.

Belt conveyers underground. Belt conveyers have been installed underground both for transport exclusively and also to afford opportunity for hand-sorting of ore in transit. Usually, the conveyer delivers to loading pockets or final disposal, not into mine cars.

For examples of simple transport, see Mesabi (Art 96); also Tri-State district, Grand Saline salt mine, and Boleo (below). Other examples follow.

New Idria quicksilver mine, Cal. A belt conveyer, installed in an adit 300 ft lower than original outcrop, is used both to dispose of stripped waste and to permit hand-sorting of ore from glory-hole workings. At bottom of glory-hole chute, boulders are bulldozed to pass a grizzly of 4-in round steel bars spaced at 14-in centers; material is delivered to conveyer by apron feeder and a chute punched with 1-in holes, to allow fines to cushion large pieces; usual rate of feed, 350 tons (capac, 1 000 tons) per hr. Belt, 42 in wide; length, c–c of pulleys, 1 250 ft, of which 670 ft is inside and 580 outside of adit; belt speed, 310 ft per min when discharging open-pit strippings, 45 ft per min when sorting ore (320).

East Geduld No 1, So Africa. Recent installation of a belt conveyer at the loading pocket near bottom of the 3 225-ft vert shaft (195) was a new development in Rand practice. Coarse ore from a grizzly is hand-picked, and waste returned (by cars) for stope filling. Method offers advantages to deep mines where filling is needed, other means of sorting are inapplicable, and shaft facilities could be fully occupied with hoisting of ore.

Tri-State district. C. W. Nicolson (191) records in 1938 that 2 new mines have installed belt conveyers, 500 ft and 700 ft long, both intended to be lengthened, for moving ore received from scrapers to skip-loading pockets at shaft. Before falling on belt, the ore passes over a 10-in grizzly, but large slabs frequently pass through. Extremely abrasive character of ore entailed special design of belts. At 200 ft per min, 24-in belt carries 100 tons per hr; labor cost, 0.9¢ per ton. For operation at one of these mines, see D. C. & E. mine, Art 31.

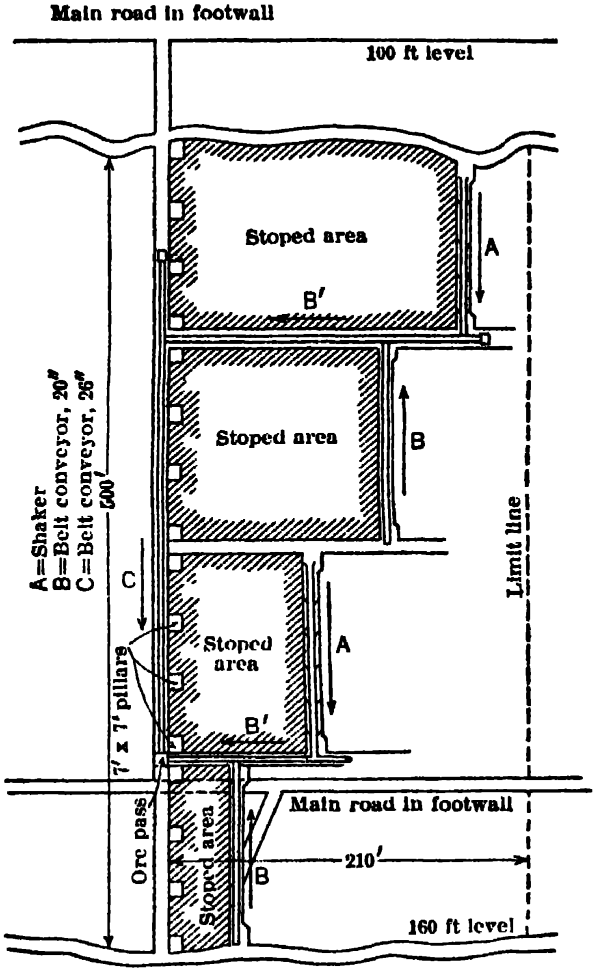

Fig 654. Stoping with Shaking Chutes and Belt Conveyers, Boleo Mines

Cie du Boleo (552). After experiments in 1927, conveyers, both shaking troughs and belts, have almost completely replaced the 0.5-ton cars formerly used. Pay ore, disseminated chalcocite, occurs in a seam about 60 cm thick in a bed of wet clay about 2 m thick, dipping 9°, under heavy and weak roof. Straight-faced breast stopes are advanced in direction of strike, working both up and down dip from sub-levels about 60 m apart (on slope). Mining is by hand; a miner usually extracts a block 2 m high, 2.2 m wide, and 1.1 m advance in 4.5 hr, including 1.5 hr on timbering. At a face to the rise, ore is thrown into a motor-driven shaking chute (Fig 654, *A*) 30 m long (in 3-m sections) either suspended by chains from roof or supported on rollers; 3 men can move such a shaker in 2 hr. At a face down dip, a 20-in belt conveyer *B*, of 18-in overall height, carries ore upgrade. Both face conveyers deliver to a 20-in belt *B′* on the sub-level, of which the max length is 60 m; this delivers to a 26-in belt *C*, in an incline at edge of stoping area, from which the ore is dropped through chute to main haulage level 6 m below, in the footwall. Adoption of conveyers increased output per man-shift from 1.352 met ton in 1927 to 2.126 tons in 1931. An incidental advantage, especially important under the difficult roof conditions, was that a given area could be stoped more quickly, with larger sub-level intervals, and at less expense for drift maintenance. Further details in Bib (552).

Scrapers in stopes. Scrapers, usually operated by double-drum hoists (occasionally 3-drum, as at El Potosí, below), are widely applied in nearly all forms of stoping, though most often in stopes at inclinations where ore will not roll or slide unassisted. In some cases, they serve only for transport, as distributing waste in filled-back stopes (Art 62), or working ore downward over irregular footwall, as in Golden Messenger mine (Art 40, and below), but their chief function is loading ore, directly into cars by a ramp or slide, or into loading chutes in bottom or lower edge of a stope, or at end of a special scraper drift. They have been particularly useful in top-slicing and sub-level caving systems of Lake Superior iron-ore mines. In some mines, as Flin Flon (Art 43), Utica Extension (Art 71), and Climax (Art 87), the whole development and extraction plan has been devised to include scraping as its chief feature; in Tri-State District (Art 31), Michigan amygdaloid mines (Art 41), Rand gold mines (Art 33), and many others, scrapers have been adapted to former practice (sometimes slightly modified) to economize in labor. Following examples illustrate other scraper applications.

Tri-State district. Ore is hoisted almost exclusively in cans 30 to 32-in diam and same height, holding 1 100 to 1 400 lb; for movement underground, can is mounted on a low truck, and then requires vert clearance of 54 in. An aver shoveler ($5.25) loads 25 tons per shift. During 1937, according to C. W. Nicolson (191) several of larger mines adopted 36, 42, and 48-in scrapers, both air- and motor-driven, for 3 purposes: (*a*) scraping to winzes or hoppers delivering to cars or cans on a slightly lower level; (*b*) scraping into cars or cans on same level, via ramp or slide, permanent or portable; (*c*) scraping to a conveyer belt delivering to shaft pocket. Data in Table 62 include some experimental installations and hence are subject to improvement. For data on scrapers in 3 mines of the Commerce Mining & Royalty Co, see Bib (583).

Table 62. Data on Scraping, Tri-State District

Delivered to	Hopper	Cans, by permanent ramp	Cans, by portable ramp	2.5-ton cars with 2 semi-portable ramps	Belt conveyer
Tons per shift....	144	190	182	123	200
Men occupied...	3	2	3	2	2
Tons per man-shift	48	95	61	61	100
Total cost per ton	13¢	9¢	9¢	10¢	8¢
Power cost per ton	1 2¢	1.5¢	1.5¢	1.5¢	1.2¢

Salt mining. Data from H. B. Cooley (553) in 1932. Salt bed, lying 700 ft below surface, Grand Saline, Tex, is uniform throughout, free from horiz seams or vert cleavages, and may break into blocks of 500 lb or more. Fig 655 shows alternative methods of mining; in both, a room 60 ft high and 60 ft wide is advanced from shaft, the bottom of which is far enough below room level to accommodate a crusher and skip-loading pocket. The shovel-loading method, a variation of shrinkage stoping, has advantage of permitting a large reserve of broken salt during periods of slack shipments. In the scraper method, an inclined heading 60 ft wide is driven up a 20° slope from near the shaft pocket; on reaching a height of 60 ft it is continued horiz. Inclined underhand slices are broken with vert 6-ft holes, 3 ft apart. Broken salt is scraped to shaft pocket by a V-scoop of 2-ton capac, operated by 3-drum hoist. Max effic distance from shaft to bottom of inclined face is about 600 ft. When the room, producing about 75 000 tons of salt, has advanced that distance,

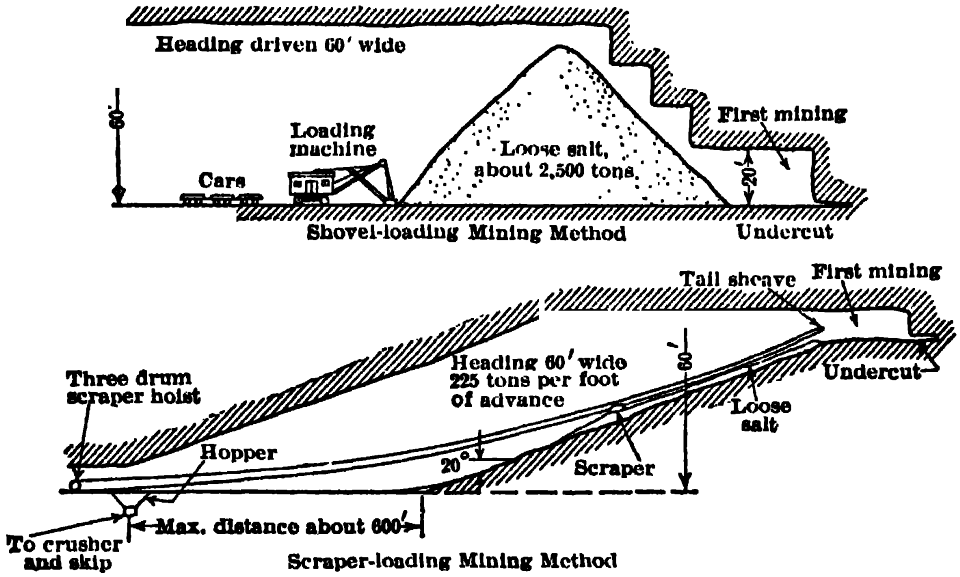

Fig 655. Salt Mining at Grand Saline, Tex

a similar room is turned at a right-angle about 120 ft from shaft, the scraper hoist is moved opposite to it, and a belt conveyer is installed in the first room to transfer salt to shaft. A corresponding room can then be turned in opposite direction and worked without shifting hoist or extending conveyer; the 2 rooms maintain production for about 2 yr before moving equipment again.

N'Kana mine, N Rhodesia. Scrapers are used in sub-level open stopes, when the dip is less than 50°, and in connection with rock chutes delivering ore by gravity to footwall haulage tunnels (528). Stope widths, in direction of strike, are 35 ft (under weak roof) to 80 ft; length on dip, up to 150 ft; scraper drifts are usually at 125-ft vert intervals. For details, see Bib (528, Dec, 1935). Hoe-type scrapers are 60 in wide and weigh 2 400 or 2 800 lb; respectively operated by 50- and 100-hp motor hoists. A bracket bolted outside of one end aids in righting scraper if it overturns. Tail-rope blocks, 14-in diam, are fastened: (*a*) by 2 or 3 eyebolts wedged into holes and connected by chain from which the block is suspended; (*b*) by a piece of $^3/_4$-in wire rope, clamped around a thimble, and its ends wedged and cemented into 2 holes 4 in apart and 2.5 ft deep; a row of such slings is connected by chain across top of stope and tail block attached where needed. Scraping may be continuous, or on 2 shifts; a 35-ft stope may yield 6 000 tons a month; larger ones, 10 000 tons. Blasting of boulders facilitates scraping and passing through the grizzly with 22-in openings. A scraper crew, working 2 or 3 stopes, comprises 1 European and 12–15 natives. Cost of scraping during a 6-mo period, 7.2 d per ton, including labor, explosives, supplies and power. See also Roan Antelope mine, Art 43.

Pickands Mather & Co. Study of slicing with scraper-loading into 60-cu ft hand-trammed cars, at the Bennett mine on the Mesabi Range, showed that loading and tramming consumed 30% of the time for a complete cycle, the slices being 50 ft long, 10 ft wide, 12 ft high (268). Substituting a scraper for cars in the transfer drift (terminating at a chute delivering to main haulage-way in footwall) and working 2 slices at once from opposite sides of this drift (3 men taking the place of previous 4), increased man-shift output from 27 to 30.8 tons where transfer drift was 150 ft long, and from 24.5 to 30.7 tons in a 200-ft drift, an increase of 25% in latter case. Necessity for building and moving scraper slides was also eliminated. Same Company's UTICA EXTENSION MINE (Art 71) was thereupon developed for scraper handling exclusively; ore bed, 10–12 ft thick, is nearly horiz but slightly undulating. Transfer drifts, 6 by 6 ft, were driven from tops of footwall loading chutes along bottom of ore to boundary of the block to be mined; these drifts averaged about 340 ft long and required no uniformity of grade (an added economy over car transport). Slices were started on both sides and at right-angles to end of transfer-drift, and staggered by width of one slice (Fig 482). Each slice was worked with a box scraper 42 in wide, 18 in high, and of 10 cu ft capac; this proved better than a higher 14-cu ft scraper. Scraper hoists were 7.5–15 hp, with 440-v motors. Transfer drifts were floored about 4 ft wide with 2-in plank; the box scraper used here was 48 in wide and 30 in high; normal capac, 24 cu ft, but actual vol dragged over floor was about 29 cu ft. A scraper 60 in wide had less loading effic. Pull rope diam, 0.5 in; speed, 450 ft per min; tail rope, $^3/_8$-in diam; speed, 550 ft; return tail rope was carried on 6-in sheaves along drift. Operation and reversing of the 35-hp hoist at chute end of drift was entirely automatic, though under control from either end of scraper-road; speed was retarded within an adjustable distance (usually 25 ft) from each end; overwinding at either end was also prevented automatically. By this plan, 1 miner could watch the transfer scraper and operate the feeder scraper in 1 slice while 2 others were drilling or timbering in opposite slice; output of 23.7 tons per man-shift was thus attained.

Woodward Iron Co. The upper bench (10–12 ft thick) of the "Big Seam" hematite at Bessemer, Ala, is worked by a room and pillar method (Art 40), loading cars almost entirely by scrapers (177). Dip is gentle but variable. Main haulage-ways are 12 ft wide, but widened for double-track opposite bottom of each room. These are turned 12 ft wide up the rise at 75-ft intervals, beginning at property line, and driven for 25 ft with hand loading. Scraper slide, then installed, is mainly of 12-in, 25-lb channels, 16 ft long; bottom requires 12 channels, flat side up, bolted together, and supported by trestle near outer ends. Double-drum, 55-hp hoist, on a self-propelling truck, serves 3–5 rooms alternately, standing on side track opposite the slide. Beyond its neck, a room advances 30 ft wide, to the next higher haulage-way, usually 220 ft (sometimes 300 ft) and is then stripped 10 ft on each side, making 50-ft rooms and 25-ft pillars. A round of 14–18 8-ft holes, by 2 or 3 tripod drills, breaks 100–125 tons per drill-shift. Box-type, 3 100-lb scraper loads out 2 rooms while a third is being drilled and blasted, and 2 others are being started. Including a slice finally taken from wall of haulage-way, first mining yields about 65% recovery, increased to 75% by splitting the pillars.

Flin Flon sulphide ore is excessively hard, and breaks into large, angular pieces; it is mined by sub-level open stoping (Art 43) and as the surface equipment includes a 42-in crusher, no effort is made to break ore in stopes smaller than 36 in (565). A stope 300 ft long (dip 70°) discharges through 8 untimbered raise chutes, 40 ft apart, into a "scram", drift, each end of which connects through a grizzly raise with main haulage crosscuts 12 ft below (Fig 279). The chutes are inclined at 50° and offset to footwall side of drift, so that broken ore rolls onto the floor and is bulldozed if necessary. At each end of scram drift, and beyond the grizzly, a 75-hp, double-drum hoist operates a scraper, dragging ore from the nearest 4 chutes, or 150 ft max travel. Scraper is of arc-hoe type, 6.75 ft wide, weighs 2 800 lb, and delivers about 5 tons per trip, or 500 tons in 8 hr. Haul rope $^7/_8$-in, tail rope, $^3/_4$-in, passing over 24-in sheaves. Floor of drift is laid with longit 40-lb rails, 2 ft apart, to reduce scraper friction.

El Potosí mine, Chihuahua, Mex (see Art 37). Scrapers are utilized in the glory-holes in chimneys and thick mantos (when the benched area becomes too wide for gravity discharge to central chute) and especially in open stopes in thinner mantos, opened through raises from haulage drifts in footwall (174). In 1933, scrapers handled 154 750 tons, or 34% of total output. When suitable, scraping saves 10–30¢ (U S) per ton over hand shoveling, due to increased output per man-shift; it has also permitted working of numerous otherwise unprofitable orebodies. Hoe scraper, made in Co shops, is 3 ft wide and 15.5 in high; back plate is curved to 16-in radius, and has replaceable edge; ropes are strands from discarded 1.25-in shaft-hoisting rope. Preferred hoist has 3 drums, with 15-hp motor; as compared with a double-drum, this hoist can scrape a larger area from one set-up, and with less frequent shifting of tail-rope sheaves. Scraping distance is normally 100–125 ft; occasionally 150 ft, with some loss of effic unless a higher-speed motor is warranted. Fig 656 shows scraper installations in a typical manto stope, worked by underhand benches to height of 40–65 ft above a nearly horiz floor. (See also Sec 27.)

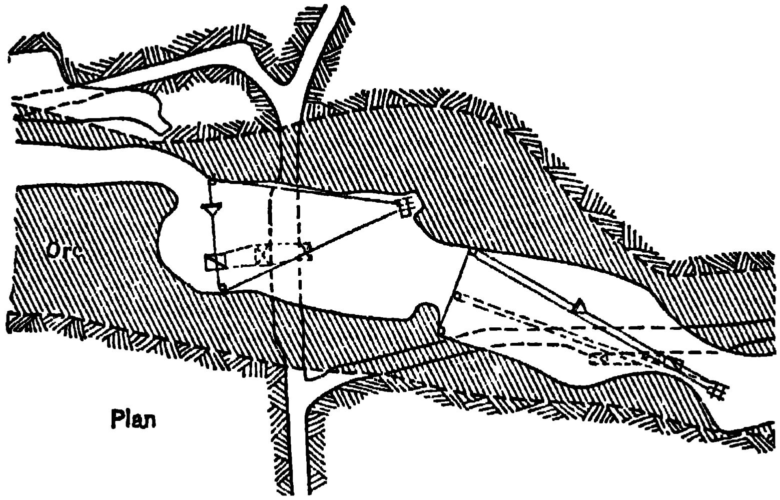

Fig 656. Scraping in El Potosí Mine, Mex

Golden Messenger mine, York, Mont. Scrapers move nearly all the ore from stopes, about 125 tons a day (Art 40). Veins, 4–10 ft wide, dip 30°–60° (aver 40°), and are often interrupted by step faults of small throw; these produce an irregular footwall, and require numerous pillars (Fig 245). Stopes are worked both over- and underhand, through drift chutes 15–30 ft apart. At chutes 60–75 ft apart, scraper hoists with 7.5-hp motors are mounted on top of drift sets. By adjusting snatch blocks, ore can be scraped into chutes 40 ft on either side, as well as into the hoist chute. Due to small capac of chutes at this low dip, ore is often drawn into stock piles at points where it can be reached quickly when chute is being drawn. Drag of 125 ft is about the limit for these hoists, using 36-in box scrapers. Similar scrapers are installed inside of the stopes, aiding flow of ore over high spots in floor, through openings between pillars, and to within reach of chute scrapers (69).

Witwatersrand. Data from C. L. Butlin (559) in 1930. Adoption of single-hole benches drilled by jackhammer, together with reduction in stoping widths, greatly increased the area from which ore had to be removed to maintain the output. At MODDERFONTEIN MINE, for example, in 1923 each 100 ft of stoping face produced 23 tons per shift; in 1928, the aver was only 10 tons. Experience with shrinkage stoping (Art 33) and scraper loading has shown the most favorable conditions for such work to be: (*a*) stope face straight and nearly parallel to dip; (*b*) absence of faults, and of roof supports in scraper path, (*c*) scraper pull not longer than 200 ft, sometimes requiring a subdivision by intermediate haulage levels. Breaking and scraping are conducted alternately in adjoining panels, the scraper removing about 40% of ore broken and thrown back from face; rest remains in shrinkage pile for subsequent disposal by another scraper (Fig 196).

Comp-air, 10-hp motors were usual; now replaced by larger elec motors. Rope speeds, 60–100 ft per min under load, and 100–180 ft empty. Scrapers could handle 12–15 tons per hr; actual performance, about 37 tons per scraper-shift, employing 6 or 7 natives for entire work. Aver of 5.5 tons per man-shift compares favorably with effic of former hand shoveling in wider stopes. Advantages of scrapers used in shrinkage stopes, as proved at Modderfontein, are: (*a*) ability to work with good effic in thin reefs (36 in or less); (*b*) saving in labor by eliminating hand shoveling under adverse conditions; (*c*) reduction by 85% of car trackage required in hand-loading stopes. For further details of scraper practice, see papers by H. Clark and R. B. Smart (556).

Power-shovels in stopes. The utility of these shovels in stopes, as contrasted with headings (Art 20), is limited to nearly flat orebodies with height of at least 9 ft, worked in wide, open stopes, as in S E and S W Mo. Under these conditions, a caterpillar shovel has following advantages over a scraper: (*a*) greater flexibility, as it can move freely in stope, and from one stope to another; (*b*) ability to load cars without need for a slide, and at any place to which cars can be brought; (*c*) does a completer job, leaving less ore to be cleaned up by hand. Examples follow.

Hartley mine, Tri-State District A caterpillar-mounted, elec-driven, dipper shovel in 1932 loaded part of output of this mine into 32 by 32-in cans, standing on trucks 13 in high above rail. Motor, 15-hp, chain-drive, has enough power to move boulders several tons in wt. Dipper is specially designed for loading cans. Shovel can work in a room 9 ft high. During a test period of 127 working days, the shovel loaded 16 565 tons (24 516 cans) at following cost per ton: Connected energy charge, 0.382¢; power consumed, 0.946¢; depreciation and repairs, 3.070¢; interest, 0.776¢; labor (1 operator, 1 helper, 1 extra trammer), 7.830¢; total, 13.004¢. At same time, hand loading by contract (averaging 35 tons per man-shift) cost 21.202¢ per ton, plus 0.167¢ for wear of tools; total 21.369¢ per ton (323).

Barr mine, Tri-State District. In 1929, 30% of the output was loaded with dipper-type (10-cu ft), elec-driven (25-hp) caterpillar shovels into 1.5-ton cars hoisted on self-dumping cage (unusual in this district). Cars were loaded alternately on both sides of shovel. Usual duty was about 100 cars per shift of 3 men, or 49 tons per man-shift. Contract price for hand-loading from plank floor was 38 to 41.5¢ per car (25–28¢ per ton); aver duty, 24.9 tons per man-shift. Shovel thus doubled output per man, and reduced labor cost per ton (shovel crew totaling $13 per shift) to about one-third that of contract hand loading (143).

St Joseph Lead Co, S E Mo. This Co has made extensive use of the Thew shovel, modified in some details. It is elec-driven, has caterpillar traction, but is transported from stope to stope by climbing onto a truck hauled by loco. At MINE LA MOTTE, the shovel is rarely moved into a stope until 400–500 tons of broken ore has accumulated, which it then loads into 48-cu ft (2.7-ton) cars, 42 in high, at rate of 160–300 tons per shift. Cars are moved by cable-reel loco. Shovel needs min headroom of 6 ft 2 in (560).

92. "SAND FILLING" OF STOPES IN METAL MINES (See also Art 110)

General. Sand or similar granular material has following advantages as mine filling: (*a*) rapidly and cheaply transported by air, water, or both; (*b*) spaces can be filled solidly and completely, and in places inaccessible or costly to reach by other means of transport; (*c*) when well placed and drained it has greater compressive resistance than any other material except concrete; (*d*) at any mine equipped with a nearby concentrator or cyanide plant, abundance of suitable sand is usually assured; (*e*) ultimately, when well settled and not violently disturbed, sand will stand unsupported in an almost vert face; if it contains iron sulphides, it may become, through oxidation, almost as firm as rock; at Horne mine (Art 43), pyrrhotite mill tailings are added to coarser filling for this reason; (*f*) solidly placed sand, being almost impervious to air, prevents short-circuiting of ventilating currents through stopes thus filled. Sand and even coarsely crushed material (max size about one-third diam of conducting pipe) has been conveyed by low-press air in some European coal mines, and sand $^3/_8$-in max size by high-press air, at Champion mine, Mich (Art 63); but water is commonest transporting agent, as in following examples (note use of air jets in conjunction with water at Hodbarrow mine). The gold mines of So Africa have widely employed sand filling, utilizing the leached residues from cyanide plants. Method was first applied to reinforcing shaft pillars and important underground stations; later to support of heavy ground in general, especially to aid extraction of pillars and other remnants, or recovery of ore temporarily used as filling for "pig-styes." In some mines, sand filling has been placed close to faces of active stopes. According to R. S. G. Stokes in 1936 (195), sand filling has been abandoned in mines of Central Rand, though still advantageously employed in some deep mines of Far Eastern Rand, as where parallel gold-bearing "leaders" have been found in hanging wall of main reef; in such cases, sand serves as footwall for further developments. When a suitably situated shaft is not available, special boreholes, 7–11 in diam, are shot-drilled, at cost of about $4 per ft, for dropping sand. A large mine usually needs at least 2 such holes; New Modder has used 8 holes to distribute 3 000 tons of pulp per day; Simmer & Jack had 2 boreholes besides pipe lines in inclined shafts. Government Gold Mining Areas has 2 holes 1 000 ft apart and drops 4 000 tons of sand (dry wt) in 8 hr (576, 630).

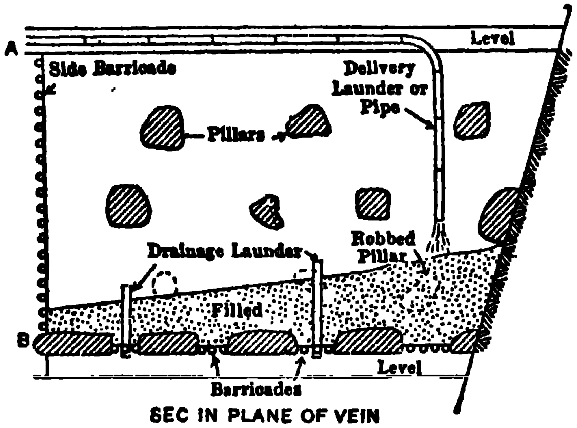

Fig 657. Sand Filling, Transvaal Gold Mines

Details of So African practice. Following notes are from papers by E. Pam, W. A. Caldecott, O. P. Powell, B. C. Gullachsen, R. E. Sawyer, and others, on practice between 1910 and 1916 (251, 329); more recent data are fragmentary (576, 589, 630). Preparation of stopes. Fig 657 shows typical filling operations. Barricades are erected in box-holes between level-pillars, and along the sides of areas to be filled; where possible, work is so arranged that faults, dikes or shaft-pillars are utilized to retain filling. On flat dips, the sand is sometimes shoveled up to make a dam along the side of area being filled (*AB*, Fig 657); to do this, the pulp must be very thick. Construction of barricades depends on their position and length of time they are expected to stand without rotting. After draining and taking weight from the hanging, sand compacts so that a free face of fill will stand without support. Hence, barricades may only be needed for the period of filling and draining, though for safety they are best kept unbroken during the life of the level. If there is danger of running water entering the stope, the barricades must be strong and permanent; the water should be isolated and piped off through the fill; otherwise, it may develop a disastrous hydrostatic pressure. The types of barricade in Fig 658 have been successful; (*a*) and (*c*) are common at bottom of open stopes; (*b*) is built in box-holes; (*d*), less expensive, is used on sides of filled area; woven wire, 6 by 18-in mesh, is sometimes used instead of split lagging for support of cocoa matting. At Simmer & Jack, cost of such barriers, 6 ft high, is 7 sh per lin ft. Treatment of sands. Cyanide salts break up in tailing lying on the edges of old dumps, exposed to air and sun; such material may be sent underground without danger. But, to save cost of rehandling, tailing direct from the cyanide vats ("current tailing") is most frequently utilized. Current tailing requires oxidizing treatment to destroy cyanide salts. $KMnO_4$ and bleaching powder are commonly used, the amount depending on strength of the last cyanide solution used, and on moisture content of the sand from the vats. At Simmer & Jack mine, the tailing contains 12% moisture, carrying up to 0.02% total cyanide. From 0.2 to 0.25 lb of $KMnO_4$ is used (5% solution) per ton of sand. Frequent moisture tests are made on the pulp entering the borehole, which has never contained more than 0.0025% total cyanide, and no traces of HCN have been found in stopes being filled. As Rand sands contain H_2SO_4 from decomposing pyrite, some alkali (as lime) is added to prevent generation of HCN. At East Rand Proprietary mine, in 1916, ashes from coal were found to contain enough CaO and $CaCO_3$ for this purpose. Slime should be removed from sand to be used as filling, since it retards drainage through barriers; this is done by classification in the mill or in cones erected usually close to point of discharge to underground. Govt Gold Min Areas has a battery of 16 cones, 9 by 9 ft, at each of its 2 boreholes, receiving 1 : 1 pulp through pump and pipeline from mill 2 miles away. In former years, Rand tailings were mainly coarser than 100-mesh; later tendency towards finer grinding has diminished somewhat the pro-

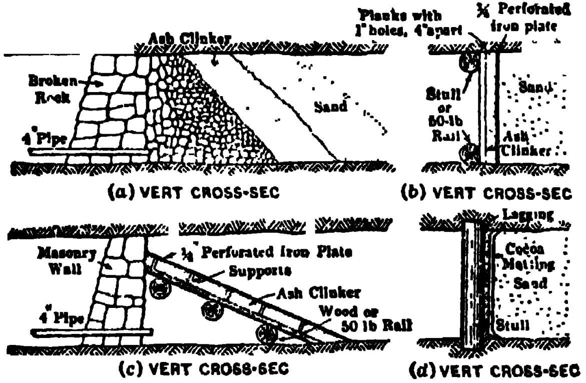

Fig 658. Types of Barricade fo Sand Filling on the Rand

portion of sand most suitable for filling. PASSING SAND TO STOPES. Boreholes for this purpose, 7 to 11-in diam and uncased, are so located as to minimize cost of lateral handling. Their up-keep is nil. Clogged holes are easily reopened by running into them a small stream of water. Sand may also be conveyed through pipes in a shaft ladderway (note use of a wooden box for fairly dry sand in Cinderella shaft, below). As delivered to bore-holes, thickened and de-slimed pulp usually has about 70% solids, by wt, requiring a slope of 30% (17°) for satisfactory flow in such launders as may be needed on surface. Underground, the pulp, usually diluted to about 1 : 1, is carried laterally to the stopes from the borehole or shaft in pipes or open launders. Launders are best if the requisite grade is obtainable. Fig 659 published by W. A. Caldecott in 1914 (329), shows the launder grades for carrying Rand tailings in pulps of different fluidity; it is platted from following formulas:

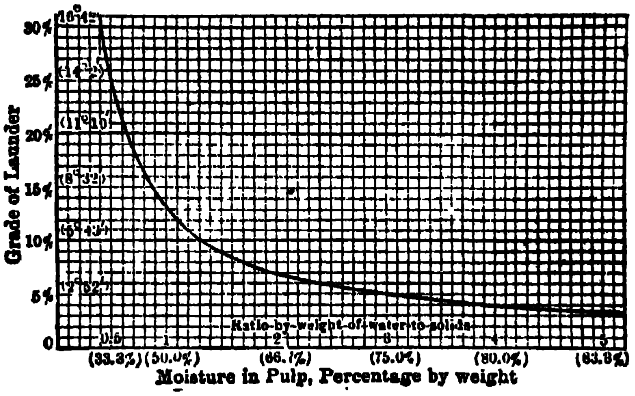

Fig 659. Launder Grades for Sand Pulp (Rand)

$$W = \frac{12}{G-1} = \frac{P}{100-P}\,; \quad P = \frac{100\,W}{W+1} = \frac{1\,200}{G+11}\,; \quad G = 1 + \frac{12}{W} = \frac{1\,200}{P} - 11$$

where W = ratio of water to solids, by wt; P = per cent of water, by wt; G = grade of launder, per cent. These formulas are based on observations (within the limits platted) upon flow of pulp under large-scale working conditions; they refer to ordinary mill sands, containing about 4% pyrite; as much as 10% of the solids are retained on a 0.01-in aperture screen. The exact grade varies with many factors. "In general, the conditions tending to require increased launder grade or higher water ratio are: small volume of pulp, frequent sharp curves in launder, wrong shape and rough internal surface of launder, unevenness of grade, large size of sand particles and high percentage of pyrite. Conversely, a large volume of pulp flowing in a well designed and laid launder without curves, and containing much slime and few coarse or pyritic particles, requires less grade than is usually needed for sand pulp. In installing a launder, it is desirable to increase the grade by say 20% around curves, as well as for some distance at the head of the launder, to overcome the initial inertia of the pulp" (Caldecott). Fig 660 shows FORMS OF LAUNDER. The simple V launder (*a*), with hardwood liner, is good and easily shifted. Type (*c*), with concrete liners 3-ft long, has been used in the Robinson mine. Launders are laid on the floor of the level or hung from the roof; they may terminate near the top of the stope or be carried down the dip (Fig 657). PIPES, required for moving sand horizontally along levels, wear fast and are turned frequently to distribute wear. Ordinary C-I, steel, and wood-lined pipe, and some with porcelain lining, have been used; wood-lined pipe was popular at first, but gave trouble and is now little used. Steel pipe is preferable to that with special linings and in flat places has a long life; at Village Main Reef mine, an unlined pipe passed 75 000 tons of sand before the wear was considerable; vertical pipe wears fastest. After stopping and before starting the sand, clear water is run through the pipes for a few minutes, to prevent clogging. If the depth is great and the flow in a vert pipe too rapid, hoppers may be inserted every 300 ft. See Art 110 and examples below for data on the horiz length of pipe through which sand may be forced by the head in a vert pipe. DRAINING SAND IN STOPES. Water runs off from the sand through pipes or filter beds in barricades at the sides and bottom of filled areas. Drainage launders (Fig 661), laid on the footwall and extending through the barriers, were formerly widely used, but have lately

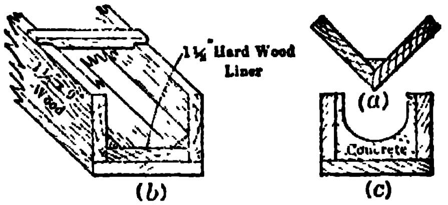

Fig 660. Launders for Handling Sand Underground (Rand)

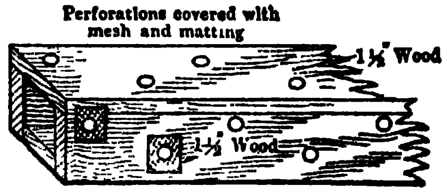

Fig 661. Drainage Launder for Sand Filling (Rand)

been largely eliminated. Cost of sand filling (Table 63.) In 1931, costs at Witwatersrand Deep and Simmer & Jack mines were reported as 15¢, and at Modder Deep Levels, as 13¢ per ton of sand (576). Filling operations should be continuous rather than intermittent. If current tailing is used, the cost of rehandling at dump is avoided; the water content of pulp should be as low as possible, to reduce pumping cost.

Table 63. Cost of Sand Filling, Witwatersrand

Mine	Period	Aver tons lowered per month	Aver cost per ton, cents			Per cent of cost on surface
			Surface	Underg'd	Total	
Simmer & Jack......	9 mo	19 171	6.73	13.11	19.84	33.9
East Rand Prop......	Aver mo	19 490	4.64	9.22	13.86	33.5
Witwatersrand Deep..	12 mo	27 387	7.64	7.48	15.12	50.5
Robinson Deep.......	4 mo	25 815	3.55	15.29	18.84	18.8

Examples. Robinson mine (data from E. Pam). The plant handled 200 tons of dump sand per hr, which was sluiced or conveyed to a brick lined bin (500 to 600 tons capacity) near hoisting shaft. A 6 by 8-ft tunnel ran from side of bin to the shaft; bin sloped 30% toward the tunnel and discharged through 30 by 18-in holes into which water was sprayed; the launder in the tunnel sloped 20%; sluicing water at 50-lb pressure was supplied to launder through 2 by $1/8$-in nozzles, the mixture in launder being 35 to 40% water by weight. At the shaft, the sand flowed down a 5 or 6-in unlined pipe, with loose flanged joints so that sections could be readily turned or replaced. Pulp was distributed laterally to stopes in pipes; on the 2 000-ft level, a 600-ft length of horiz pipe was used successfully. Stopes were prepared (Fig 657) with bulkheads composed of stulls and lagged with 1.5-in plank, which fitted close to floor and roof, all crevices being calked with hay. Excess water ran off top of filling through 12-in apertures in the side barriers; these openings were blocked up as the sand level rose. Area to be filled should be as long as possible, to reduce pressure on barriers and give free overflow for water. It was planned to fill working stopes, as well as old ones. Barriers impervious to water require greater strength, since, due to its incompressibility, any water left in sand transforms roof pressure into lateral pressure; such barriers were not used elsewhere (see below). Robinson Deep mine (Caldecott and Powell). Current tailing in form of thick pulp was run by a small stream of water containing $KMnO_4$ through a tunnel and borehole to the stopes. Tunnel was 4.5 by 6 ft, 1 125 ft long, and ran from sand plant at 36.4% grade, intersecting the borehole 390 ft below surface; it had a vert grizzly across it. The borehole was 10 in diam at surface and 7 in at 1 729 ft depth. The sand in borehole contained 28% water. Underground handling was like that at the Simmer & Jack mine (Caldecott and Powell, A. R. Hughes). Sand was trammed from cyanide vats to a mixing box 10 by 5 by 4 ft, where water containing $KMnO_4$ was added. The pulp (3.5 parts water to 1 part sand by wt) was pumped by a 4-in centrifugal pump through a 6-in pipe, 900 ft to diaphragm cones erected on surface at the mouth of a 6-in borehole. The underflow of the cones, containing 30% moisture, was delivered to the borehole by launders with a 30% grade. Two 8-ft cones, handling 200 tons per 10 hr, eliminated much of the slime. At bottom of the borehole a wooden launder, 9 by 7 in, sloping 15°, conducted the pulp to stopes, more water being added. In 1910, bulkheads at sides of stopes were of 3 by 9-in plank, supported by 8 by 8-in stulls; planks were perforated and covered with cocoa matting. Box-holes at bottom of stope were blocked by building a dry wall across them, through which a 6-in pipe projected into the stope. A wooden drain launder (Fig 661) ran from the pipe to a point 2 to 12 ft above top of sand; upper side of launder was covered with cocoa-matting filter frames. Later barriers had an ash-clinker filter bed (Fig 658). Cinderella Consol mine (R. E. Sawyer). Sand from edges of old dump was conveyed to shaft by mechanical haulage and dumped into a vert wooden conduit, 12 by 11-in cross-sec. The conduit gave no trouble from wear or clogging when sand contained less than 5 to 6% moisture; wetter sand collected on the sides and gradually choked it. The conduit, 3 900 ft long, discharged on a steeply inclined plate, from which a stream of water washed the sand into a launder; thence, after mixing, it was delivered to the stopes by pipes or launders. Capacity of plant, 400 tons per shift. Filling actually reduced pumping, as sand sent down averaged 3% moisture, while that in stopes retained 10%. This system is stated to be cheaper than flushing from the surface, as the plant is small and pumping is reduced by sending down dry sand. Witwatersrand Deep mine. 12 000 tons per month of current sand was sent underground, part down a borehole and part down a winze; practice was similar to that at Simmer & Jack. Filling entering mine contained 28% moisture; pillars and hitherto inaccessible ore were mined under its protection.

Matahambre, Cuba. Data from D. D. Homer in 1938; see also Bib (237, 590) and Art 62. Conveying mill tailing to stopes through rubber-lined steel pipe has been successful since July, 1927; special advantages: (1) reduction in cost of placing fill to about 29¢ per ton, against 55¢ for surface material (shale) previously used; (2) an increase of about 33% in rate of output from a given stoping area, due to more rapid filling. Total economy estimated at $1 per ton mined, at 1930 wages and normal 30 000 tons per month. Current mill tailing (quartzite and shale), or as much as needed, is de-slimed in 2 Dorr bowl classifiers, each set close to top of a raise connecting with underground; one, 7 by 29 ft with 21-ft bowl, is 200 ft higher than foot of mill and, supplying a few upper levels of mine, is fed by a Wilfley pump; the other, 6 by 27 ft with 16-ft bowl, fed by gravity, supplies lower levels; either can treat whole flow of tailing. As received, tailings aver 49% finer than 200-mesh; as discharged, sands are 49% coarser than 65-mesh and 97% coarser than 200-mesh; about half the mill tailings is thus available for filling, and supplies 60% of all material required (remainder coming about equally from ore sorting and rock development). Such sand compresses 11.2% by vol at 1 530 lb per sq in, and 18.2% at 3 060 lb; slime, unless removed, tends to filter out of stopes into drainage ditches and sumps. Classifier rakes discharge into a screen-covered hopper, where water is added, by a spray above and a 0.75-in hose below it, to make a pulp of about equal parts water and solids, by wt (sometimes 50% excess water). Outlet from hopper has a belled, bronze bushing, flanged to delivery pipe. When not in use, it is plugged to avoid trickling of dry sand into the pipe.

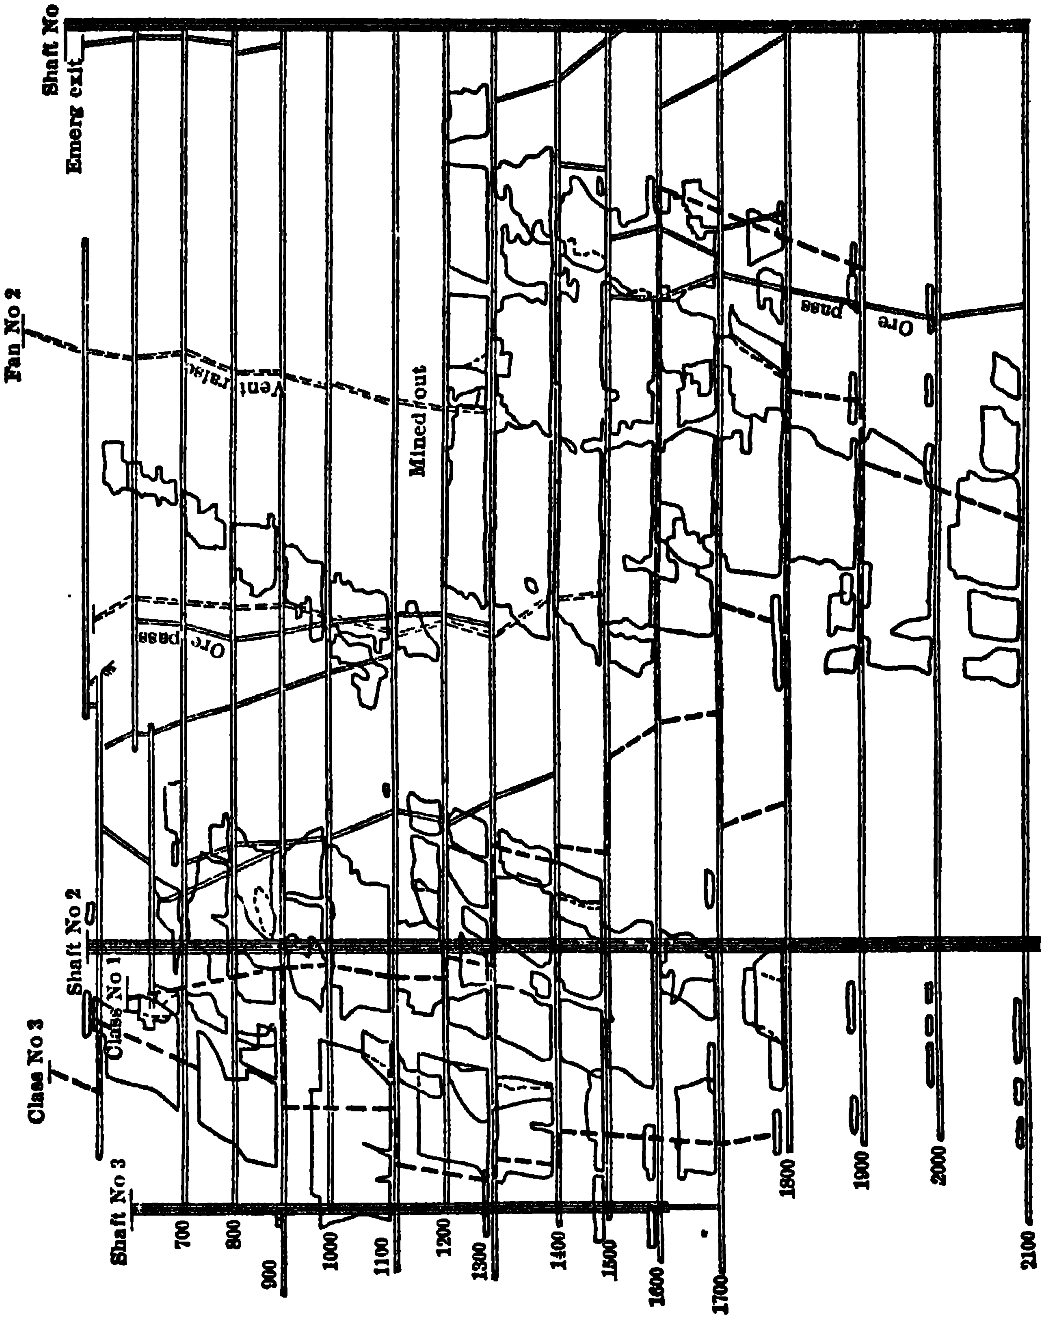

Fig 662. Main Sand Distributing Lines, Matahambre, Cuba, as in 1938

Early experience proved that, in main lines, ordinary steel pipe lasted only about 2 weeks; extra-heavy pipe, 3 weeks. All main lines were then installed with rubber-lined pipe, 3.5-in outside, 2.5-in diam inside of 0.25-in rubber wall. Pipe is in 12-ft lengths, with 7.5-in, 4-hole flanges; rubber is flared outward over face of flange to diam of 4.75 in, forming a gasket permitting some angular deflection at joints and preventing access of sand behind the rubber. After passing 500 000 tons of sand in 7 years, no piece of straight pipe has had to be replaced because of wear; corrosion and some wear at curves have required replacements. Branches are at angles of 15° and 30°, also flanged, and always placed where flow is not retarded by a curve. Pipe is bent cold, to match an iron rod bent to desired curvature underground. Pipe is protected against acid water by painting and, in very wet places, by an inverted trough of light boards. Ordinary 2-in pipe is still used in less active branch lines, and at entrances to stopes from levels above. Special fill raises are no longer required; manways and ventilating raises, as much as 300 ft apart, serve for the filling lines. Whole installation is calculated on basis that 100 ft vert head will propel the 1 : 1 pulp 300 ft through horiz pipes. Rubber-lined pipe has conveyed as much as 35 tons of sand per hr; in one case, a vert head of 290 ft discharged 12–15 tons per hr through 940 ft of horiz pipe with several curves; in another, a 939-ft head discharged 25 tons per hr through 1 800 ft of horiz pipe with 1 bend of over 90° and one over 45°. In 1938, filling was in progress on 21st level, 1 790 ft (vert) below foot of mill, and 22d level was under development. Main system of rubber-lined pipe for supplying lower levels included about 3 700 ft of horiz and 3 200 ft of vert or steeply inclined lines (Fig 662).

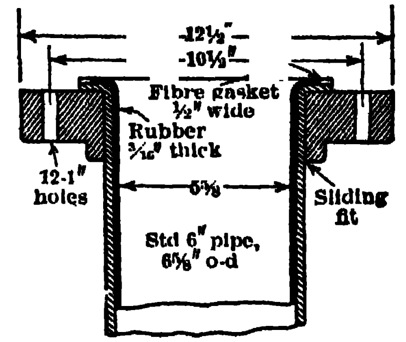
On completing an overhand horiz slice to height of 12 ft above fill, cribbed chute or manway is raised 6 ft and wrapped outside with 10-oz burlap, upper jackets overlapping lower; bottom edge of lowest jacket is anchored with rocks and sand. Burlap may also be laid over old fill, especially at places where channeling is suspected. Sand is directed first to ends of stope, through 40 ft of 2-in, 4-ply rubber hose. A shallow sump is dug near the chute, whence excess water is siphoned down the chute through 1.5-in, 4-ply ordinary hose in 25-ft lengths. Eventually, the whole stope is filled nearly level with top of cribbing. Sumps for mine pumps are of extra large volume to permit thorough settlement of slime in returning fill water.

Labor per shift for sand filling includes: 1 boss, 3 men in stope, 2 pipe men on main and branch lines, 1 man at classifier. Flow is diverted from section to section of mine by disconnecting and re-connecting pipe lines; no valves are permissible. Before starting to discharge sand from classifier, the pipe line is flushed with water (50 gal per min); amount is gradually reduced to 1 : 1 ratio when classifier begins to discharge sand. At ending of fill, procedure is: stop flow of tailing to classifier (diverting to tailing pond); increase wash water to 50 gal per min; stop classifier after it has emptied itself; continue wash water for 15 min. Cost of placing 25 587 tons of sand during 6 mo of 1934 was 29¢ per ton, including: labor, 14.10¢; burlap, 2.98¢; pipe, 1.74¢; misc, 1.81¢; pump parts, 1.48¢; power, 0.89¢; pumping fill water from mine, 6¢.

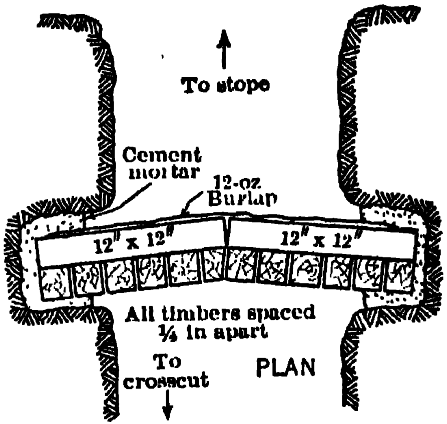
Homestake mine. Data from A. J. M. Ross (331) in 1939. For ore occurrence and mining methods, see Art 68. Cyanide-plant sand tailings, available at rate of 2 100 tons per day, were used first to augment and consolidate coarse filling; more recently, as sole material for delayed filling of both shrinkage and square-set stopes. Sand, averaging 50% finer than 200-mesh, is sluiced from cyanide vats to a Dorr dewaterer 12 ft diam by 6 ft deep, and discharged at about 60% solids to a header leading underground. There are 2 such installations, serving different parts of the mine. At plant No 1, the pulp first descends vert 756 ft, then nearly horiz 2 560 ft on the 1 100-ft level, thence vert to the 2 600-ft level. At plant No 3, entrance is by 45° incline 306 ft long, then 1 334 ft on −2% grade on 500-ft level, thence vert down the Ellison shaft to the 2 150-ft level (as of 1939). Laterals extend from the shafts on each level; 100-ft head propels 300 ft laterally. Main headers are of 6-in pipe, with $^3/_{16}$-in rubber lining, giving 5 $^5/_8$-in inside diam. Ends of pipe sections, and the rubber lining, are flared 1.5 in outward at 90°; adjoining sections are brought together by 12-hole, loose flanges, Fig 662*a*; curved sections are bent to 10-ft radius. Lateral distribution is through unlined, 4-in steel pipe (commonly, discarded comp-air pipe). Connection between vert header and lateral pipe is through rubber-lined T and bell reducer, similarly connected by loose flanges. Sand is diverted into a lateral pipe by inserting a rubber-covered blind disk, $^1/_2$ in thick, with bolt holes bored to correspond with flanges, between lower leg of T and the next lower section of header. Laterals above the one momentarily in use are similarly closed by blind disks on the side legs of the Ts. Since both the T and bell reducer on the 4-in pipe are fixed, a "dummy" disk, of same thickness, but having a 5.5-in central hole, is also inserted at all T-joints through which flow is to be maintained. Reversing the disks at a T requires about 40 min. Standard valves, at first used, proved too expensive to maintain.

Preparatory to filling an emptied SHRINKAGE STOPE, some of which are more than 150 ft high, all drifts or crosscuts, leading to drawholes, except one, and any other openings from sublevels, are bulkheaded with 2 layers of 12 by 12-in timbers, 0.25 in apart, and covered

inside with 12-oz burlap, Fig 662a. Ends of all timbers are cemented into hitches in walls, floor, and roof of the drawhole drift. Just inside the one unclosed drawhole, a square-set raise, lagged and burlaped on 3 sides, is started close to the stope wall, and continued upward a little in advance of the rising level of sand (compare Matahambre, above); this raise later serves as air and manway, when the pillar is to be mined. Wherever possible, sand is delivered into the stope through an opening from level above; occasionally by a riser from the stope level. Filling a SQUARE-SET STOPE, which is usually 7 sets long by 3 sets wide (the 6 by 6-ft sets having 9-ft posts on sill floor, 8-ft posts elsewhere), involves close lagging on all sides with 3-in plank, burlaped on inside; floor boards are then removed. A manway (middle set on one side of stope) is similarly lagged, except that each piece of lagging, 8–12 in wide, on the side facing the middle of the stope, has a 2 by 12-in slot, which, as sand builds up, are successively closed by wedges, surplus water overflowing through the next higher slot. Sand is delivered through a riser in the manway, terminating at top in a horiz pipe discharging as far as possible from the manway. This method has worked successfully with 1 400 ft of pipe in the drift and a 75-ft riser. An aver square-set stope can be filled in 8 hr on each of 3 successive days, which allows time for each run, of about 700 tons, to drain and settle before the next addition of sand. A sill-floor set takes about 15 tons; other sets, 12 tons each. It formerly took more than 2 weeks to fill such a stope with coarse waste.



Detail of Pipe End



Bulkhead at Bottom of Shrinkage Stope

Fig 662a. Details of Sand Filling, Homestake Mine

Hodbarrow mine, England, applied sand filling to recover 1 000 000 tons of hematite in 2 widely separated remnants of a thick, almost horiz bed, of which about 90% had been removed by top-slicing (591). One area was covered with glacial clay and gravel; other had limestone roof, and lay under surface reclaimed from ocean. At both places, dune sand in a bed 15 ft deep was available close by. In the first area, fill was flushed down an 8-in steel pipe in a 240-ft shaft; at other, down 2 boreholes (a third in reserve) 350 ft deep, cased with 7.5 and 9-in pipe. At each hole, about 17 100 cu yd of sand (enough to replace 57 700 tons of ore) was obtained within a radius of 170 ft by flushing through a launder on 5° slope; top of casing pipe was cut off in successive segments until 1 ft below top of clay underlying the sand, and covered by plate with 0.75-in holes. Subsequently here, and from start at shaft location, sand was delivered by loco with 7-cu yd, side-dump cars loaded by 3-ton crane. Three men delivered 250 cu yd in 8 hr, replacing 850 tons of ore. Each borehole required 100 gal water per min; at shaft, sand was dumped into a brick-walled pit, from which it was flushed to column pipe with 2 water jets from 3-in pipe; pulp averaged about 1 : 1 ratio, by vol. DISTRIBUTION at bottom was through 4-in iron pipe. At first, pipe lines were laid to grade of − 1° or more; later, use of air-jets, through a 1/8-in orifice bored on center line of 90° elbow with 14-in radius, greatly accelerated flow and permitted parts of a line to be laid on an up-grade. Longest line (to May, 1930) was 900 ft, including many bends and 300 ft of + 1% grade; it had 3 air jets about evenly spaced and supplied at 60–70 lb press.

Usual slices in the mine were 50 ft long, 10 ft high, 10 ft wide; bottom and one side were previously placed sand; top, end, and other side were ore. Before filling, all ore exposed on wall was curtained with brattice cloth hung loosely on a row of stulls; entrance to slice was dammed with plank only 2 or 3 high at start, and every possible leak was stuffed with hay. Filling was then run in at rate of 112 cu ft (6 tons) of sand, per hr. Allowing for delays, a slice could be filled about 25 times faster than it could be mined by hand, or 11 times faster than when machine-mined. By careful blasting, adjoining ore in next slice could be removed without serious inflow of sand from the filled slice; when drained, the fill was very firm; surface subsidence over filled area was estimated at not over 5% the height of ore removed. Costs for filling only, per ton (8 cu ft) of ore removed (min wages, Apl, 1932, 6s 5d per shift) were estimated (at 1d = 2¢): Wages, surface and underground, 12¢; fuel and lubricants, 8¢; brattice cloth, 3.5¢; overhead, 4¢; total, 27.5¢. Timber consumption was reduced about 30% below that required by former top-slicing.

Australia. For use of sand tailings as contemporaneous filling for stopes at Kalgoorlie, W Australia, see Art 65.

Extinguishing fires. Sand purposely containing a large proportion of slime has successfully controlled and extinguished mine fires; notably at Butte, Mont (543) and

Jerome, Ariz (544). At Butte, thickened mill tailings, 50% finer than 200-mesh, in pulp containing 18–30% solids, was dropped through 8-in c-i pipe and distributed laterally in 4-in pipe; a head of 100 ft propelled pulp 800 ft horiz. Launders required 2% grade. At Jerome, surface rock was crushed 35% finer than 100-mesh and dropped through boreholes, at 65 tons per shift, in 1 : 1 pulp.

93. CHOICE OF UNDERGROUND METAL-MINING METHOD

General. The selection of a method of mining for a given orebody is aided by making an inverted statement of the limitations and applications of the methods already described, but no concise statement can be framed to cover all the variations that occur in nature. Usually several methods are more or less adapted to the grade, size, shape, and attitude of the orebody, and the strength of its ore and wall rocks; from these a choice may be made or a method evolved which will best suit the geological, economic, and local conditions (Art 25). Table 64 groups the mining methods for this purpose; it is intended merely to suggest methods available under ordinary conditions, each of which may be studied in connection with peculiarities of the orebody in question. The ideal method provides safe and humane working conditions and yields the greatest ultimate profit, but a mining method is generally a compromise between conflicting factors.

Under some conditions, a low-cost method yielding a low extraction may give greater total profit than a method which recovers a larger proportion of orebody; under other conditions, the reverse may be true. Following equations (H. L. Smyth) show relations between factors involved: Let Q = total tons of ore recoverable by the method yielding highest extraction; X = tons abandoned by another method; p = profit per ton by method Q; p' = profit per ton by the other method; $p' - p$ = saving per ton effected by the other method. When $p'(Q - X) = Qp$, the 2 methods are equally desirable and, in such case, $\frac{X}{Q} = \frac{p' - p}{p'}$ The proportion of the deposit which may properly be sacrificed therefore depends on ratio of saving to the profit per ton by the other method. This ratio increases as the profit diminishes; hence, for a given saving, more ore of low than of high value may be sacrificed (172). Calculations like the above may be elaborated by varying the milling, freight, and smelter charges on ores of different values; in such cases, the effect of the variables and the point of max profit may be determined graphically (Fig 99 and Bib 330).

Safety. Table 65 gives averages for 7 years 1931-1937, from data on metal-mine accidents published by Bur of Mines; no more recent data were at hand at end of 1940. Choice of method should be based on assumption that no method need be unduly hazardous if properly applied. For more detailed analysis of accidents during 1930-1931 and 1935-1937, by causes as well as by mining methods, see Bur Mines *Bull* 362, 422, 428. See Sec 23 for other data.

OPEN-CUT MINING

94. GENERAL

Open cuts ("Open workings," "Open pits," "Open casts") are surface excavations; in connection with coal mining they are called STRIPPINGS. (For quarries, see Sec 5.)

Field of use is in mining deposits that outcrop or lie under shallow cover. The upper parts of narrow, rich veins may be thus mined, with small equipment and no expense for development; this is a favorite "poor man's" mode of obtaining capital for subsequent work, regardless of ultimate economy. Large open cuts, involving extensive development and equipment, are often made on outcrops of wide, veinlike orebodies, because they produce ore cheaper than is possible with underground methods. Veins can be worked by open cuts only to a limited depth, chiefly because of danger of falls of wall rock; weak walls and flat dips decrease possible working depth. Open cutting is the only profitable method of mining thin, flat beds, with shallow cover (Art 96, 97, 98). Large bed-like masses, covered by rock or alluvium, may often be mined cheaper by open cuts than by underground methods (see Mesabi, Ajo, Nevada Consol, Art 96). Large orebodies that can be excavated in a series of hillside benches are well adapted to open cutting (Art 95). An orebody can seldom be entirely mined by open cut; underground work is usually required in depth, and in some cases to mine the ore around edges of deposit.

General plan. Open-cut methods are combinations of loosening, loading, and transporting earth and rock in surface excavations (Sec 3, 5).

The combination selected depends on shape, size, and depth of pit, local topography, and output required. Output and method should be adjusted to size of deposit, to secure minimum cost of production, including interest and amortization on capital for equipment and removal ("stripping") of waste overburden. STRIPPING may be completed before beginning mining, or mining and stripping may proceed simultaneously, after a sufficient area has been uncovered to avoid interference between the two operations; the latter plan is best, as it reduces the initial investment required before production begins. Stripping may be done in one or more slices, depending on the depth; stripped material must be disposable within a reasonable distance, and at points where dumps will not embarrass subsequent mining. BREAKING GROUND. Open-cut faces are usually worked in benches (for details, see Art 95–101). Hydraulicking (Art 98 and Sec 3) may be used for breaking down unconsolidated material. In general, ground is broken cheaper in open cuts than in stopes, because of the large faces and use of heavy blasts. LOADING is by hand or mechanical excavators, depending on the scale of operations; where glory-holes (Art 99) are feasible, chute-gates are used. TRANSPORT (see Sec 3, 5). An underground haulage system may aid in handling output from an open-pit, material being dropped through chute raises in bottom of open workings.

Classification. An arbitrary grouping of open-cut methods, based on modes of loading, is used in Art 95–99 for presenting details. For small-scale work, with pick and shovel or

plow and scraper, see Sec 3. See also under placers, Art 117 *et seq.* For elaborate suggested classification of surface-mining methods, see Bib (181).

95. OPEN-CUT WORK WITH HAND LOADING OF ORE

Field of use: (*a*) in small pits, where total tonnage does not warrant the first cost nor permit efficient use of mechanical excavators (Art 96, 97); (*b*) in large pits, the shape, location, or other features of which (such as erratic mineralization and need for selective mining and sorting) make mechanical loading or glory-hole methods (Art 99) inadvisable; (*c*) in large-scale work, where labor is cheap.

Plans of work. Faces are generally carried in benches (Fig 663, 664), the height of which depends on factors outlined in Sec 5. With several benches, the width of each should be sufficient to provide room for road or tracks, and to catch loose rocks falling from above. Some foreign laws specify minimum width of 10 ft for safety; this is usually exceeded. (See Bib 470.)

Ground is broken as in broken-stone quarries (Sec 5), or in large underhand stopes (Art 27, 28). Holes are usually drilled by hand or by machine drills, since deep churndrill holes and gopher or tunnel blasts (Sec 5) are apt to break large masses, requiring excessive blockholing for hand loading. Ore is shoveled, forked or lifted into cars, trucks, buckets, or stone-skips at the foot of the benches. Transport methods from pit to surface vary with the shape, size, and depth of pit, and topography. Typical practice follows:

Narrow veins. The outcrops are often mined underhand (Art 35). Ore may be hoisted in buckets on skids on the footwall, or dropped through a winze to a haulage drift (Fig 206). At Cobalt (Art 68) many veins were thus worked to depths of 50 to 100 ft. Stulls support loose slabs of wall rock, as in open stopes (Art 38).

Large orebodies outcropping on hillsides are easily worked by open cuts. Fig 663 shows one method. A long face is advanced as a single bench, ore being shoveled

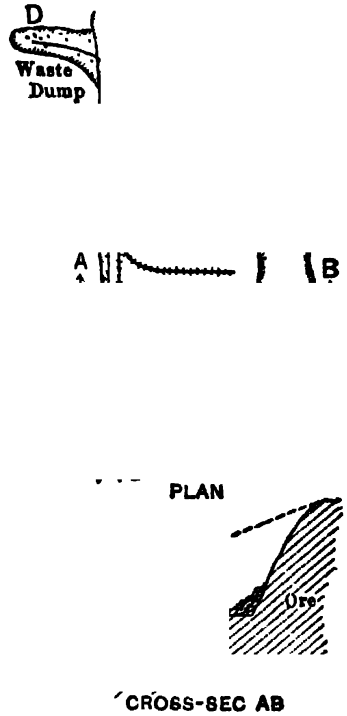

Fig 663. Open-cut on Hillside, Hand-loading

ming or horse-haulage of loaded and empty cars, without delays or interference. Track *C* may lead to mill or shipping bins, to loading bins of an aerial tramway, or to a gravity plane for delivering to bins below. Hillside topography usually furnishes nearby locations for waste dumps, as at *D*. The height of face, as in Fig 663, soon exceeds the economic max for breaking ground; chances of injury to workmen from falls of rock also increase rapidly with height of face. Hence the face may be divided into benches, with tracks on each for transport; this involves the problem of collecting the ore from successive benches; inclined wooden chute is a simple means for doing this. Automotive trucks are being used in increasing numbers (with both hand and machine loading); compared with track systems, they have advantage of allowing steep grades and sharp turns, while avoiding cost of laying and shifting track.

Examples. PUERTOCITOS, Cananea, Mex. In 1910 there were 3 benches, each 80 to 100 ft high. Ore was loaded into 0.5-ton cars; the track layout was like that in Fig 663, but with a single fringe-track connecting the loading tracks. Ore from the lowest bench was dumped down a raise to an adit leading to bins at the R R. Ore from the highest bench was dumped down a raise from a tunnel driven into the face at the 2nd bench, which was connected with the R R bins by aerial tramway (282). ARIZONA COPPER Co (Art 62) mined oxidized ores in open cuts. Benches were up to 30 ft high; the faces were kept at max length, to afford numerous points of attack and a steady output. Ore from all benches was dumped through raises to a haulage tunnel driven in connection with underground operations. If ore could not be shoveled direct to raises, it was trammed in 25-cu ft cars. An aver man in 9 hr loaded about 13 cu yd and trammed it 50 ft (178). At EISENERZ and ERZBERG, Styria (333, 659), a conical mountain of limestone partly replaced by siderite and ankerite is attacked on 60 benches to a height of 2 326 ft (Fig 664); total length of benches, 16.75 miles in 1936; width, 33-39.5 ft; aver height, 39 ft; 18 benches are combined in pairs for part of their length, for more economical operation of power shovels which are used mainly for moving waste on lower benches. Max annual tonnage (1929) was 5 500 000 tons, of which about 2/3 was waste; approx same ratio since maintained; min shipping grade of 30% Fe requires some hand sorting on belts after crushing and screening. Erratic mineralization and need for close sorting on benches favor hand loading; in 1929, about half of all material was thus loaded. Group of 4–6 men works 130 ft of face, drilling with jackhammers; explosive (ammonite and dynamite), 0.068–0.082 lb per short ton; holes fired singly, with fuse, 5 times a day. Hand-loaded cars are hauled outside by steam locos, or by elec locos through inside connections (one for each bench) to vert raises delivering ore to 3 main haulage levels at different elevations. Underground haulage system (also serving some underground mining) has 46.6 miles of narrow-gage track. Inclined planes, both inside and out, rack roads for elec locos, and underground belt conveyers, all assist in movement of ore. **Fresnillo mine,** Zacatecas, Mex. Data from D. B. McAllister in 1921 and T. C. Baker in 1923 (640). Orebody is a stockwork in graywacke; area 1 200 by 400 ft. estimated content, 5–6 million tons, assaying 5.25 oz Ag and 20¢ in Au. Surface quarrying by hand work was carried on intermittently from 1910 to 1920. Benches, 20 ft high; holes, 20 ft deep, 6–10 ft apart and 6–10 ft from face of bench, first 5 ft of a hole were drilled double-hand, the rest with jumpers. Holes were sprung, then loaded with split charges of 40% dynamite. Ore was blockholed or sledged to 8-in size on quarry floor,

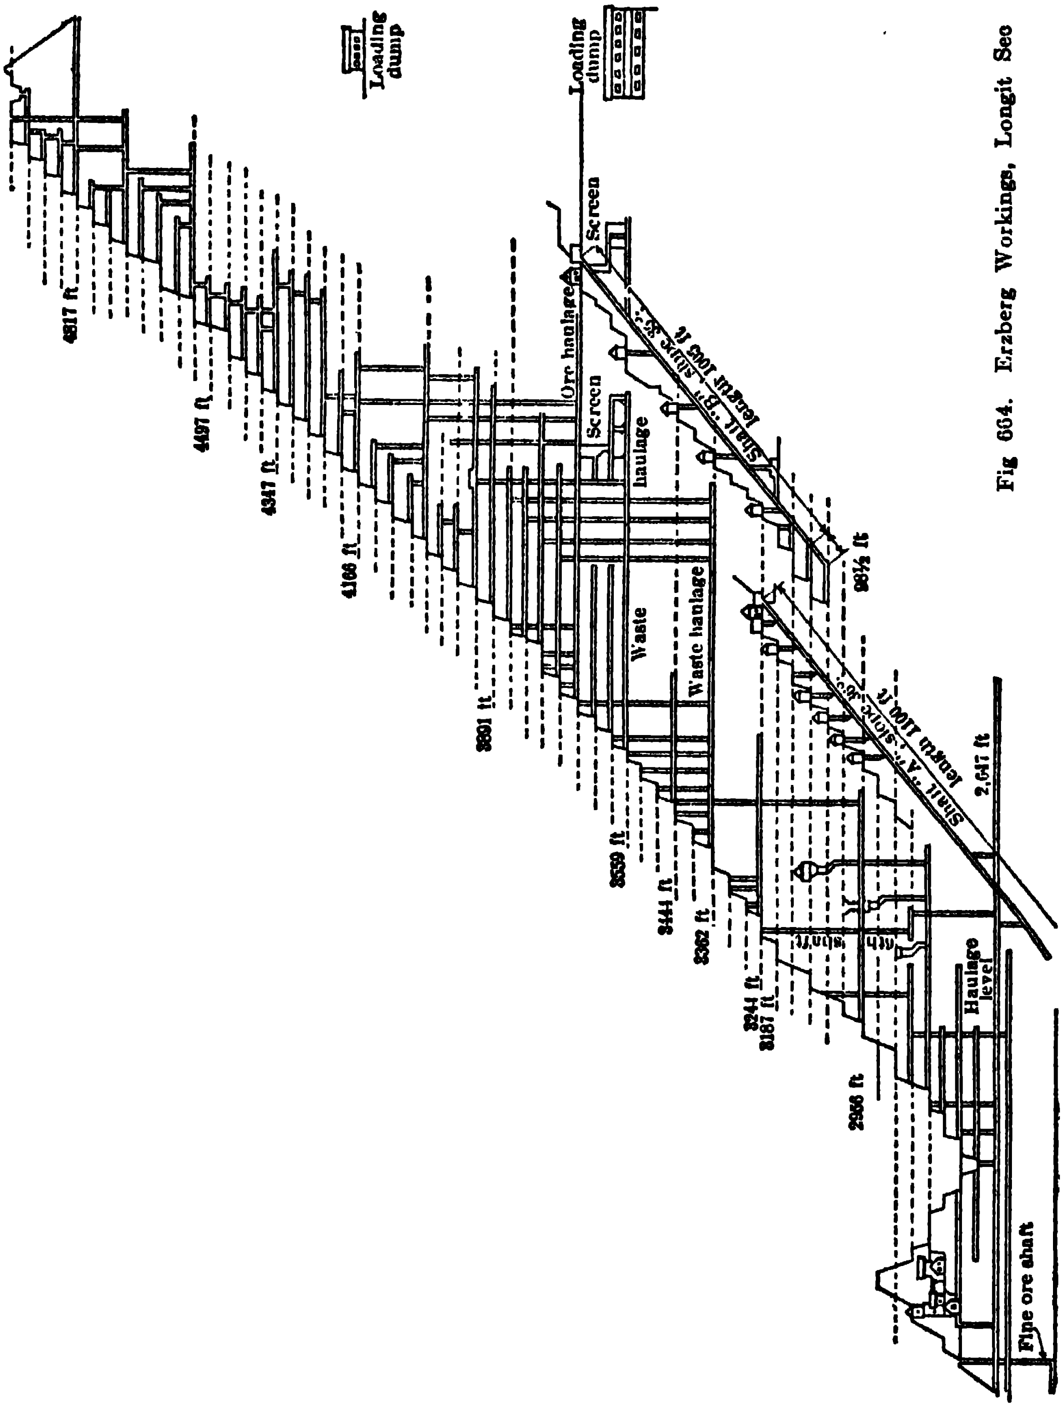

Fig 664. Erzberg Workings, Longit Sec

loaded into 26-cu ft cars, each trammed by 2 men to mill bins. Monthly tonnage, 15 800; tons per man-shift breaking, 5.5; tons per man-shift for all operations, 2.39. Explosives per ton: 0.122 lb; 0.091 cap; 0.333 ft fuse. Orebody was later mined by a glory-hole method (Art 99). BLUE DIAMOND GYPSUM deposit, Arden Nev. Data from W. G. Bradley (193) in 1932. The outcrop of a horiz bed of gypsum 16 ft thick is quarried on hillside until overburden (removed by gasolene shovel and scraper) reaches same depth; deeper parts are mined with rooms and pillars (Art 34). Space 20 ft wide by 100 ft long (to yield about 2 300 tons) having been cleaned, vert holes 15–16 ft deep are drilled by jackhammer at rate of 10 holes per 8 hr. Spacing of holes is half the depth of face. Holes are sprung first with 5 8-in sticks of 30% gelatin dynamite, again with 8 or 9 sticks; after cooling for 24 hr, holes are loaded with 25–30 lb of black powder in the chambers and 10–20 sticks of Hercomite No 6 above; chamber is primed with 1 stick of 30% gelatin dynamite. Up to 25 holes are fired at a time by elec. This method entails considerable blockholing of lumps over 3 ft diam. Explosives per ton, 0.25 lb for primary and 0.13 lb for secondary blasting. Tons broken per ft of hole, 3.68. Track is parallel with and 10–16 ft from working face, with sidings for 10 cars, of 2.5-ton capac; all haulage by 4-ton Plymouth gasolene loco, pulling 7 cars 1 000 ft to crusher. Duty of labor in hand loading, 20 tons per man-shift.

Deep pits of small area require hoisting apparatus. ENGINE PLANES (Sec 11) may be built on one wall of the pit. Cars serve for dips less than 30°; above that, skips are better. SHAFTS may be sunk near the pit and connected with it by crosscuts. Fig 665 shows early work of this kind at Creighton mine, Sudbury, Ontario. The shaft dipped 60° and had 2 skipways. Double-track crosscuts were run to the orebody at the 60- and 160-ft levels, with raises between levels and to the surface. The pit was started as a glory-hole (Art 99); on reaching a level, the pit bottom was kept flat, and radiating tracks were laid from the crosscut tracks. Blasted ore fell to the pit floor, where it was loaded into 1.5-ton cars. In 1908, this pit was about 350 ft diam by 160 ft deep (354). CABLEWAYS AND DERRICKS allow extraction of ore from deep pits without preliminary underground development. Fig 666 shows their application in an open cut 450 ft long, 300 ft wide and over 200 ft deep (Art 42). Ore or waste was loaded by hand on the pit floor into 1.1-cu yd stone-skips, which were picked up by cableways or long-boom derricks and placed on trucks on surface tracks near rim of pit (353).

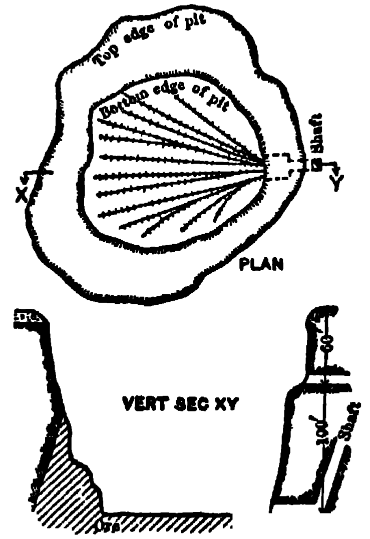

Fig 665. Open-cut, Creighton Mine, Ont

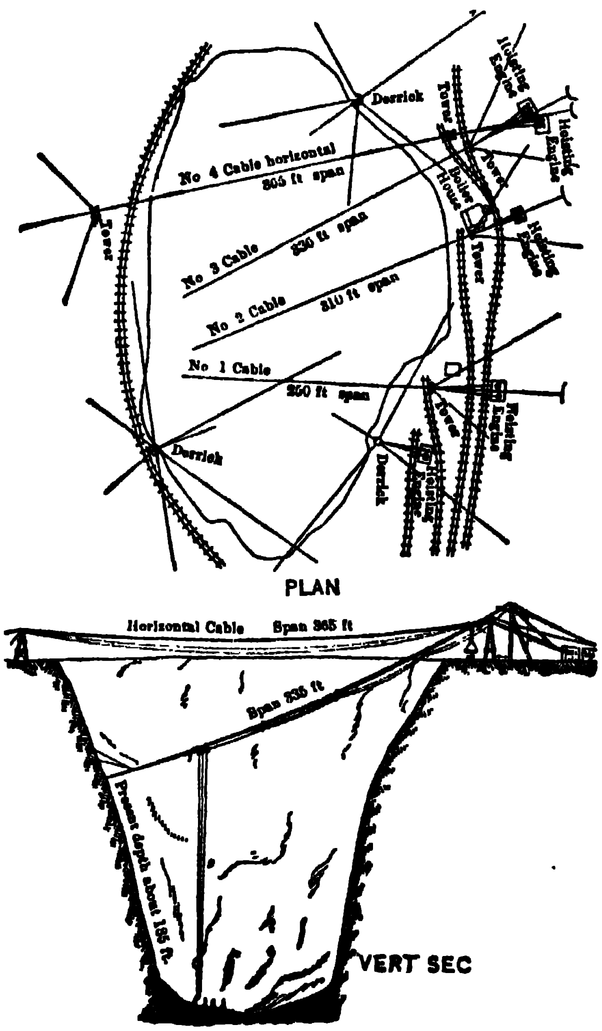

Fig 666. Open Pit, Tilly Foster Iron Mine, N Y

Large-scale work, cheap labor. PREMIER DIAMOND MINE, Transvaal, So Africa (332). A kimberlite "pipe" (Art 88), about 0.5 mile long by 0.33 mile wide, was mined in 50-ft benches. The faces were kept steep, and were broken in steps by vert holes drilled with jumper drills. The material was shoveled into 20-cu ft cars at the foot of the benches. Tracks were in loops 200 to 300 ft long, paralleling the faces and connecting with main haulage tracks. The layout in Fig 663 was impracticable, because of enormous tonnage and length of benches necessary to produce it. Endless-rope haulage (Sec 11) was used on main tracks, and on inclines to surface. In 1912, 11 000 natives were employed in the pit, in 2 11.5-hr shifts; 2 100 per shift were drilling on the main benches, 700 in development cuts for opening lower benches, 600 blockholing and spalling, and over 1 300 on tramming. Monthly output, 1 000 000 16-cu ft loads of "blue ground" and 87 000 loads of waste. Aver cost of mining and haulage was slightly less than 30¢ per load, including waste. The pit in 1912 was 200 ft deep. Underground methods (Art 88) are now used.

96. OPEN-CUT MINING WITH POWER SHOVELS

Field of use: (*a*) removing shallow overburden from coal, iron ore, phosphates, etc, which are then mined by other open-cut methods; (*b*) stripping and mining deposits of large area and tonnage, which are fairly uniform in character and lie near the surface, and may or may not be covered by overburden.

General. Power-shovel methods involve large capital outlay, for equipment and preliminary stripping; hence they are limited to work in deposits large enough to return this outlay plus interest during life of mine; properly applied, they yield enormous outputs at low unit costs.

The general features of power-shovel mining appear simple; but good management, close attention to details and systematic work are essential. Shape and position of orebody must be predetermined, to allow intelligent planning of approaches and track layouts, for minimizing delays and handling max amount of material by the shovels; maintenance and repair of track, cars and shovels are important. As the unit cost with a given equipment varies inversely with output, there should be no preventable delays. For details of shovels, see Sec 3. See following examples; also Art 101 and Bib (631).

Practice on Lake Superior Iron Ranges. Data from C. E. van Barneveld, 1912 (35), L. D. Davenport, 1918 (632), E. E. Hunner, 1930 (660), A. H. Hubbell, 1931 (661), M. H. Barber, 1932 (662), W. R. Meyers, 1932 (663), and L. C. Moore, 1938 (664).) See Art 10-b for ore occurrence.

Plan of work. Orebodies are thoroughly explored by boring; surface and ore contours are platted on maps, on which complete plans for stripping and mining are laid out before excavation begins (Art 11). Overburden is stripped by power shovels or draglines, and dragged or hauled to waste dumps; hydraulic stripping was feasible at Tilden mine, Marquette Range. Ore is excavated by power shovels; at some of the largest mines, with suitable approaches, it is loaded directly into R R cars for shipment to Lake Superior ports; at others, and always if crushing or washing is necessary, it is loaded into pit cars of 4–30 cu yd for delivery to plant or R R. Small pits are usually stripped completely before mining begins; in large pits, stripping and mining may proceed simultaneously; some companies strip only in winter, using all equipment and crew for mining ore during shipping season. Mesabi open pits vary in area from 20 acres up; the Mahoning-Hull-Rust orebody is a mile wide and 3 miles long; the pit, in 1939, covered nearly 2 sq miles, and, from beginning in 1895, had delivered 487 100 000 tons of ore and waste. Engineering problems involved in opening and operating these mines are largely those of equipment, and arrangement of tracks and approaches; track layouts are often complicated by presence of layers of paint rock, etc, and necessity for grading the ore as it is loaded. Approaches. As the topography is fairly flat, approaches are excavated as through cuts on descending grades; for loco haulage, a 2% compensated grade is the max desirable; some 3% grades are required and 4% is possible, though not effic. At Volunteer mine (Marquette Range), a 6–7% grade is negotiated by Woodford remote-controlled elec cars (661, Dec 14, 1931). In some pits 300–400 ft deep, steep approaches are avoided by sinking hoisting shaft in wall rock, connecting with pit bottom by crosscuts, which may also serve for drainage. Belt conveyors in inclined shafts serve similar purpose at some deep open pits. Motor trucks (Sec 27) can climb 10% grades with 20-ton loads. Sometimes separate approaches are cut for stripping and mining; for stripping, they are located to minimize the haul to waste dumps; for mining, there must be a track or road system which will reach the max amount of ore without unduly steep grades.

Stripping faces usually have a 1 : 1 slope (Art 113) with a 20-ft berm at bottom of bank. In deep overburden, the banks are broken at least every 75 ft vertically with a 25–30 ft berm. Stripping is so arranged that shovels work against a 25–35-ft bank. Stripping is done with side cuts just as wide areas are graded in R R work. Regular stripping stops 6–8 ft above the orebody; remaining cover is removed by a smaller "clean-up" shovel, with a crew of 6–8 laborers. As the top surface of orebodies is uneven, final cleaning is done by scrapers; small revolving shovels have also proved useful. Overburden is mostly glacial drift, containing boulders 2–12 ft diam; large boulders are "chained out" when uncovered, and blockholed. Overburden is often loosened ahead of the shovel by blasting. STRIPPING EQUIPMENT varies widely; much stripping is done by contractors who furnish plant. Common equipment includes a revolving, caterpillar power shovel, with 8–10-cu yd dipper; reach, to 95 ft; lift, to 56 ft. Such a shovel often has interchangeable dragline boom 100–150 ft long, using 4–6-cu yd scraper (Sec 27). R R type of shovel is nearly obsolete, and steam is rapidly giving way to elec power, both for shovels and haulage. Small shovels, 1.5–3 cu yd, for cleaning and other shallow work, are sometimes driven by gasolene or gas-elec power. Chief advantage of long-reach shovel for stripping is that it can make a through cut in one operation, loading cars on the surface, which would require several successive cuts with accompanying track work, if dug with smaller shovels. STRIPPING DUMPS are located on barren ground, or where open cuts are impossible. A low area, sloping away from initial dumping point and offering a downhill haul, is ideal. Dumps are started by dumping alternate cars on opposite sides of the track, and gradually jacking up the track until the dump reaches required height. After this, the dump is "fanned out" by moving the track sidewise. Usually, dumps are started from trestles, 20–25 ft high and strong enough for the empty, but not the loaded, train. Desirable lengths of dumps are 1 200–1 400 ft; heights, 20–40 ft, preferably the latter; 60-ft dumps are excessive, as the tracks settle badly. Straight dumps are best; curved tracks are hard to shift. The muskeg swamps of Mesabi Range are unsatisfactory locations for dumps; dumps settle, and the muskeg bulges on each side; but swamps may be employed with advantage in winter.

Mining ore. Amount of loosening required varies widely with compactness of ore. Former practice of chambering small holes, drilled by wagon-mounted drifters and finished at 1-in diam at about 26-ft depth, entailed excessive blockholing besides so loosening adjoining ore that subsequent blasts lost some effectiveness. Present practice on Mesabi adopts 6-in holes, churn-drilled to about 40 ft, or 5 or 6 ft below bottom of bench, loaded to half-depth with 60 and 80% Gelamite, and fired (as many as 100 at a time) with Cordeau; smaller blasts may be fired electrically. In harder ores of Marquette Range, 6-in holes are churn-drilled to depths up to 110 ft (aver 45 ft at Volunteer and 68 ft at Tilden mine), spaced about 15 ft in a row 13–20 ft back of face. Usual explosive is 40, 60, or 80% gelatin or Gelamite, column loaded. Volunteer mine fired 535 holes in 1 blast, breaking 630 000 tons; Tilden mine, with 2 blasts in 1930, broke 450 000 tons with 129 550 lb of 60% and 80% explosive in 225 holes; 24.3 tons per ft of hole, or 3.48 tons per lb of explosive. Faces of benches in ore are sloped 0.5 : 1 on the Mesabi, or down to 1 : 1 on the Gogebic and Cuyuna Ranges (Art 113). A 1 : 1 slope is allowed on faces carrying a series of tracks and switchbacks. Ore is mined in side cuts; benches, 25–30 ft high on the Mesabi, or higher in the harder ores of Marquette Range. Popular shovel is elec operated, full-revolving, caterpillar-mounted, with 2–5-cu yd dipper (Sec 27); its maintenance costs about 25% that of a steam shovel.

Track haulage. As example of steam haulage, the Hull-Rust-Mahoning pit uses 120-ton locos for trains of 12 30-cu yd cars up 1.5% grade, returning empties on grades not exceeding 5%. At pits where R R cars are inadmissible, side-dump pit cars of 20–30-cu yd capac are common. Recent tendency has been towards elec haulage, with 60–75-ton trolley locos. A 60-ton loco, with 600 hp in 4 d-c, 600-v motors, exerts a starting pull of 30 000 lb, and can haul a gross load (including loco) of 340 tons up a straight 3% grade at 7.5 miles per hr (see Sec 11). A 75-ton elec loco hauls 6 loaded 75-ton cars up 2% grade at 10 miles per hr, while a steam loco of same wt can haul only 5 such cars, on same grade, at 8 miles per hr. L. C. Moore, basing his computation on a typical Western Mesabi wash-ore pit yielding 700 000 long tons of concentrate from 1 050 000 long tons of crude ore, and moving 500 000 cu yd of stripping per season, estimates a saving of 6.58¢ per ton of concentrate in favor of elec over steam haulage, including fixed charges in both cases. Haul involves a rise of 260 ft in a run of 4.4 miles, with trains of 4 30-cu yd (55-long ton) cars. For details, see Bib (664). "DIFFERENTIAL" SYSTEM has been adopted by Susquehanna, Wakefield, and Richmond pits; at Susquehanna, a train of 6 4.5-yd (8-ton) cars is hauled through a tunnel on −0.5% grade to shaft by a 190-hp motor-car carrying same load of ore; such a train weighs less by 10% when loaded and by 18% when empty than a 7-car train hauled by elec loco (660). The empty motor-car has enough tractive force to pull an empty train, while its 8-ton load adds enough tractive force to draw the loaded train. TRACKS AND LAYOUTS. 80–90-lb rail, well graded and ballasted, is used on large-scale work. Temporary tracks are lighter and laid with less care. Grades of main tracks should be below 2% or at most 3%; short stretches of 5% grade may be unavoidable. Special tracks on 5–6% grades are sometimes laid for short-cuts for quick return of empties to pit. 7.5° curves are the max desirable, and 15° the max allowable, but 50° curves are required and operated successfully in some cases. Fig 667, 668 show general layouts; they are variously modified. Switchbacks are also used to connect benches in small pits or in deeper parts of large pits. The SPIRAL SYSTEM (Fig 667) is ideal. It permits easy grades, curves, and turnouts, and requires few switchbacks, but is limited to large pits of regular outline.

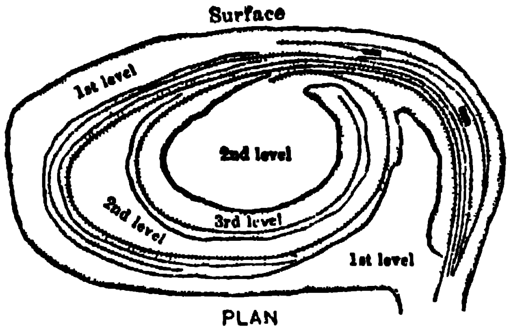

Fig 667. Spiral Track Layout, Mesabi Range

Truck and tractor haulage (Sec 27) was adopted experimentally on the Mesabi about 1936 (664, 665) and quite widely in 1937–8 among smaller and deeper mines on Mesabi and Cuyuna Ranges. Side- or end-dumping trucks to 15- and 20-ton capac, and tractor-drawn, crawler-mounted, side- or bottom-dump wagons to 15- and 18-ton capac are used.

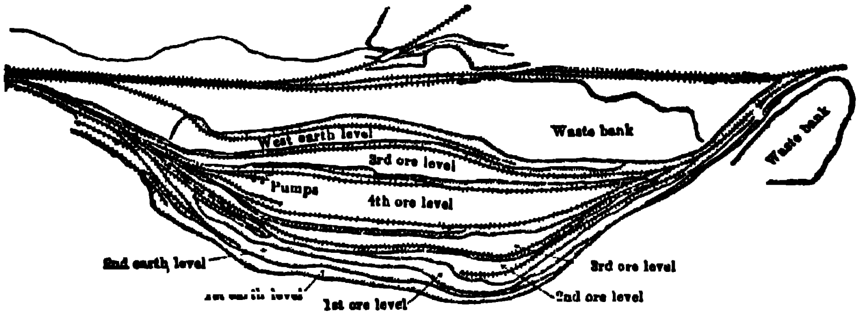

Fig 668. Track Layout, Mountain Iron Mine, Mesabi Range

The larger trucks, with 125- to 150-hp Diesel engines, come out of pits on (max) 10% grade at 5 miles per hr and return down 14%–20% at high but safe speed. Trucks are used also for dumping into raises on pit floor, but their chief advantage over the slower tractor-wagon is seen on hauls of 800–1 000 ft or more (665, 667). R. W. Whitney and G. J. Holt (667) offer following data in 1939, based on 2 years' experience with 15-ton trucks on Cuyuna and Mesabi Ranges, hauling from pit bottom to surface dump; 6-wheel type, with dual rear wheels, is preferred to the 10-wheel (with 2 sets of dual rear wheels) because: (*a*) can turn sharper curves (20-ft rad); (*b*) more economical of tires; (*c*) saves time for servicing (0.5 hr against 1 hr); (*d*) lower maintenance. Diesel engines consume less fuel than gasolene: under 3 gal of fuel oil per hr against 5.75 gal of gasolene; overspeeding of Diesel engines is checked by recording tachometers. Life of closely inspected tires is approx 4 000 hr,

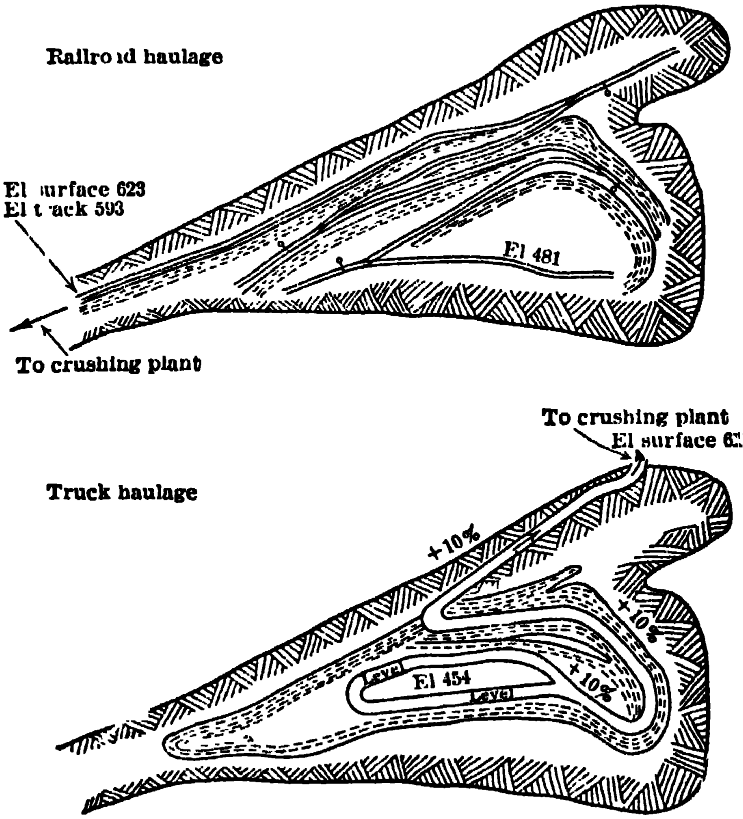

Fig 669. Two Haulage Systems, Louise Pit, Cuyuna Range

equivalent to 16 000–20 000 miles on a highway. Life of truck estimated at 10 000 hr. In ore, two 4-yd dippers make a load of 15.4–18.2 (aver, 15.7) long tons; on stripping, sideboards are added, and load is then 3 dippers. Road grades of 8–10% are feasible for loads, and on return 20% is permissible. In Louise pit (Fig 669) 214 ft deep, 3 185 ft of road at 10% replaced 8 500 ft of R R at 2.6% grade, and 3 trucks displaced 2 locos serving same shovel. Truck speeds with loads are (miles per hr): level, 10; up 5%, 8; up 7%, 6; up 10%, 5. For other data, see Table 66. At another Mesabi pit, stripping during mid-winter at a partly frozen bank, largely of clay and 20–25 ft high, loading with 4-yd shovel, 15-ton trucks hauled 1 mile over nearly level road on snow, making round trip in 6.7 min; loading, 1.4 min; delays, 1.2 min.

Table 66. Data on Truck Haulage out of Lake Superior Iron-ore Pits (667)

	Cuyuna	Mesabi	Mesabi
Total haul for loads, ft	3 185	4 200–4 600	1 925
of which, up 7.5–10% grade	2 135	1 800	1 200

Total time per truck	14.5	9.6	7.1

(*a*) Incl delays. (*b*) Not counted a delay, since shovel was picking up a load during this interval.

Belt conveyers (Sec 27), receiving ore directly from shovels or through pocket or chute with regulating pan conveyer at bottom, have recently been installed at several Mesabi mines, notably La Rue, Canisteo, St Paul, and Spruce. At ST PAUL, the 30-in conveyer is 854 ft long, in 3 equal sections, on 19° incline; max capac, 300 tons per hr at 350 ft per min; it is fed through a 1 500-ton pocket with gate 40 ft below present pit bottom; pocket is centrally situated in ore, so that aver haul for tractor-wagons is 600 ft (max, 1 200 ft). SPRUCE MINE, in 1937, installed a 30-in conveyer in 9 zig-zagging sections, totaling 4 481 ft and rising by non-uniform grades (max 25.6%) 386 ft from its lowest point to top of R R loading bin. Aver capac at 500 ft per min, 500 tons per hr. It is fed with crushed ore through 10 by 10-ft raises at 3 points in pit bottom, 2 supplied with ore by tower excavators with 600-ft radii, and 1 by a 2.25-yd shovel and four 20-ton trucks. For details at Spruce mine, see Bib (664, 665, 666).

Drainage. Many Lake Superior pits make from 0.5–1.5 million gal of water per day. As the topography usually prevents opening self-draining pits, drifts are run under the pit to collect water and lead it to a shaft near the pit edge, whence it is pumped to surface. For economic limit of stripping depth, see Art 101.

Nevada Consol Copper Co, Ruth, Nev. Following data are contributed by courtesy of D. C. Jackling and W. F. Boyd in 1938. Copper Flat orebody was originally a fairly flat, massive deposit of monzonite porphyry containing disseminated chalcocite and chalcopyrite and having a leached capping aver 110 ft thick (307). Ore averaged 500 ft thick. Mining has always been done with power shovels on benches 50–100 ft wide, and at approx 50-ft vert intervals. Tracks on each bench form a closed loop with a spiral approach; favorable for handling trains (Fig 670). Grades of main approaches are 2.5% max; loading tracks, level. Slopes between benches are 45°–80° from horiz, depending on character of rock. On reaching final pit limits, benches are consolidated 3 into 1, making final slope of banks 45° in hard, and 40° in soft, material. Both ore and waste require blasting; 9-in holes are drilled with Bucyrus-Armstrong, 29-T, elec churn-drills (5 in service) to 10 ft below the next lower level. Holes are 18–21 ft apart and usually placed 10 ft from edge; this puts 35–40 ft of burden on hole at the toe; they are sprung with 40% stick powder. Wet holes are loaded with stick and dry holes with 70% bag powder. Over 5 tons broken per lb powder. Equipment comprises 5 Bucyrus-Erie, 120-B, full-revolving elec shovels with 4-yd dippers, and one Marion elec, with 1.5-yd dipper. Motive power for haulage is 4 saddle-tank and 12 side-tank, 80-ton, 0-3-1 steam locos.

Table 67. Operating Data, Nevada Consol Copper Co, Ruth, Nev

	1936	1937	1938
Tons per shovel-shift (ore and waste)	5 030	4 513	4 661
Tons per loco-shift (" " ")	1 443	1 284	1 718
Feet of hole per drill-shift	73.72	75.54	68.62
Tons broken per lb of explosive	5.73	5.39	6.05

Waste is handled in 20-, 25-, and 30-cu yd side-dump cars, and ore in 70- and 80-ton cars, dumped in a tipple at the mill. Other equipment: Jordan spreader, caterpillar bull-dozers, trackshifters, service cars. Rail on the main lines is 90-lb and that on the loading and dump tracks is 75-lb. (See Table 67).

Chino mine, Nevada Consol Copper Co, Santa Rita, N M. Data from H. A. Thorne (63) in 1931, revised 1939 by Co officials. Orebody is a disseminated chalcocite, in porphyry and adjoining silicified sedimentary rocks; most ore is hard and tough and breaks large, involving much blockholing. Ore ranges 0.70–2.00% Cu; grade of reserves estimated (1938) at 1.17% Cu. Leached capping is 0–150 ft thick; orebody is irregular, both top and bottom, up to 600 ft thick. Pit (Fig 671) is elliptical, 5 000 by 4 000 ft, with large mass of unprofitable rock near its center, on which principal mine plant is situated. Topography is favorable for easy disposal of stripping, but a stream had to be diverted and confined in concreted flume 7 500 ft long, around N edge of pit. Parts of orebody were extensively developed by old workings; remainder tested by churn-drills (Art 10-b) to aver 900-ft depth. Shovel benches 42 ft high have proved most economical; face of a bench will stand nearly vert for years, and a 25-ft berm assures safety from casual falls; aver slope, top to bottom of pit, 45°. Breaking ground. Vert top holes and inclined toe holes are

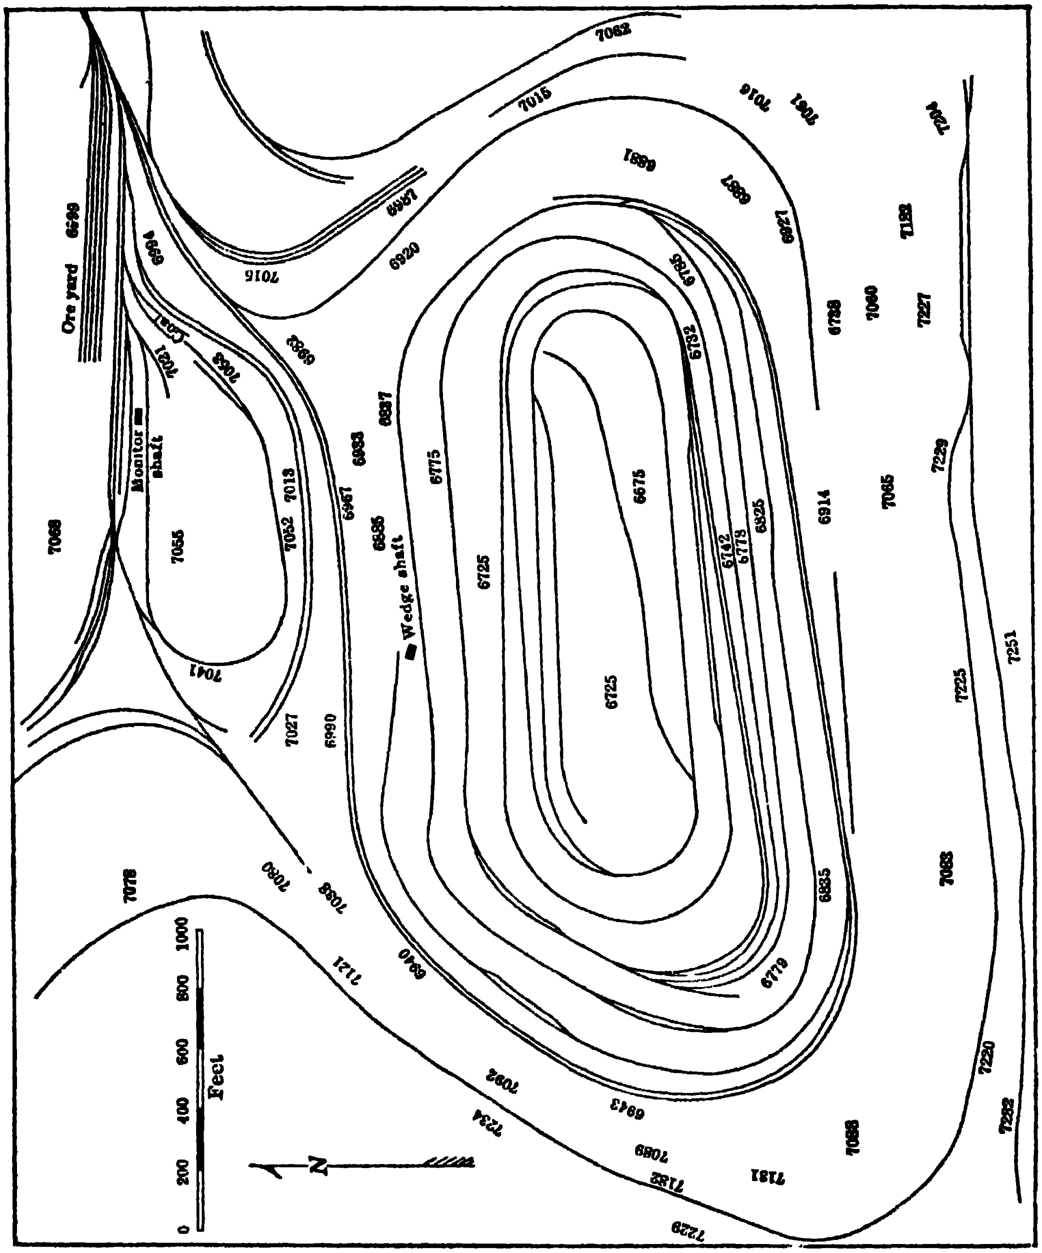

Fig 670. Trackage in Ruth Mine, Nevada Consol Copper Co, April, 1938. (Figures represent elevations, in feet)

used. Former are spaced 18–25 ft in a row approx 10 ft from crest, and drilled 5–10 ft below bench grade, for breaking to bottom, or 30 ft deep for trimming face; these 6-in holes are drilled by elec, self-propelling churn-drill rigs. The 6-in tools are to be replaced by 9-in. In Aug, 1938, 12 such rigs drilled 10 459 ft of hole in 1 108 machine-hr (9.44 ft per hr, incl 9.2% delays). Toe holes, 22 ft deep, inclined about 30° to reach 5 ft below grade, and spaced 15 ft apart, are drilled by heavy air-hammers, starting at 3.75 and finishing at 1.375-in diam. Aver speed in toe holes, 5.8 ft per hr, total time. All holes are sprung at least once, using 40% gelatin, with water for stemming. Blasting charge in vert holes is 35% and 50% bulk powder, if dry; gelatin, if wet, stemmed with screened dirt. Charge in toe holes, 40% or 60% ammonia dynamite if dry, gelatin if wet, unstemmed. Blasts are fired with Primacord wherever possible; otherwise by elec detonators, not over 10 holes at a time. Powder for secondary blasting, for 9 mos in 1938, averaged 5% of total consumption. Including secondary blasting, aver for entire pit is 6.43 tons of material broken per lb explosive. Loading. Equipment includes 8 R R-type elec shovels on caterpillars, with 4-yd dippers; 2 full-revolving elec shovels on caterpillars, with 4.97-yd dippers; and 1 truck-mounted elec shovel, with 8-yd dipper and 80-ft boom, which can make a through cut 80 ft wide at bottom and load into cars on track 42 ft above it. Power consumption by the 4-yd shovels is 0.76 kw-hr; by the 4.97-yd shovels, 0.72 kw-hr; and by the 8-yd shovel, 1.41 kw-hr, per cu yd loaded. Crew on 8-yd shovel consists of 4 men; on the others, 2 men. Haulage. In 1938, Chino mine had 26.7 miles of std-gage trackage, plan of which is shown in Fig 671. All main lines are 85-lb rail; bench tracks, 85- and 75-lb; latter is being replaced with 85-lb. Dump tracks, 75-lb rail, are

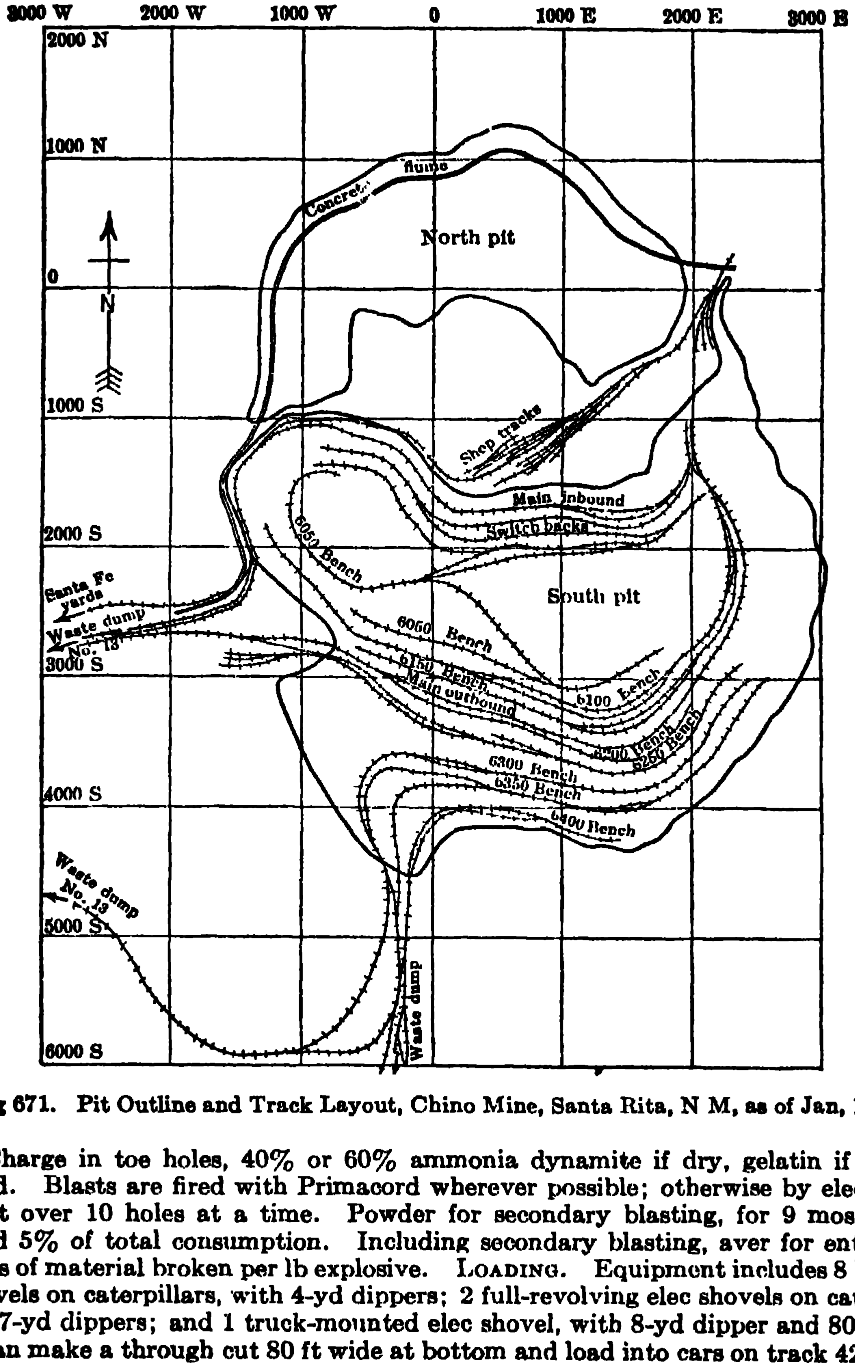

Fig 671. Pit Outline and Track Layout, Chino Mine, Santa Rita, N M, as of Jan, 1939

also to be replaced with 85-lb. Aver haul for both ore and waste is 2.23 miles. Curvature of tracks is kept under 20°, and grades do not exceed 2.5%, compensated. Motive power includes 11 American, 6-wheel, 90-ton; 6 Baldwin, 6-wheel, 85-ton; and one 4-wheel Porter, 42.5-ton, locos; the latter for switching only. Air-dump, 20- and 30-cu yd, cars are used. Trains of 200 cu yd are hauled on level or down grade; 140-cu yd trains on adverse grades.

Utah Copper mine (Kennecott Copper Corp), Bingham, Utah. Data from A. Soderberg (119) in 1930, revised in 1938 by Co officials. Orebody, a trough-shaped mass of monzonite porphyry about 6 000 ft long, 4 000 ft (max) wide, 2 000 ft (max) deep, contained originally 800 000 000 tons workable ore, carrying disseminated Cu sulphides, chiefly chalcopyrite with local enrichments of chalcocite, covellite, and bornite. Orebody is blanketed by an almost barren capping of porphyry and quartzite, averaging 115 ft thick, but only 20–50 ft in places. To end of 1937, 265 706 395 tons of ore, averaging 1.13% Cu (0.98% aver for last 10 years), were extracted, requiring removal of 145 604 780 cu yd of barren or low-grade material (1 cu yd weighs 2.077 tons), a stripping ratio of 1.14 ton waste per ton of ore mined. Reserves last reported (1930) were 640 000 000 tons, averaging 1.07% Cu. Recent minimum workable grade was taken at 0.4% Cu, when within the stripping area. Precipitation plants recover about 25 tons cement copper per day during the spring water run-off, leached from waste dumps by natural percolation. For prospecting and sampling by churn drill, see Art 10-b. GENERAL PLAN. Main orebody lies between 2 deep, conjoining canyons; hence is well situated to produce large tonnage by open-pit work (up to 75 000 tons of ore and equal or greater amount of waste per day). The 1 500-ft rise from R R yard at fork of canyon to highest rim of pit is attacked on 23 benches (Fig 672), 50–80 ft high (about 50 ft is most economical) and 30–450 ft wide (aver, 100 ft); 3 more benches have been opened below yard level. Max economical overall working slope, top to bottom, 28°; ultimate overall slope, 35°; individual faces, variable, but about 50°. Benches are connected by switchbacks, on 4% max grade, with extensions to waste dumps (usually 1 per bench to nearby dumps, but 2 or 3 are combined for the longer hauls) in canyons outside of orebody. In 1937, there were about 85 miles of std-gage track; rail distance, yard to remotest shovel, about 7 miles; aver haul, 2.6 miles. Trains of 10–14 cars, 80–90 tons per car, are collected at yard and hauled thence in 50-car trains, by steam locos, 18 miles to concentrators. Waste cars, holding 30 cu yd, are in 4 to 9-car trains. BREAKING GROUND. Early practice of heavy blasting with coyote holes proved destructive of benches. Fig 673 shows present method. Holes averaging 22 ft deep are drilled by reciprocating drills; hammer drills are unsuitable, because continuous water supply can not be distributed in winter. Driller and 2 helpers average 45 ft of hole per shift, besides blasting and trimming; 1 set of steel makes 4–5 holes before losing gage. Toe holes, spaced 15 ft, start 3–5 ft above floor, and pitch 5°–15° downward to bottom on grade; mid-face holes (not always required) are horiz but pointed backward towards advancing shovel: vert top-holes are rarely needed in higher benches. Progress requires 2 drill crews per shovel. Toe holes are sprung, usually 4 times, with 7, 15, 30, and 50 sticks, stemmed with water. Final charge is 150–250 lb of low-freezing ammonium nitrate powder, 60% Ngl for dry holes, and semi-plastic for wet holes, fired by fuse in such sequence (usually 18 per round) that each shot is partly blanketed by its predecessor, to

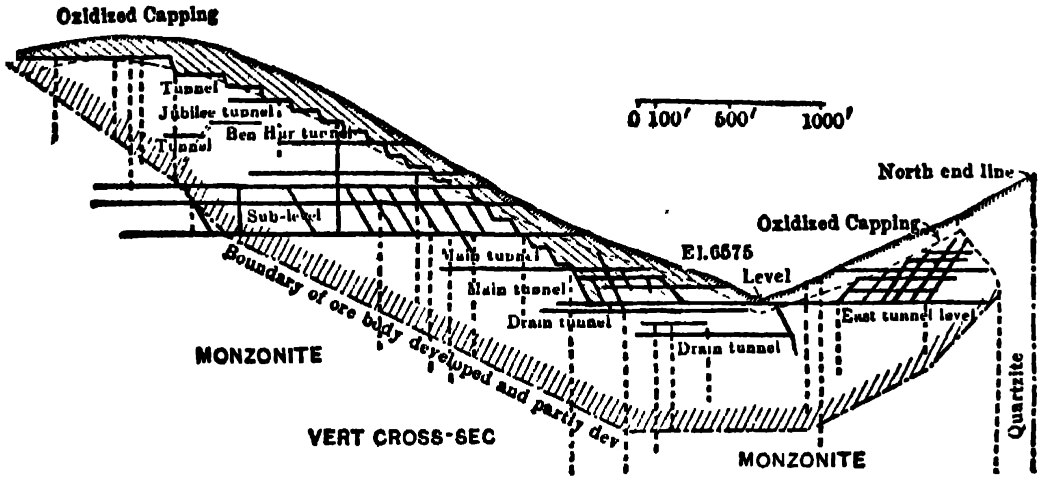

Fig 672. Open-cut Mining, Utah Copper Mine

reduce throwing. Breakage beyond 21-ft reach of shovel is avoided, to save delay in setting up for next row of toe holes. Mid-face holes are drilled from top of pile produced by toe-hole blast, but are not fired, and then only 1 or 2 at a time, until shovel has made space for their broken ore to fall. Top holes, if needed, are fired after shovel has passed by. Some bulldozing and blockholing is necessary. Powder consumption averages $^1/_8$ lb per ton broken, of which 16% is for chambering, 69% for main blasts, 15% for secondary blasting, mainly trimming. Drilling averages 0.022 ft per ton broken. Tests proved that vert holes were less effic, more costly, and left hard digging at toe of bank. Loading. In 1937, mine had 22 elec, caterpillar shovels, with 4.5-yd dippers and 30-ft booms swinging 190°; also 7 full-revolving elec shovels, with 5-yd dippers. All types work about 25% faster in ore than in waste (longer trains of larger cars), overall aver being 4 136 tons per shovel-shift. Aver per shovel-shift (Oct, 1938) was 6 000 tons in ore and 4 600 tons in waste. Loading averages for full-revolving shovels are about 15% higher than for the others. Power at 5 500 volts for shovels is carried on benches by portable 25-ft steel towers, which also support trolley wire. Haulage. At end of 1937, 75 miles of pit track had been electrified for 75-ton trolley locos (ballasted to 85 tons), of which 2 serve each shovel; each hauls 12 empty cars (252 tons plus its own wt) up 4% grade at 12 miles per hr. A few combination trolley and storage-battery locos have been used. The others carry a reel with 2 000 ft of cable for use beyond electrified track; recent purchases are without reels. Loading an ore train takes 1.25–1.5 hr; round trip from yard to most remote shovel, about 1.25 hr. Performance data (see Table 68).

United Verde mine, Jerome, Ariz.

Data from E. M. J. Alenius in 1930 (544, 656), with additions by J. R. Bloom in 1939. For description of orebody, see Art 62. Open-cut mining was adopted to recover ore in upper levels, mining of which by underground methods was interrupted in earlier years by mine fires, which spread to the sulphide orebody itself and prevented further underground work in this area. Major problems in open-cut mining involved: (1) stripping about 11 000 000 cu yd of waste, chiefly hard, blocky diorite; (2) mining extremely hot sulphide ground; (3) maintaining high degree of selectivity in mining and handling smelting ore, concentrating ore, converter flux, and waste; (4) operating in a deep pit of relatively small diam. Fig 674 shows the geol conditions and relationship between orebody and stripping requirements. Original plan proposed mining by glory-hole after completing major stripping; decision to use small elec shovels and automobile trucks came after stripping proved need for selective mining.

Stripping. Method and equipment used above 160-level were distinct from those below that level. Major stripping consisted of carrying back, at a proper slope, a face of diorite about 600 ft high. For this, steam shovels, steam locos, standard-gage track, 25-cu yd air-dump cars, and complementary equipment were used. Waste disposal and access to benches involved construction of more than 5 miles of switch-back R R line; waste was mostly placed in nearby gulches. TRACKS, semi-permanent, were of 90-lb rail; bench tracks and upper switch-backs, 75-lb rail; 60-lb rail on dumps. Loaded cars usually moved to dumps on a max down grade of 3%; where material had to be moved upgrade, the grade was reduced to 2%. All tapered and grade was compensated. Table 69 lists the HEAVY EQUIPMENT. The 8-cu yd, full-revolving shovel operated entirely on the 160-level, against a bank which, during the major stripping, varied in height from 110-315 ft. It was mounted on traction wheels running on 130-lb rail. The 4-cu yd, R R-type shovels excavated the upper benches, generally 50 ft high; originally operating on rails, they were later equipped with caterpillar traction. The 0.75-cu yd caterpillar shovel was used for excavation on switchbacks and roads. Shovels and locos originally burned coal; later equipped for oil The 82.5-ton locos hauled 6 loaded cars; the 53.5-ton locos, 4 cars. HOLE DRILLING AND BLASTING. Churn drills, used at first, did well in weathered diorite. On 50-ft benches, holes were spaced 35–40 ft lengthwise of bench and 5–10 ft back from edge; they were drilled 12.5% deeper than height of bank and loaded

with 10–12 boxes of 35% gelatin powder; toe holes were sometimes needed for removing hard ribs. On the 110-ft bench, churn-drill holes, cased with 6-in pipe in loose ground, were placed close to edge of bank and 30–50 ft apart; they were drilled 10–15 ft deeper than height of bank; distance from bottom of hole to toe of bank, 55–95 ft; this distance and the character of ground governed the powder charge, which was 4 000–8 000 lb; drilling speed, 5–30 ft per shift. Beneath zone of weathering, diorite was too hard and blocky for churn drills, which were replaced on the 50-ft benches by air drills. Combination of toe-holing with jackhammers and drilling vert holes with tripod drifters (Fig 675) was found best for the conditions. Toe holes were 6–15 ft apart; vert holes, 12.5 ft apart. Powder charge for toe holes, 100–250 lb; for vert holes, 75–150 lb. Holes, 20–30 at a time, were blasted electrically from a 440-v line. COYOTE BLASTING. To equalize progress of 8-cu yd shovel with that of 4-cu yd on upper benches, some lower benches were consolidated, in a bank over 300 ft high at one end of pit. Due to height of bank and difficulty of churn-drilling in fresh diorite, coyote blasting was thereafter used on the bottom bench. Six such blasts were made, breaking a total of 793 000 cu yd; largest single blast, 259 000 cu yd. Procedure was to drive a 4.5 by 6-ft drift parallel with and 75–135 ft behind the face, and, at 30-ft intervals along the drift, to sink 5 by 5-ft winzes to depth 20–30 ft below the pit grade (Fig 676). A case of gelatin dynamite with 4 No 8 elec caps was placed in bottom of each pocket. Powder for main charge was unloaded at the tunnel mouth and transported to the pockets on special wooden cars. Black powder was used in first 3 blasts; for greater shattering effect, "Quarry Special" in the next 3, with addition of 60% ammonia dynamite in the last 2 blasts. The powder was covered with paper and sand tamping, and the tunnel back-filled. Table 70 gives data on these blasts.

(*a*) Pockets under slope only.

Pit slope. Original stripping was based on assumption that a 0.5 : 1 slope would be safe in the dense, unaltered diorite of hanging wall, and a 1 : 1 slope in the softer footwall. Stripping was completed in 1927; no difficulties as to pit slope occurred until late 1929, when a subsidence, originating from underground stoping, fractured the high, steep diorite bank on hanging-wall side. A subsequent large slide, Mch, 1931, proved that a slope as steep as 0.5 : 1 was no longer practicable, and it was decided to flatten the diorite side of

pit to a 1 : 1 slope. This involved removal of 4 000 000 cu yd of waste besides the original estimate of 7 000 000 cu yd.

Mining in lower pit before 1931. Work below 160-level (Fig 674) has been mostly confined to main orebody. Required flexibility and selectivity led to choice of low benches and small equipment. Benches were 25–63 ft high. Major equipment included 1.75-cu yd elec shovels, 10-ton automobile trucks, service trucks, elec churn drills, air drills, gasolene crane, and road scraper (bulldozer). Automobile trucks delivered to transfer raises extending to pit from main haulage tunnel on 1 000-level (Fig 674). Drilling was chiefly by churn drills, but air drills were used in places not easily accessible for churn drills. Churn-drill holes were close to edge of bank, generally 10–12 ft apart, and 5 ft deeper than height of bank. In hot ground, where use of powder was limited, spacing might be 4–5 ft. Holes were usually sprung, and loaded with 150–250 lb 35% or 50% gelatin dynamite; blasted electrically. Holes in hot ground were cooled to 120° F or less, before loading, by running in water for 1–24 hr, or using wet sand. For sand, holes were chambered to hold both sand and explosive. Using a little water, the sand was washed into crevices, sealing off hot gases. For holes that could not be cooled, charge was in form of a torpedo. For a 6-in churn-drill hole, a 4-in paper tube, 6–8 ft long and 0.5-in wall, was used (Fig 677). Bottom of tube was sealed by a wooden plug to which a wire was fastened for lowering into the hole. Charge and detonators were placed in the tube and covered with sand. When shooting a round of hot holes, torpedoes were first wired together electrically; when blasting signal was given, they were then lowered into the holes and detonated. Such holes were not chambered, nor stemmed. For toe holes in hot ground, torpedoes were ordinary mailing tubes filled with gelatin dynamite. Operating data during 1929 are in Table 72.

Operations since 1931. Ore production at United Verde was suspended in 1931 and resumed in 1935, when the mine was acquired by Phelps Dodge Corp. Removal of waste from the open-pit, largely due to a slide in Mch, 1931, continued during the interval. J. R. Bloom, Pit Foreman, contributes following data in 1939 on work since 1931. To end of 1935, 5 282 000 cu yd of waste was removed. Stripping consisted in cutting back the diorite bank to a 1 : 1 slope above the 160-level and maintaining a 0.5 : 1 slope below. Benches were left at various intervals above the 160-level. All material was hauled by locos to waste dumps about at same elev as the loading. In 1935, dump space was no longer easily accessible, requiring longer hauls on heavy grades. The 4-cu yd, full-revolving, crawler shovel proved far more satisfactory than the R R-type steam shovels used earlier. The smaller elec shovels were used mostly as alternate units. **Blasting practice** resembled that employed on the original stripping; coyote blasting was unsuited to maintain a safe final bank. Four elec churn drills, with jackhammer and Leyner air drills, were used; explosive, 35% and 60% quarry powder, 35% and 60% gelatin stick.

(*a*) Includes caved material.

Ore mining in lower pit was resumed Jan, 1935, and continued that year in conjunction with stripping. Since 1936, stripping has been confined to waste from within the orebody, and caved material from the banks. For proper classification of material loaded, the smaller shovels were best. Three classes of ore, direct-smelting, concentrating, and converter, and waste material, were dumped into separate transfer raises. After passing through the 900-level grizzly chamber, they were hauled out the 1 000-level haulage tunnel to outside transfer bins. Blockholing of large pieces was required on 900-level to pass the material through the 15-in grizzly. **Breaking ground.** The 100-ft vert block between mine levels was removed in 3 cuts from 27 to 37 ft, depending on location of ore pillars beneath. Drilling was similar to that described above. Hot ground was blasted with same precautions, but 4 by 4-in wrapped 35% blasting gelatin powder was used in churn-drill holes at temp to 120° F. Type of drill was determined by the hardness and broken or solid character of the ground. Approx 20% of mining crew's time was for barring down and trimming the high banks above the lower pit; this had to be done when falling rock would not endanger shovel and churn-drill operators below. Table 77 gives data when all material was passed through transfer raises and haulage tunnel. **Conclusion:** It is estimated that the completed United Verde pit (Fig 674) will have a vert depth of 1 100 ft; area within the excavated outline, 60 acres; area of lowest level, 0.9 acre. A total of 19 200 000 cu yd (in place) will have been removed, representing 10 200 000 tons of ore and approx 31 000 000 tons of waste.

New Cornelia mine, Phelps Dodge Corp, Ajo, Ariz. Data contributed through courtesy of H. M. Lavender, Gen Mgr of Mines, in 1939; see also Bib (100). Copper minerals, chiefly chalcopyrite, occur in fracture planes and disseminated in quartz monzonite, also to a lesser extent in adjacent diorite and rhyolite, and form a large orebody mined by open pit. Deposit was overlain by an oxidized zone from which 17 000 000 tons of carbonate ores, averaging 1.38% Cu, were mined and treated by leaching. Operations now confined to underlying sulphide ores. Orebody is about 4 800 ft long and 2 700 ft wide; aver original thickness, 425 ft; max thickness about 1 000 ft; it pitches under waste covering at one end, where pit limits are determined by economic depth of stripping. Ore reserves at Jan 1, 1937, were estimated from the pit layout then planned as approx 155 000 000 tons, averaging about 1% Cu; added tonnage lies outside of pit limits. Much of the ore area is hard and siliceous, breaking into large boulders; overburden generally softer than ore

Exploration involved 270 diamond-drill and 15 churn-drill holes, totalling 146 569 ft (Art 10-b). Mining carbonate capping involved removal of 3 mineralized hills; elevations, 115–165 ft above general surface. These were mined in a single lift (without benches). Banks higher than 45 ft were broken by "coyote" or tunnel blasting; lower banks, by churn and air drills. Ore was loaded by steam shovels into 20-cu yd air-dump cars and hauled by steam locos to crushing plant; aver haul, 1 mile. After carbonate hills had been leveled, remainder of oxidized ore was mined by 30-ft benches. Mining sulphides. Fig 678 shows lay-out of present pit. Entry is through an approach cut starting 2 000 ft from the crushing plant, and roughly paralleling the E side of pit; track in bottom of approach is on 2% adverse grade. Near entrance, branch lines extend E to waste dumps. At Jan 1,

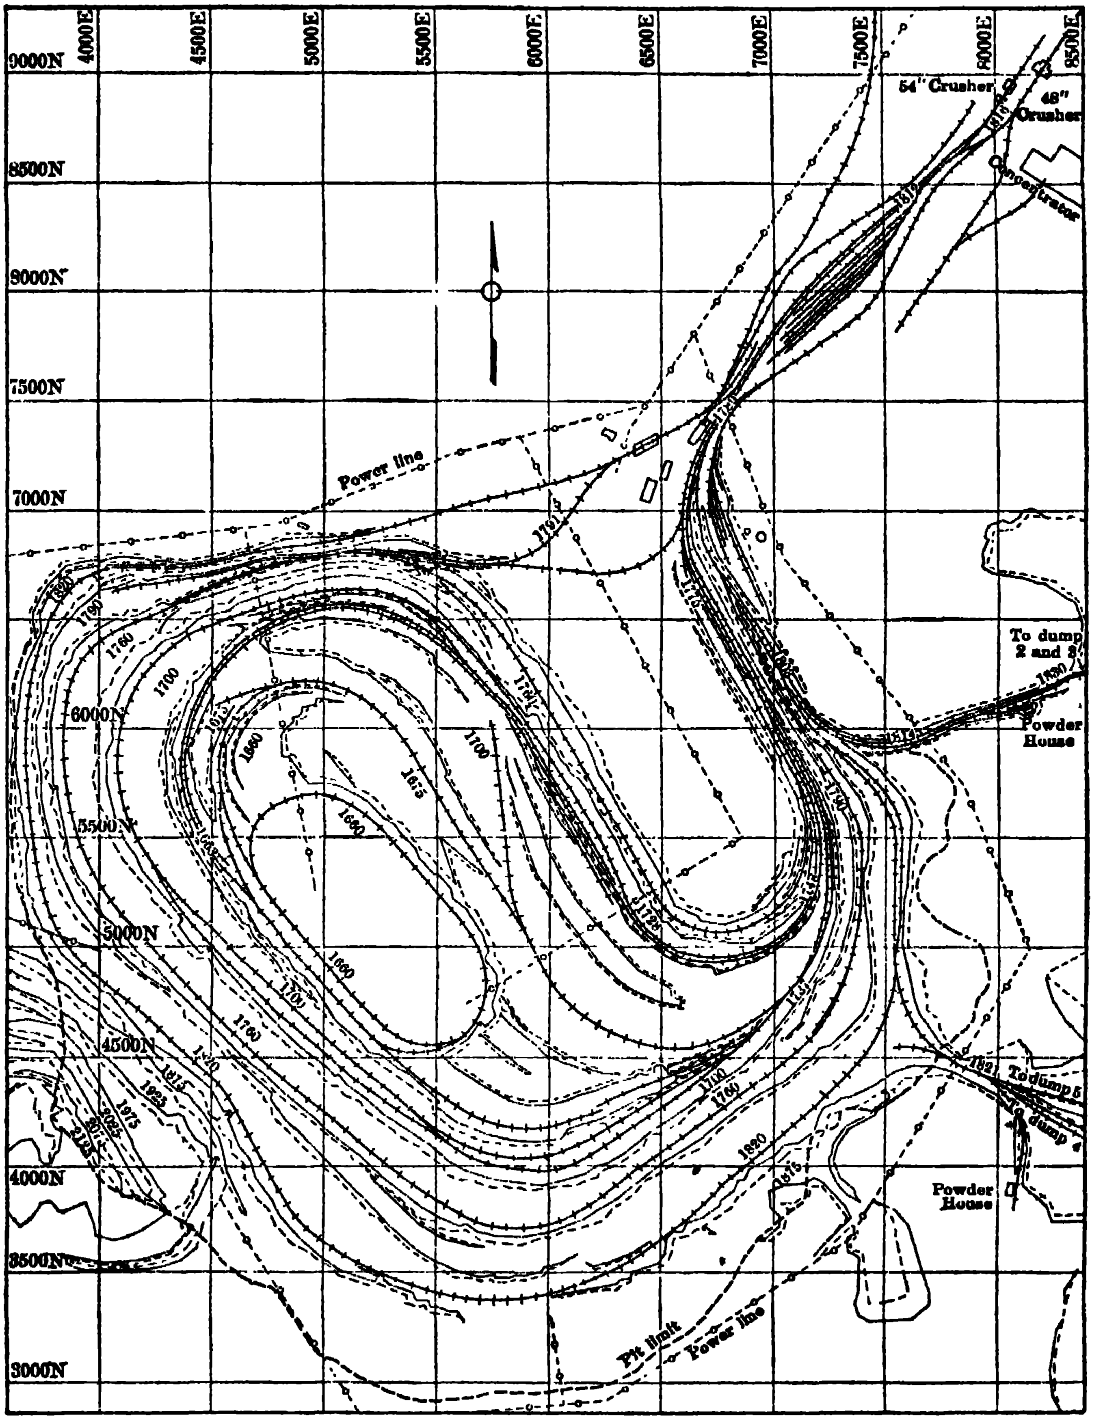

Fig 678. New Cornelia Open-pit, Ajo, Ariz, as of Jan 1, 1939

1939, bottom of pit was 465 ft below topmost level, and 175 ft below aver elev of the rim. Aver height of banks, 50 ft. Bench tracks are kept level and make a complete loop within the pit; 5% grade is used on ramps; 90-lb rail on approach and 70- and 90-lb on pit tracks. Drilling and blasting. Primary drilling is chiefly with elec churn drills; in 1938 about 80% of ground broken was thus drilled. Wagon-type air drills are used where depth of hole is less than 20 ft; where topography is too rough for them, air drills are suspended from tripods. Churn drills use 9-in bits. Fig 679 shows arrangement of holes, drilled to 5 ft below grade. They are column-loaded and detonated with Primacord. Bottom charge is 40% gelatin dynamite in 6 by 8-in cartridges; charge in the column, 60% granular powder. Amount of ground broken per blast is 1 000–400 000 tons; aver about 40 000. Wagon drills have 4-in pistons, and use 1 1/4-in round steel, with 4-ft changes. Same machine, with special mounting, is used for hard toe holes. Air-drill holes for primary blasting are chambered with 60% gelatin; final loading, except in wet holes, is with granular powder of 60% or 70%. Cuttings from all holes are sampled for grade control. Loading and hauling.

Air-drill maintenance	1	Drill sharpening shop as follows: 3 bit grinders with low-press exhaust system 3 elec tempering furnaces 1 pot and crucible furnace; fuel oil 1 oil tempering bath 1 salt bath 1 threading machine 1 bit sharpener 1 power hacksaw 5 air compressors
Blasting equipment	2	Powderhouses

Ore and waste are loaded by 4.5-cu yd elec shovels into 20- and 30-cu yd side-dump cars, hauled to the coarse crushing plant by oil-fired steam locos. Stripping on upper benches is facilitated by 22-cu yd dump trucks. Bulldozers are used to build ramps and roadways, to clear areas for drills to operate, and to grade benches for laying tracks. EQUIPMENT. Table 78 lists main items in use in 1938; OPERATING DATA are shown in Table 79. From the beginning of operation to Jan 1, 1939, a total of approx 55 000 000 tons of ore (carbonate and sulphide) and 30 000 000 tons of waste had been mined. Production in 1938 was 4 974 893 tons ore and 5 825 004 tons waste.

Arkansas Mountain stripping. Overburden is being stripped from a hill at S W side of the New Cornelia pit, with elec shoveling and truck haulage. The steep slopes and limited space for tracks prevented rail haulage, and the short haul to available dumping space was favorable for truck haulage. Shoveling started Mch, 1937, and to Jan 1, 1939, approx 3 000 000 tons were stripped. A 4.5-cu yd elec shovel, and 4 22-cu yd dump trucks were used. Benches were at 50-ft vert intervals, progressing upwards from bottom of the slope to top level, 300 ft above uppermost level in main pit. These levels are now being worked back to their final limits, by progressing from the topmost downwards. The shovels, trucks, drills, and other equipment were shifted over ramps with grades up to 28%. Air drills were used on the steep slopes; churn drills, when the benches were established.

Morenci, Ariz (Phelps Dodge Corp). W. C. Lawson in 1938 described the preliminary stripping operations begun in 1934 (668). Orebody is a large, low-grade deposit of copper minerals, chiefly chalcocite, disseminated in porphyry. Exploration by diamond drilling and underground openings indicated total reserve of 284 000 000 tons, assaying 1.036% Cu, with small amounts of Au and Ag. Pit limits are planned to extract 230 000 000 tons, having 1.06% Cu; reduction from the total represents establishment of grade cut-off limits, excluding portions of orebody carrying high stripping ratios. Aver thickness of capping, 216 ft; max, 500 ft; estimated stripping ratio, 1.04 ton of waste to 1 of ore. Ultimate pit depth of 1 300 ft, below highest point of capping, and over-all slopes of 45° are planned. Character of capping varies, but drilling conditions are generally good, though occasional ribs of high-quartz material break with difficulty. GENERAL PLAN comprises uncovering an area nearest the millsite, and developing the pit for rail haulage, including switchbacks to upper benches and waste dumps and roadbeds to the mill, $3^1/_3$ miles by rail from the pit (Fig 680). Banks will be 50 ft high, with 100-ft bench widths.

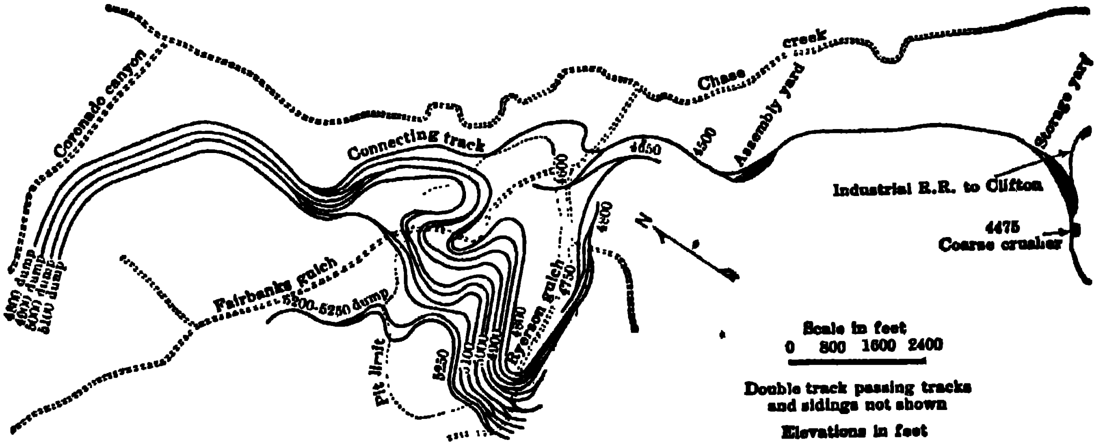

Fig 680. Layout of Pit, Morenci, Ariz

For many years, grades for both ore and waste haulage will be favorable. Aver haul between pit and assembly yard will be about 2 miles; from the yard, haul to crushing plant will be $1^1/_3$ miles, on 0.4% grade. Upper benches will be reached by 4 switchbacks over a ruling grade of 4%; tracks to main dumps, on 0.2% grade. About half of total stripping will move in direction opposite to ore movement; remainder will go to dumps over same tracks as ore. Longest waste haul, about 3 miles. Extreme roughness of topography led to choice of automobile trucks for haulage during preliminary stripping. Trucks proved highly flexible, disposing of waste in canyons to be crossed by rail. PREPARATION. First work was building about 6 miles of service and truck-haulage roads. About 75% of all roads required drilling hillside slopes with large jackhammers suspended from tripods with block and tackle. Drills were chucked for 1.25-in round steel; all holes drilled dry, with detachable bits. Some through-cuts were made with a 1-cu yd Diesel shovel, and 5-cu yd trucks with wheel-base of only 121 in, permitting short-radius turns. Other preparatory work included extension of water, air, and power lines to pit, building shops, and grading for a new townsite. DRILLING AND BLASTING. For all primary drilling in stripping, elec churn drills with 9-in bits are standard. Holes are drilled 8–10 ft below grade and column-loaded with bag powder, with 1 case of gelatin in each hole as a primer, detonated by Cordeau or Primacord. Easily accessible holes are stemmed with mill tailings, using 1 line of wire-bound fuse; other holes are stemmed with rock screenings, using 2 lines of double-countered fuse, because the coarser stemming may injure the fuse. Aver advance per churn-drill shift, 85 ft. Drill bits aver 55 ft per sharpening. In blacksmith shop, 3 men with mechanical sharpener can sharpen and temper 22 bits per 8 hr. LOADING. In 1938, 4 full-revolving, Ward-Leonard control, elec shovels were in service; 3 had 4.5-cu yd, manganese-steel dippers; the fourth, a 5.5-cu yd, alloy-steel dipper, which weighed, plus full load, less than the loaded 4.5-cu yd dipper. Shovels receive power at 2 300 v through trail cable. Automatic water sprays are located ahead of the shovel to control dust. During first few months of 1938, about 5 000 tons were loaded per 8-hr shovel-shift. On a 2-shift basis, delays to shovels in waiting for trucks and in repairs were only 8% of total possible loading time. Power consumption averaged 0.186 kw-hr per ton loaded. HAULAGE. Equipment (1938) consists of 18 22.5-cu yd, end-dump, 6-wheeled, gasolene trucks, each of the 4 rear wheels having 2 13.5 by 24-in pneumatic tires; pay load, about 35 tons. Bench widths permit a truck to be spotted on each side of shovel; this minimizes arc of shovel swing, and an empty can be backed into position while shovel is loading truck on opposite side. A bulldozer at each shovel keeps surface smooth. Aver haul (1938) is 0.6 mile; max, 1 mile. On favorable roads, grades to 15% can be negotiated at very slow speed; max grade of 10% is set where possible; for long stretches, 6 or 7% grade is preferable. Top speed on slightly favorable or level grades, loaded or empty, is 15 miles per hr. Sprinkler trucks control dust on roads. While mining is suspended on "graveyard" shift, half the trucks go to repair shop for servicing; hence, each truck is serviced after 32 hr operation. There is a complete tire-repair shop, including vulcanizing equipment. Delivery of gasolene to trucks and incidental servicing is by a specially designed truck, the carrying tank of which is divided into 2 compts for gasolene and Diesel fuel oil; greasing equipment and a small gasolene-driven compressor are attached to the truck frame. When length of haul one way is 1 mile and a shovel is loading 5 000 tons in 8 hr, 10 trucks are needed for uninterrupted work. COSTS. During first 5 mo of 1938, cost of operating a 4.5-cu yd elec shovel per 8 hr, including maintenance, was $52.81; of a 22.5-cu yd truck, including road maintenance, $31; bulldozer, $22.32; churn drill, $30.75. Cost of truck haulage per ton was 3.8¢; per ton-mile, 6.1¢, distributed as follows: maintenance, 32%; tires, 21%; driver, 19%; gasolene, 14%; road maintenance, 10%; misc, 4%. Above costs are on basis of new equipment and relatively short period of operation.

Chile Exploration Co (Anaconda), Chuquicamata, Chile. Data from W. D. B. Motter, Jr, in 1939. Orebody, comprising a mineralized shear-zone in granodiorite, is the world's largest known copper deposit; developed for a length of 1.85 mile, with max width of 3 300 ft. Antlerite (formerly referred to as brochantite), kröhnkite, and chalcanthite are chief minerals of oxidized zone, below which lies, first, a zone of mixed oxide and sulphide copper minerals, and, deeper, a body of sulphide ore. In 1935, a preliminary estimate indicated reserves of approx 360 000 000 tons of oxidized ore, aver 1.75% Cu; 100 000 000 tons of mixed oxides and sulphides, aver 2.87% Cu; and 575 000 000 tons of sulphide ore, aver 2.27% Cu; total, 1 035 000 000 tons, aver 2.15% Cu. Some areas are overlain by waste capping. Ore is moderately hard and, due to soft mineralized seams, breaks coarsely in blasting; gyratories at coarse-crushing plant have 60-in openings, thus reducing block-holing in the pit. Topography permits long working faces, for many shovels and ore trains. In Jan, 1939, 15 benches had been opened and 11 were being worked, with 13.6 miles of bench faces. Upper benches are 37–64 ft high; lower benches, all 40 ft. The pit has produced as much as 59 142 tons of ore and 33 510 tons of waste in 3 8-hr shifts. PIT EQUIPMENT comprises (Mar, 1939): two 8-cu yd full-revolving elec shovels on R R trucks, one mainly for development, the other held in reserve; six 4-cu yd caterpillar elec shovels; six 4-cu yd

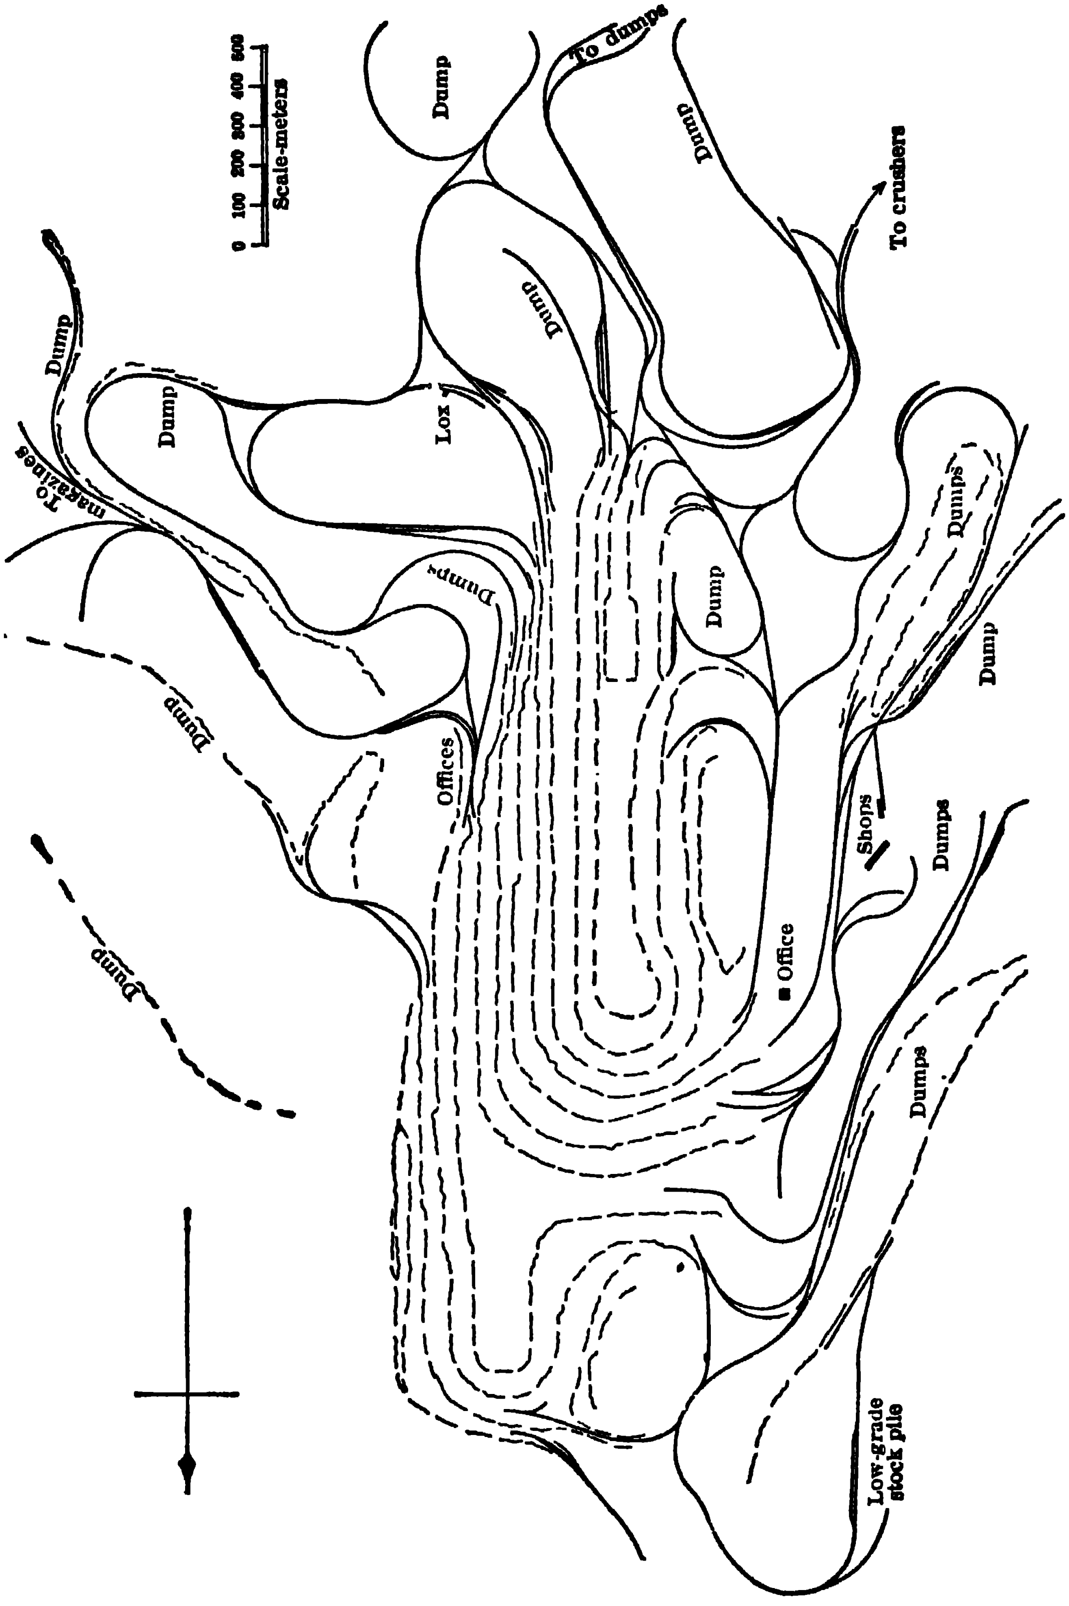

Fig 681. Plan of Open-pit, Chuquicamata, Chile, at Jan 1, 1939 (RR trackage on benches omitted)

R R-type caterpillar elec shovels (all of the above, except one 8-yd shovel, are Ward-Leonard control); seven 4-cu yd R R-type caterpillar elec shovels with a-c motors; total, 21 shovels, all equipped with cable-drums for spotting cars while loading, thus relieving the locos; three 0.75-yd Diesel shovels on caterpillars for misc clean-up work; 2 road graders; 3

Nordberg track shifters; 93 Cyclone elec churn drills; one 29-T Bucyrus-Erie drill; 19 elec locos, 75–87 tons, combination cable-reel, third-rail, and some with trolley (operating on third-rail on main lines only and with cable on benches and waste dumps); 15 steam locos, 85–91-tons; 460 70-ton steel ore cars, dumping in a rotary dumper; 32 30-cu yd and 80 20-cu yd air-dump waste cars; 5 steam cranes 15–120-ton capac, 4 of which are self-propelling; one 45-ton all-elec self-propelling crane; 14 flat cars; dropped-center cars for transporting small shovels and drills; 1 steam spreader plow. As of Jan, 1939, there are 58.8 miles of std-gage R R track, of which 38.7 miles are electrified.

General pit operations. All benches but the first are on level grades. In general, approach tracks (Fig 681) have a max compensated gradient of 3%; 100-lb rail on main lines and approach tracks, and 80-lb on benches. On approach tracks the max curvature is held to 10°, and on bench tracks to 20°. The 40-ft height for benches in lower part of the mine was adopted because an 8-yd shovel with a 90-ft boom can readily load into cars spotted on the bench above; such shovels are used for opening new benches. The min width of bench, of 3 times height of face, reduces interruptions to traffic when blasting. It is now planned to carry the pit depth to about 200 ft below the outlet, before changing to underground mining, but this point will not be reached for many years and the pit may be continued much deeper. Unusual features of operation at Chuquicamata are the method of spotting cars at the shovels by drum and cable mounted on the shovel, and the use of LOX explosive, as described below.

Breaking ground. During early operations, tunnel blasting was found the best method, because upper horizons were honeycombed with old underground workings. Churn-drill holes are now used exclusively. The older rigs drill an aver of 46 ft of 8-in hole per 8 hr. Modern rig drills 88 ft of 8-in hole, or 56 ft of 10.5-in hole, per 8 hr; the latter size is being tested (1939) to replace 8-in holes. Gill bits are used, drilling an aver of 35 ft between sharpenings. Holes are cased at collar, and are column-loaded with split or deck charges. Single blasts may break 70 000–150 000 tons or more; 60% free-running ammonia dynamite is used. LOX (liquid-oxygen explosive) has been largely used since 1926, breaking more than 22 000 000 tons; it is cheaper, more effective, and somewhat safer than dynamite. In Jan, 1937, a premature explosion of black powder occurred; its use was thereupon permanently abandoned. Due to the fact that LOX also is inflammable, its use was suspended until it could be rendered non-inflammable. Experiments sponsored by Chile Exploration Co and conducted by U S Bur of Mines have succeeded in producing a non-inflammable LOX. Carbonized lignin residue, packed in canvas bags, is the absorbent; rendered non-inflammable by addition of moisture and phosphoric acid, and the canvas is fireproofed by diammonium phosphate. The volumetric effectiveness of LOX is reduced about 5% by this treatment, still leaving it more effective, on the weight basis,

Table 81. Operating Data, Chile Exploration Co, Chuquicamata, Chile

	1937	1938
Tons ore mined	13 761 262	11 605 569
Tons waste removed	8 690 366	6 333 430
Total tons material moved	22 451 628	17 938 999
Stripping ratio, waste to ore	0.631	0.546
Aver daily tonnage, all material	69 931	58 030
Tons moved per lb explosive	2.79	2.83
Tons moved per man-shift (incl employees and labor—shops and all outside labor)	24.45	21.98
Aver tons (dry) loaded per shovel-shift:		
Ore	2 331	2 588
Waste	2 052	2 595
Average (weighted)	2 213	2 590
Electric power consumption per ton material (ore and waste) moved, kw-hr per ton:		
Electric shovels	0.355	0.333
Electric locomotives*	*0.419	*0.537
Electric drills	0.046	0.047
Compressors	0.193	0.197
Shops	0.032	0.038
Miscellaneous	0.067	0.071
Total	1.112	1.223
Aver ore haul, miles	2.96	2.52
Aver waste haul, miles	1.73	1.69
Ton-miles per kw-hr	4.60	3.63

* Some material handled by steam locos; consumption by electric locos alone was, in the respective years, 0.523 and 0.592 kw-hr.

than the 60% dynamite. Substitution of LOX for dynamite entails no change in depth, chambering, or spacing of drill holes, but an 8 $^5/_8$ or 10 $^1/_2$-in hole is better for LOX than an 8-in, to concentrate this less dense explosive at the bottom. The Co makes its own liquid oxygen in a plant with a capac of 250 liters per hr. LOX blasts are fired within 1 hr after beginning charging. All blasts, except secondary shots, are detonated with Primacord, which has replaced Cordeau. Considering a typical single-row blast (multiple rows are occasionally used) in a 40-ft bank, 8-in holes would be spaced 13 ft c–c, 23 ft back from toe of bank or about 6 ft from the rim, resulting in a burden of 850 tons per hole; with 20% overbreak, the broken ground is 1 020 tons per hole. For data on earlier practice at Chuquicamata, see Bib (638).

Flin Flon open-cut. Data from M. A. Roche (669) in 1933 and 1935. Orebody is a steeply dipping lens of hard pyrite, banded with greenstone ledges and fringed on one side by softer disseminated ore. Outcrop is 2 600 ft long and 450 ft wide at middle, tapering out completely at ends. All but about 600 ft at its mid-length lay under 12–15 ft of water (an arm of Flin Flon Lake) and 15–90 ft (aver 20 ft) of mud and clay. After building 2 dams from shores to a conveniently situated island, an area enclosing all the submerged outcrop was emptied of about 4 million gal in 3 mos by 2 Morris 10-in dredging pumps, against aver head of 50 ft; mud and part of the clay was dragged to the pumps by 3 V-scrapers with 35-hp slusher hoists, aided by high-press water jets. Another scraper handled boulders. In 3 summer seasons, 789 300 tons of material were thus removed, costing 15¢ per ton; remaining 288 500 tons of bottom clay was removed later by power shovels and Shay loco. Only the upper 300 ft of orebody will be mined by open-cut (see Art 43 for underground methods), involving about 1 000 000 tons of overburden, 5 000 000 tons of ore, and 2 000 000 tons of waste rock. In late 1933, the pit was 150 ft deep and 1 300 ft long; approached by through cut on 6% grade from narrow north end, track being laid on hanging-wall (greenstone), with switchbacks near opposite schistose wall. BREAKING GROUND. During 3 yr, 8 No 29 Armstrong elec drills (550-v, a-c), caterpillar mounted, averaged 15–17 ft of 6-in hole per 10-hr drill-shift, mainly in hard sulphide and greenstone. Holes, usually 50 ft or deeper, to about 5 ft below grade, are 16–20 ft apart, and staggered in rows 20 ft apart; first row about 20 ft from edge. They are chambered by successive charges of 50% gelatin, stemmed with water; then loaded with about 700 lb gelatin in 5 by 16-in cartridges, to about 20 ft from bottom, and stemmed with 10 ft of sand; above this, a "deck" charge about 15 ft high is confined by sand to top of hole. Owing to conductivity of sulphides if in contact with wires, a defective circuit can not be detected by galvanometer; enameled lead wires are therefore laid into grooves along opposite edges of a wooden strip and taped in place; primers are also attached to this stick. Besides the main blast holes, a row of unchambered rim holes, spaced 5–10 ft, is loaded with alternating top and bottom charges only sufficient to break hole to hole. As much track must be moved before blasting in this narrow pit, large blasts are made at long intervals; the ore is also better broken by firing many holes simultaneously. In a blast of Nov 23, 1932, 639 holes, averaging 44.43 ft deep (which took 1 930 8-hr rig-shifts to drill and 16 050 lb explosive to chamber) and containing 239 650 lb of 50% gelatin, broke 443 153 tons, of which 292 484 tons were ore. Blast of Sep 13, 1933, broke an area 700 ft long by 150 ft wide with 232 main holes and 175 rim holes (aver 30 ft deep) along foot and hanging walls, affording 471 980 tons of ore and 33 613 tons of waste; explosive (50% gelatin), 15 850 lb for chambering and 246 000 lb in blast. Aver consumption of explosive since beginning this work has been 0.351 lb per ton broken, incl 0.031 lb for chambering. LOADING AND HAULING. Each of 2 Marion 4 160 elec, 150-ton, full-revolving, caterpillar-mounted shovels, with 4-yd dippers and 29.5-ft booms, loads 1 000–1 500 tons in 10 hr, dumping 20 ft above grade with 37-ft reach. Cars (23 in service) are 22.5-yd (60-ton), drop-door, side-dumped by air. Motive power includes 2 General Electric 85-ton locos, and several 20-ton size for spotting. The large locos haul 2 60-ton cars from pit on 6% grade; they have hauled up to 3 000–3 500 tons 2 miles in 10 hr; usual aver is a little over 1 000 tons per loco. When pit reaches its full proposed extent, it will have about 8 000 ft of track (85-lb rail), besides that in yards and waste dumps.

Asbestos mining in Quebec. Data from W. A. Rukeyser (670) in 1932. In scattered places in a long serpentine belt, fractured rock carries chrysotile in seams to max of 3-in width, usually much narrower. Rock containing as little as 2% asbestos has been mined; general aver, 5.25%. Fiber 0.75-in and longer commands premium, and has commonly been hand-sorted for special treatment, remainder going to crushing and separating mills. Where sorting and loading is by hand, requiring rock to be broken small, benches are usually blasted with 10 to 16-ft vert holes, drilled by light hammer drills at cost of 3–17¢ per ton broken; sorted material, incl waste, is shoveled into steel boxes holding 2.5 tons, which are dumped by crane into 10-ton cars, hauled out of pit as described below. Recent trend, induced by diminishing proportion of long fiber and its smaller premium, is towards mechanical loading direct into cars, with only such sorting of waste as a shovel can accomplish. Of rock mined in 1929, 30% was waste compared with 13% in 1919. Power shovels permit heavier blasting with deeper holes and higher benches. Breaking rock. Vert holes 32–40 ft deep (75 ft at one mine), 10–25 ft back from face, and spaced 5 ft or less, are made with heavy hammer drills on portable derricks, starting at 3.375 in, finishing at 1.125 in. Toe holes are drilled by same machines, differently mounted. Lower third of hole is loaded with 75% gelatin; remainder of charge, 30–50 lb of 40% dynamite; about 20 holes are elec fired at a time; some blockholing is needed. Aver break, 8 tons per lb explosive; cost of explosive, 4–7¢ per ton. Loading and hauling. Caterpillar steam shovels with 2.5-yd dippers have been commonest; gradually replaced, since 1929, by elec shovels of same or 4-yd size. Side-dump, 10-ton cars are usual; one large mine has air-dumped, 30-ton cars. In pit bottoms, steam, gas-elec, and elec locos of trolley, battery, and cable-reel types, have all been used. At Jeffrey mine, a circular pit 2 000 ft across and 200 ft deep, developed by spiral benches with 6.5 miles of track, trains of 30-ton cars are hauled by 60-ton elec locos from pit bottom to mill. In smaller and deeper pits, locos deliver cars at bottom of an inclined tunnel, up which the cars are hoisted, 2 at a time, to or near the mill; 3 such tunnels are 967, 1 045, and 1 100 ft long; grades from 10 to 37%. King mine, with a pit 1 200 by 1 000 ft and 400 ft deep, retained suspension cableways (1 400-ft spans) after they had generally been abandoned at other large mines, using them to hoist 10-ton loads hauled into pit from underground shrinkage stopes on 300-ft level. For method of block-caving at King mine, see Art 80.

Gasolene shovels in open-pits. According to W. R. Moorehead (320) New Idria mine, Calif, in 1931 produced daily about 750 tons of low-grade ore (0.085% Hg), in a fractured sandstone with seams of cinnabar, from open-pit workings at outcrop of a steeply dipping lens (max 800 by 180 ft), from which richer portions had previously been extracted; material was dropped through a central raise to grizzly and conveyer belt in adit 200 ft below bottom of pit (Art 91). Hanging-wall stripping was glory-holed through another raise to same adit. Elliptical pit was worked by 2 benches at opposite ends. Dry jackhammers drilled vert holes 15–20 ft deep, spaced 8–15 ft, and 6–12 ft back of crest; after chambering with 40% gelatin, each hole was loaded with 50 lb black powder, primed with gelatin. Of 4 caterpillar-mounted, gasolene shovels, 2 had 1-yd, and 2 had $^3/_8$-yd dippers. They loaded into end-dump auto trucks of 5.25–6.25-ton capac; aver haul, 300 ft. On basis of 21 516 tons in Sep, 1930, unit expenses included, in man-hr per ton: drilling and blasting, 0.343; shoveling, 0.368; trucking, 0.053. Explosives: gelatin (40 and 35%), 0.829 lb; black powder, 0.589 lb. Carson Hill mine, Calif. Data from J. A. Burgess (297) in 1937. Gold ore is mined in 2 outcrop workings on or adjoining the Bull and Calaveras veins. In Union pit a soft schist orebody, 400 by 50–150 ft, is mined in 20-ft benches. Holes 20 ft deep, spaced 8 ft in rows 12 ft apart, are sprung once with 5 sticks of 40% gelatin, then loaded with 50–100 lb black powder, and fired elec, 1 row at a time. Cost for explosives, 2.2¢ per ton. One gasolene shovel with 1-yd dipper loads into 3 3-ton trucks; aver haul to ore-pass, 600–900 ft. Crew, shovel runner, 3 drivers, 1 or 2 drillers, averages 500 tons per day. Calaveras pit is in a long steeply dipping band of soft schist 50–100 ft wide, and has raise connection with underground workings. Vert holes, 20 ft deep, spaced 8 ft in rows 10 ft apart, are drilled from wagon mounting, sprung first with 1 or 2, then 8 or 10, sticks of 40% gelatin dynamite, loaded with 75–100 lb of black powder, and fired elec, 3 rows at a time. Cost for explosives, 6.9¢ per ton. About 1 ton of hanging-wall and other waste is moved for 4 tons of ore.

97. OPEN-CUT MINING WITH DRAGLINE EXCAVATORS

General. For structural details of draglines, see Sec 3, 27. Chief advantages of dragline over the power shovel, in suitable material: (*a*) can dig deeper below its own level; max depth 20–25 ft for small machines with 50-ft booms to 85–125 ft for those with 185–200-ft booms; (*b*) can discharge at higher elev; max dumping height above base of machine, at boom angles of 25°–40°, is 25 ft for small, to 100 ft for largest draglines; aver for most draglines is 30–40 ft, with booms from 65 to 110 ft; (*c*) longer reach for both digging and dumping; max dumping radius, at lowest position of boom, may slightly exceed boom length (due to momentum of loaded bucket), but is usually 5–10 ft less than boom length on medium-size draglines; max digging radius exceeds dumping radius by 13–15 ft with the smallest, to 50 ft with the largest draglines, and depends upon operator's skill in "throwing" the bucket; this added distance is $^1/_3$–$^1/_2$ the dumping height. Compared with shovels, chief deficiencies of the dragline are: (*a*) except in easy digging (Table 82), bucket load is 5–10% less than that of a shovel dipper of same capac, due to lack of "crowding" effect; (*b*) loads can not be so accurately discharged into a vehicle; hence a hopper or chute is usual for such loading (for exception, see Shiras pit, below); (*c*) bucket effic (% of capac actually filled) diminishes more rapidly with less suitable material (Table 82), and almost disappears in materials offering only slight difficulty to a shovel; (*d*) dragline works to less advantage on rough footwall or bedrock, and does a poorer job in cleaning up corners; (*e*) less selectivity is possible, unless the valuable and worthless portions of a deposit are stratified or clearly segregated. Widest fields for draglines thus appear to be: (*a*) stripping wide areas over fairly level deposits, as coal, phosphate beds, iron ores like those of the Mesabi Range, and where the overburden requires no added transport; (*b*) mining soft ores in wide and shallow bodies fairly uniform in composition and free from irregularities in structure. For special applications to coal stripping, see Art 100.

Bucket effic of draglines varies with nature of material, and depends chiefly upon percentage of voids in the load. Table 82 gives a classification according to suitability for draglining, and the effic factor applicable to each class. In very easy digging, as the overburden of Fla phosphate deposits (Art 98), the factor may reach 108%, due to heaping the loads. When working under water (see Art 129), the factor will be less than with dry material, due to spillage.

Table 82. Bucket Efficiencies* of Draglines in Various Materials

Easy digging factor, 95–100%	Medium digging factor, 80–90%	Medium-hard digging factor, 65–75%	Hard digging factor, 40–65%
Sand and small gravel, dry or moist Loam and loose earth Muck Sandy clay Loose clay-gravel Cinders and ashes Bituminous coal Well loosened material	Materials not hard to dig without blasting, but breaking with large voids Clay, wet or dry Coarse gravel Clay-gravel, packed Packed earth Anthracite	Materials requiring light blasting; bulky and not easily penetrated by bucket Well broken limestone, sandstone, shale, etc Ores not massive in character Heavy, wet, sticky clay Gravel with large boulders Cemented gravel	Blasted rock with large voids, difficult to enter Hard, tough shale All hard rocks "Caliche" Mixtures of coarse and fine broken material Tough, rubbery clay which shaves from bank

* % of bucket capacity actually filled

Power requirements. Bucyrus-Erie Co states that elec draglines with Ward-Leonard control require 0.40–0.75 kw-hr per cu yd, on machines of all types and sizes. On those driven by a-c motors, consumption is 0.30–0 85 kw-hr per cu yd, highest for the largest draglines. Table 83 gives consumption of fuel and lubricant by Diesel-driven draglines of the walking type.

Table 83. Oil Consumption of Walking-type Draglines Operated by Diesels

Boom ft	Bucket cu yd	Engine cylinders		Fuel oil, gal per hr	Lubric oil, gal per hr
		No	size, in		
60 70	2 1 1/2	2	12×15	3.5–5.5	0.07
60 70 80	3 1/2 3 2 1/2	2	14×17	5–7	0.10
80 90	2 1/2 2	5	8 3/4×10 1/2	7–9	0.12

165 185 200	11 9 8	5	14×17	15–20	0.26

Mayarí iron mines, Cuba (54). See Art 10-a for ore occurrence. The large area of orebodies, their softness, and freedom from overburden, favor use of mechanical excavators. Draglines are used for ore 20 ft thick or less, when both surface and bedrock are irregular; steam shovels, tried first, could not clean bedrock without digging it up, and their small radius of action necessitated frequent moves. In 1916, 2 draglines, with 2-cu yd Page buckets, handled 1 000 tons per day (1 shift) (346). The excavator worked from the original surface, the bucket swung in a radius of 60 ft and readily removed all ore to bedrock for a width of about 100 ft; projecting hummocks of bedrock, stumps, etc, were discarded. Ore was loaded into 50-ton, side-dump, steel cars, on tracks on surface. Crew: 1 operator, 1 fireman and 3 pitmen.

Balkan mine, Menominee Range, Mich. Data from C. E. Lawrence in 1915 (347). Draglines were used for stripping and mining a hematite deposit overlain by swamp, quicksand, clay, hardpan, and boulder gravel. Before beginning work a stream crossing the property was diverted, and a shaft sunk outside the deposit, with drifts and raises for draining the overburden. Fig 682 shows the pit, about 1 150 ft long by 900 ft wide; the spiral tracks (Art 96) had a grade of 2.6%; depth of stripping, 60 to 108 ft. Slopes

of banks were 2 : 1 in fine sand near surface, and 1 : 1 in underlying gravel and clay; slopes could have been steeper in dry material. The stripping (1.2 million cu yd) was contracted. Two draglines had 85-ft booms, 4-cu yd buckets, and 24-ft turntables; they were mounted on hardwood rollers, running on 4-in plank; working wt, 150 tons. Output per machine, 2 000 cu yd per 10 hr. loaded through a hopper into 4-cu yd Western dump cars; 15-ton locomotives hauled 10-car trains 0.5 mile to a dump. Height of bench taken in one cut was limited to 30 ft by the flat angle of repose of the soft material. At a depth of 60 ft, some clay banks began to cave, which was stopped by dressing them with evergreen boughs or pit gravel. After cleaning the surface of the ore, the banks were protected by gravel-filled cribs; water was kept out by a ditch in ore completely around the workings; a 20-ft berm was left to maintain the ditch and cribbing. The excavators then mined the ore, which was first shaken up by blasting with 20 to 30-ft churn-drill holes. The 2 machines loaded about 5 000 tons per day. Draglines were adopted chiefly because of the wet, mushy overburden, which would not support a steam shovel in the pit bottom; they worked successfully in the ore also, which was medium hard.

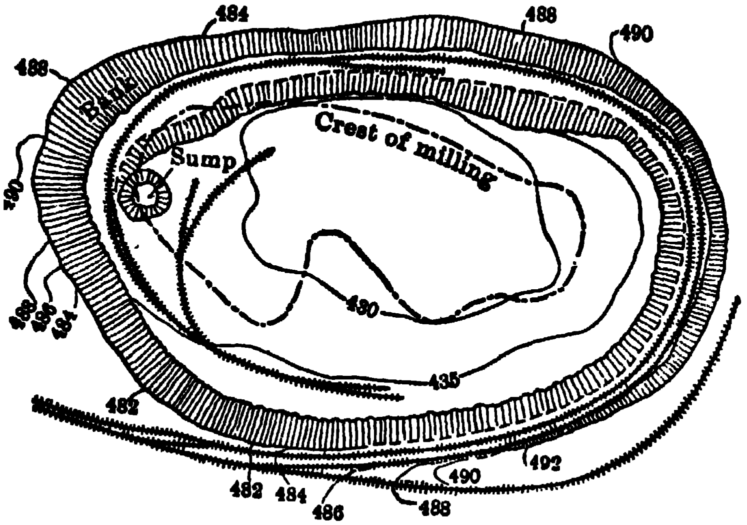

Fig 682. Balkan Mine Pit, Mich

Shiras pit, Mesabi Range, Buhl, Minn. According to E. E. Hunner (660) a revolving elec shovel equipped as dragline (Sec 27), with 150-ft boom and 5-cu yd Page bucket, was used to strip and remove ore from a long, narrow, irregular orebody. Overburden, 25–30 ft deep; ore, 40 ft deep, 125–200 ft wide, 1 500 ft long. Starting at one end, the dragline advanced on surface along one side, overcasting spoil from about 2/3 proposed width of pit; on return along other side, remaining 1/3 was similarly overcast, except what was needed for grading a loading track along edge of pit; same machine, moved to pit bottom, then loaded ore into 50- and 75-ton cars on this track, with lift of 80 ft from bottom of ore to top of car. Crew, excluding rock pickers: 1 operator, 1 oiler, 1 pitman, 2 car trimmers and brakemen. Aver output, 1 250 tons per 10-hr day.

Cuban Mining Co, Cristo, Oriente Prov, Cuba. Data contributed in 1939 by F. S. Norcross, Jr, Gen Mgr. The orebody, which occurs as a persistent bed of manganese oxides of variable thickness, is overlain by 2–40 ft of tuffs, covered in turn by argillaceous limestone. General dip of the formations is 14° N, but with steep asymmetrical folds, and normal and reverse faults with throws to 40 ft. Principal working mine is an open pit, now 2 600 ft long by 1 000 ft wide (Fig 683). Orebody outcrops to S, and dips under heavy overburden to N W. Original STRIPPING was done by train haulage; now generally superseded by the dragline. Overburden now being removed is chiefly along the N and W boundaries of the pit, where stripping may reach a depth of 120 ft, with a Bucyrus-Monighan walking dragline having a 4-cu yd bucket and 120-ft boom. To early 1939, this machine has removed 90 ft of overburden along N wall and stacked the waste in a 55-ft bank (Fig 683). To provide dump area for deeper cuts, the previous spoil will be moved back by dragline recasting or a tower cableway, making a final bank say 600 ft wide and 55 ft high. At a depth of 90 ft, pit slopes are 1 : 1 in the limestone series and 1 : 1.2 in the softer tuffs. The overburden requires little blasting; where necessary, 5 20-ft jackhammer holes are shot with 40–60% dynamite. Operating data for the dragline per 8-hr shift are: output, 1 000 cu yd when digging overburden to 90-ft depth, 1 500 cu yd when recasting an average of 200 ft back; crew, 1 operator, 1 oiler, 2 pitmen; power consumption, 500 kw-hr; maintenance and repairs, $6. Secondary stripping inside of pit limits, or where overburden is shallow, is done by a 2.25-cu yd dragline, casting into adjacent mined areas. ORE PRODUCTION (1 000 to 2 000 tons per 8-hr shift) is handled by a 2-cu yd shovel and a 2.25-cu yd dragline with 60-ft boom. The 2 units work in combination so as: (1) to maintain aver grade by mixing ores; (2) to adapt advantages of each machine to the varying conditions. The shovel is used where the ore lies quite flat; it can dig harder ore (thus saving in blasting) than the dragline, which is used in irregular areas due to its greater flexibility and reach. Ratio of shovel to dragline tonnage varies between about the limits of 2 : 1 and 1 : 2, depending on extraction areas. Ore is blasted with lines of 2-in holes (to 22 ft depth) drilled by jackhammers using chisel bits. The holes are shot with

60% dynamite or *rompe roca*, depending on hardness of ore. Ore is hauled 1.3 miles to mill in 4-cu yd dump cars. Gear-driven steam locos pull 9-car trains. Temporary pit tracks have grades to 6%; main entrance track to pit, a 4% grade. Operating data per 8-hr shift: for 2-cu yd shovel; aver output, 600 tons; power consumption, 470 kw-hr; maintenance and repairs, $7; for the dragline, aver 500 tons; power consumption, 480 kw-hr; maintenance and repairs, $5.

Stripping coal with draglines having buckets to 12-cu yd capac has been successful in the Middle West, although most work is still done by shovels, with dippers to 35-cu yd capac. Draglines have also replaced shovels at many anthracite strippings, especially on pitching outcrops. For stripping both kinds of coal, see Art 100.

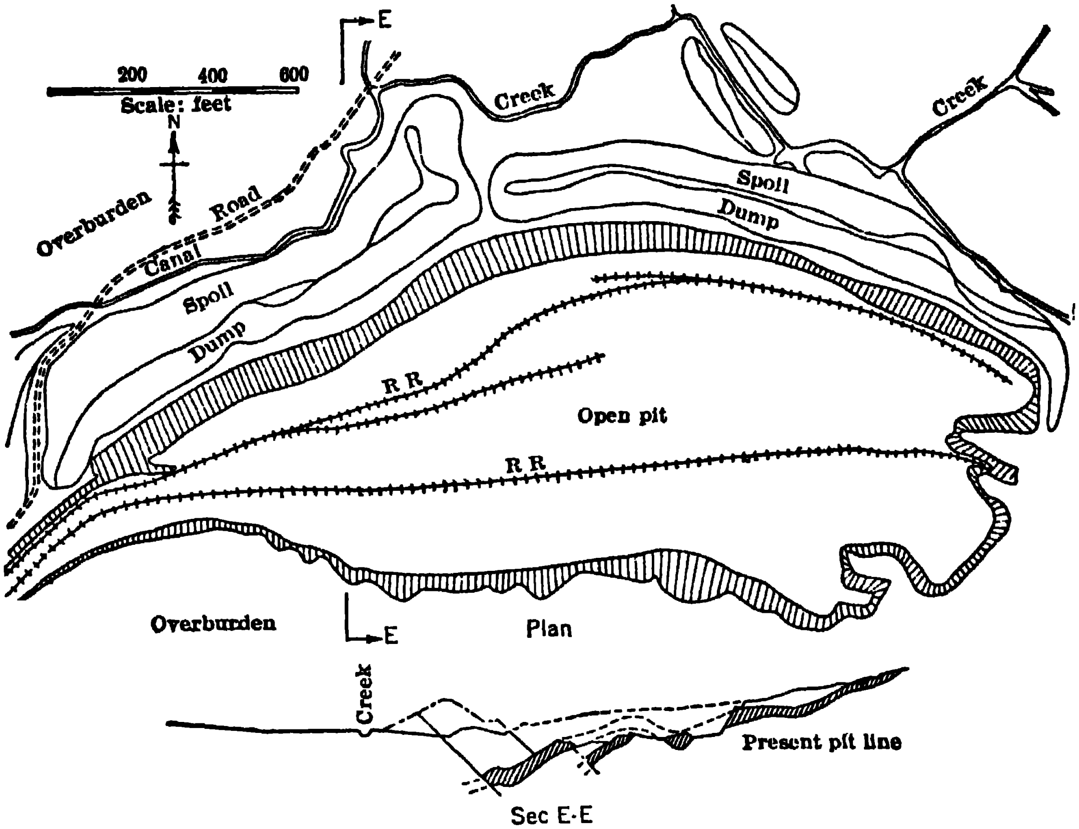

Fig 683. Open-pit Mining with Dragline, Cristo, Cuba

Tennessee brown phosphate. Data from P. M. Tyler and H. R. Mosley (338) in 1939. For prospecting, see Art 6, 10-a. "Brown rock," the most productive of phosphates mined in Tenn, is an enriched residual product from weathering of nearly horiz beds of phosphatic limestone. In the bed of clay matrix, 2–20 ft or more thick, phosphate occurs in platy slabs, to 24 in thick, and in lumps and grains down to microscopic size. Overburden of clay and low-grade matrix ranges to 20 ft or more, with few boulders. Where matrix is rich, 6 ft of overburden is profitably removed per ft of matrix; for lower-grade deposits, ratio is 3 : 1. Irregular pinnacles of unweathered rock sometimes project to surface; or, weathering enrichment may follow deeply into the original rock along joint planes. Under these conditions, considerable hand mining is entailed. In early days of hand mining exclusively, pieces smaller than about 1 in were discarded; now, with washers and flotation process, overall recovery from a matrix carrying 50–60% bone phosphate is 70–85% of phosphate content. Most STRIPPING AND MINING is now done by draglines of 1.5–4-yd capac, with 45 to 115-ft booms; shovels proved unsuitable (due to short reach) and all hydraulicking has been abandoned. Except where bedrock is fairly even, the smaller scrapers are best. Caterpillar mounting is commonest, but "walking" draglines are being introduced. A cut is usually made across the minable area, the excavator standing on the stripped matrix and loading cars on the same level or on bedrock, if it is fairly even. Stripping from next adjacent cut is then dropped into the space previously occupied by matrix. When hand work is required around pinnacles or in bedrock cavities, the material may be shoveled into steel boxes to be picked up and emptied by the excavator, but it is usually thrown into piles within reach of the scraper. HAULAGE is usually by 4-yd (3.75 dry long ton) Western side-dump cars, in trains of 12–20, hauled by coal-fired locos. At one important mine, producing 2 grades of matrix for delivery to different destinations, bottom-dump, 12-yd (12-ton) tractor trucks, on 18 by 24-in tires, have proved suitable; they are loaded by 4-yd walking dragline, standing at top of bank. COSTS. Mechanization of Tenn mines has been less rapid than in the larger deposits in Florida (Art 98) but is now nearly complete. Output of

phosphate per man-yr was 575 tons in 1937, 543 tons in 1929, 312 tons in 1919, and 207 tons in 1909, by which year the richer, hand-worked deposits were largely exhausted. Costs vary widely, even at the same plant; following ranges, per dry long ton of cleaned product (aver 78% bone phos) are typical: stripping, 15–25¢; mining matrix, 20–40¢; transport to mill, 15–30¢; washing (excluding flotation), 50–75¢; drying, 50¢. Wages (1938) per hr: common labor, 30–40¢; dragline operators, 70–85¢; loco engineers, 50–60¢.

98. HYDRAULIC STRIPPING AND MINING

General. Where feasible, hydraulicking is cheap and rapid for stripping alluvium, or for mining unconsolidated deposits. It requires large volumes of cheap water; see Art 4 and 123, and Sec 3.

Rowe and Hillcrest mines, Cuyuna Range, Minn. Data from E. P. M'Carty in 1915 (348). At the Rowe mine, 1.5 million cu yd of fine glacial drift was stripped from a hematite deposit, lying considerably above a neighboring river, from which water for hydraulicking was pumped; the overburden was about 20 ft thick. From the highest part of the surface, 81 000 cu yd of fine, free-running overburden were removed by ground-sluicing (Art 121). When the surface grade was so reduced that the return water no longer carried a full burden of soil, hydraulicking was begun, the resulting water and overburden being pumped to waste dumps by a centrifugal pump. Plunger pumps at the river furnished sluicing water, but were unsatisfactory for operating a monitor, which worked intermittently and could not be stopped without stopping the pumps. Final pump installation included: Two 10-in, 2-stage, centrifugal water pumps, each direct-driven by a 200-hp motor, and having a capacity of 3 500 gal per min with nozzle pressure of 50 lb per sq in. Two 12-in centrifugal sand pumps, each belt-driven by a 250-hp motor. Sand pumps worked against a head of 27 to 40 ft, each passing 3 500 gal per min of water carrying about 10% of sand. Pipes for water line and sand pump discharge were 12-in, spiral-riveted, of No 16 steel. The sand line had bolted connections to allow deflections to 3° or 4° at each joint; the pipe wore rapidly at bends. For aver work a 4-in nozzle was used. Overburden could be washed on a grade as flat as 4%. The sand pump was stationary, and the monitor worked around it in a gradually widening circle, until a 4% grade was reached. With an aver depth of 54 ft, this limit was reached when the monitor had swept a circle 1 350 ft in diam. Working crew: 1 nozzleman, 1 motorman, 1 suction tender, to keep stumps, etc, out of the sand-pump suction; 2 laborers. Power cost, 1.25¢ per kw-hr. Total stripping cost, 6.7¢ per cu yd, including upkeep and office expense; wages, 30¢–35¢ per hr.

At the Hillcrest mine, the conditions and installation were similar, but the work was heavier; the 12-in sand pump was geared to a 300-hp motor. Water pump gave a nozzle press of 70 lb.

Table 84. Hydraulic Stripping at Hillcrest Mine, May to Aug, 1915

First 4 mo of work	May 5 to June 1	June	July	August	Totals and aver (*d*)
Total cu yd stripped	77 704	59 728	68 195	95 539	232 971

Miscellaneous	5.42(*a*)	19.75(*b*)	1.50	....	25.17	7.9
Total	88.51	150.26	....	80.16	318.93	100.0

(*a*) Includes packing pump, 2 hr; inspection and changing pump runner, 3.33 hr. (*b*) Includes 16 hr lowering scow. (*c*) Delay record incomplete. (*d*) Omitting July.

The above work showed the economic limit for profitable hydraulic stripping to be sharply defined; operations can easily be carried to a point where the labor required overbalances the cheapness of the method. At the Rowe mine, a 6 to 8-ft layer of tough clay, sand, and boulders was left on top of the ore, to be cleaned up by steam shovels. Hydraulic stripping in this district saves considerable in original investment. Disadvantages, as compared with power shovel work (Art 96): (*a*) stripping must be completed, at least over a large area, before mining can begin; (*b*) the equipment is useless for subsequent mining; (*c*) operations must stop in very cold weather (349).

Florida pebble phosphates. Data contributed in 1926 by K. C. Browne, with revisions by C. A. Fulton (148) in 1935; see also Bib (350). The nodules, from microscopic grains to 1 in diam, occur in flat beds in a clay-sand matrix. Thickness of deposits, max 40 ft, rarely over 25 ft; minimum workable, 6 ft; area, to several hundred acres; they lie on a clay bed, and are covered by 1 to 50 ft (aver 20) of sand and alluvium containing limestone boulders. The nodules form 15–25% of the phosphate matrix. STRIPPING, formerly with steam shovels, later by hydraulicking, is now wholly by draglines. These are usually elec driven; bucket, 4–9 yd; boom, 100 ft or more; caterpillar mounting is commonest, but "walking" type and wheel trucks are also used. The cut is usually 210 ft wide, and may be 0.5 mile long; an 8-yd machine digs about 600 cu yd per hr, dumping into exhausted adjoining cut, and moves 60 ft backward after about 3 shifts. Dragline also digs 30–40% of stripped matrix, from side nearest spoil bank, dumping it on top of undisturbed bed. During 1934, an 8-yd dragline, working 4 168 hr out of a possible 8 760 hr, moved 2 471 781 cu yd at cost of: 0.74¢ labor, 0.45¢ power (0.555 kw-hr), 0.64¢ supplies; total, 1.83¢ per cu yd. MINING. At 200–400 ft behind stripping face, matrix bed is hydraulicked by monitors through bedrock ditches to a sump, whence it is pumped by centrifugals to washing plant. Water is supplied to monitors, through 12- and 8-in spiral-welded pipe, by turbines, usually 1 pump to 2 monitors. Pumps are 2-stage, direct-connected to 400–1 000-hp motors, and deliver 2 000–6 000 gal per min at 175 to 225-lb press. Large units use 3-phase, 60-cycle, 2 300-volt ac. Nozzles are 1.75–2.5 in diam. A monitor with 2-in nozzle, at 200-lb press, discharges about 2 000 gal and moves 2 cu yd of matrix per min. When distance to face reaches 125–175 ft (in about 6 shifts) monitors are moved within 25 ft of face; a move of entire equipment, including blasting new sump and bedrock ditches (holes previously drilled and loaded), takes 1–1.5 hr. Bedrock ditches have grades of about 3 in per ft; at which, to prevent clogs, there must be 5 or 6 of water to 1 of matrix (by wt). At sump, a 10 to 12-in volute centrif, with 12-in suction pipe, is direct-connected to 150 to 300-hp, variable-speed motor, running 300–600 rpm. C-I pump runners, 30–38-in diam, have life of about 250 000 cu yd; steel discharge lines are 10 to 14-in outside diam If distance to washing plant exceeds 1 500 ft, one or more relay pumps are connected to discharge line, increasing cost of operation by about 1¢ per cu yd for each relay. Practice tends toward large pits and fewer washers; pulp has been moved 0.75 mile by 3 pumps in line. One large mine in 1934, working 4 413 hr out of a possible 8 760 hr, mined and pumped 1 025 000 cu yd of matrix an aver distance of 3 000 ft at cost of: 4.72¢ for labor, 4.62¢ power, 1.75¢ supplies, 0.99¢ misc; total, 12.08¢ per cu yd. Matrix bed averaged 8.46 ft thick. Following data (657) are aver for 1925 to 1935 inclusive, from 4 companies together producing half the total output of State since 1925: cu yd overburden per cu yd matrix, 1.78; cu yd matrix per long ton phosphate, including that recovered by flotation, 4.10.

Golden Ridges mine, New Guinea. Data from E. B. Jensen (333) in 1935. Orebody is a blanket formation lying on volcanic breccia and overlain by (max) 65 ft of decomposed porphyry; ratio of overburden to ore, about 3 : 1; top surface of ore is very irregular. Overburden is loosened by blasting and removed by hydraulicking; ore is then quarried at vert face and scraper-hoisted to mill bin. Blast holes are 5 in diam and 44 ft deep (for aver 40 ft of overburden), spaced 20 ft in a row 25 ft from edge, and drilled by hand-actuated (6 natives) spudding bit and stem weighing 286 lb, at aver speed of 3 ft per hr. Holes, sometimes chambered, are loaded with rack-a-rock (potassium chlorate saturated with nitrobenzol just before loading), about 1 lb per 5 cu yd, estimating back break of 12 ft behind holes, and fired with Cordeau, usually 5 at a time, breaking about 6 720 cu yd. Sluicing water, via ditch, flume, and tunnel, is conducted to any one of 3 monitors through 300 ft of 10-in and 300 ft of 8-in, spiral-riveted pipe with stove-pipe joints. Section lengths are 10 ft on straight lines, 5 ft on curves. Static head at monitor, about 130 ft; 2-in nozzle, delivering 1.5 cu ft per sec, is best; with sluice grade of 1 : 5, that amount of water will move 50 cu yd per hr of freshly loosened overburden. To save excessive wear in sluice boxes, sluicing is best done over the rock bottom.

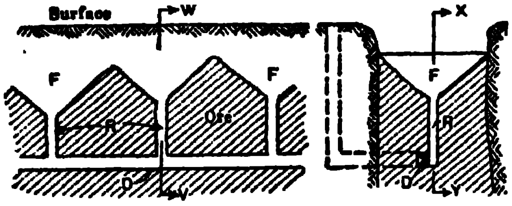
99. GLORY-HOLES (See also Art 37)

General. Fig 684 shows glory-hole work in a wide vein. Drift *D* is 50 to 100 ft below the surface, with raises *R* to the surface. The ore around each raise is "milled" into it, forming a funnel-shaped pit *F*, and is loaded through chute-gates into cars on level *D*. These pits are GLORY-HOLES, MILLS or MILLHOLES, and the method is called MILLING in some districts, as on the Lake Superior iron ranges (see Mesabi, below). The sides of glory-holes are kept steep enough for ore to slide to the raise. Ground is broken underhand; faces may be carried in benches, for convenience in setting up drills. When broken ore will no longer slide, due to flattening of the pit wall, a new cut is begun at the raise.

Unsystematic breaking of ground may result in very steep slopes, difficult and dangerous to work. When working on steep slopes, drillers should be supported by ropes and safety belts; jackhammers are practically the only drilling machines for such conditions.

Adjacent glory-holes intersect as they are deepened. The ridges remaining between the holes when the level is reached may be milled through short raises put up in them, or they may be quarried and loaded out by hand. Raises often clog, causing costly delays. Grizzlies of timber or old rails are sometimes placed near their tops, to catch boulders to be broken (compare Fig 372, Art 59; see also Mesabi and Fresnillo, below). The proper interval between raises depends on their height, the shape and size of orebody, and the angle on which broken ore will slide; raises should be spaced so as to balance their first cost against cost of removing the ore in the ridges between the holes. Raises 30 to 50 ft high give less trouble from clogging than higher ones.

Limitations. Glory-holes may be adapted to masses or thick beds (see examples below). The ore should slide on moderate slopes and not pack in the raises. Bad weather seriously hinders the work; wet ore and water give trouble in raises; snow and ice make work on steep slopes doubly dangerous. Surface water must be kept out by ditching. The work is dangerous in veins (Fig 684), unless the walls are strong; loose slabs are barred down before they become inaccessible, but their menace always limits the depth of the glory-holes. This danger and trouble with hung-up raises are the chief DISADVANTAGES. The great ADVANTAGE is in providing cheap handling and loading, in connection with the cheap breaking common to open-cut work.



VERT LONGIT SEC X Y CROSS-SEC W V

Fig 684. Glory-hole Method (Diagrammatic)

Alaska Treadwell mine (105). For ore occurrence and underground methods, see Art 68. In the first 6 years of its life (1890–1896), the entire production was from glory-holes; the resulting excavation was 1 700 ft long, 450 ft deep, with a max width of 420 ft. This work was stopped in 1906, because of a large slide of rock from the footwall and the necessity of leaving a pillar of ore to protect projected lower workings from surface water; the great depth made the danger from falling rock excessive. Glory-holes were started by a raise from an intermediate level, generally directly over a chute-raise. A stope, 20 to 30 ft high and covering 3 chute-raises, was opened around the bottom of the raise, for storage and to serve as a bulldozing chamber for breaking boulders which would block the chute-raises. The glory-hole faces were opened in a series of benches around the raise; so far as possible, large boulders were sledged in the pit. Piston drills, 3.25-in, made 12-ft holes. In small pits, where setting-up was easy, from 150 to 200 tons were broken per 10-hr drill-shift. As the pits grew larger and the sides steeper, setting up was more difficult and the output decreased to about 70 tons per 10-hr drill-shift.

Copper Queen mine, Bisbee, Ariz. Data from G. J. Young (341) in 1930. Ore remaining in bottom of Sacramento open pit, when depth became uneconomical for mechanical loading and loco haulage, was recovered by glory-holing through raises to grizzly and bulldozing chambers 130–145 ft below; pockets under grizzlies discharged through arc-gate chutes to main haulage level, 93 ft lower. For details of grizzly chambers, see Bib (341). Floor of pit, 400 by 450 ft, was divided among 11 vert raises, 10 by 10 ft, in 2 concentric circles (Fig 685). Drills employed: (*a*) Cyclone, gasolene-driven churn drills, working at top of bench and only far enough back from edge to insure firm footing; 6-in holes, 60 ft deep, spaced 18–23 ft; chambered 3–5 times, to take final charge of 400–500 lb of 40% gelatin (in wet holes), or No 2 quarry special; stemmed to depth of 25–35 ft; (*b*) tripod-mounted, Sullivan T3, working in niches on 45° slopes of pit; holes 18–25 ft deep, starting at 2.5 in; (*c*) jackhammers for blockholing and cutting niches, drilling holes to 16 ft deep. All holes fired elec. Heavy blasting did not entail excessive blockholing, due to fractured condition of ore. Max output, 2 500 tons per day; aver, 100 tons per man-shift. Crew: 6 drillers, 6 helpers, 4 blasters, 1 nipper, 1 pipefitter, and foreman.

Mesabi Range, Minn (35, 183, 275, 351). See Art 10-b, 71, 96. The MILLING SYSTEM is used here in deposits which can be profitably stripped, but are too small to warrant the investment for power shovels, or are so situated or shaped that power shovels and locomotive haulage are impracticable. Milling is also used to recover ore from deep portions of power-shovel pits, inaccessible by R R tracks on economical grades. PLAN OF WORK. A shaft is sunk outside of the orebody, with levels 50 to 100 ft apart; the 1st level is usually 50 to 70 ft below the top of the ore. Fig 686 shows a favorable layout of levels for deposits of large area. The elliptical main haulageway *H* facilitates motor-haulage; crosscuts *C* are 40 to 50 ft apart. Untimbered raises *R*, 4 by 4 ft to 5 by 5 ft, are put up to the surface every 40 to 50 ft, with chute-gate at the bottom of each. Another plan is to drive on each level a rectangular system of drifts, connecting with a main haulageway. In vein-like deposits, a central drift is driven with crosscuts to walls at 50 to 100-ft intervals, from which raises are put up.

Fig 685. Distribution of Glory-holes, Copper Queen Mine

Several mill-holes are opened simultaneously, to provide numerous working places. After starting a mill-hole, the sloping faces are attacked first at the raise; alternate blasting and picking-down proceed up the slopes; when the ore will no longer run to the raise, a new cut is started. Mosabi ores break small, and run readily on 45° slopes; in dry weather, on 38°. Slabs are barred down after each blast, by men supported by ropes; ropes are also left hanging in mill-holes for men to grasp in case of a sudden slide of ore into the raise. Effic of milling increases with size of the mill-holes. Raises often hang up, especially when starting mill-holes. Clogs are lessened by breaking large boulders before they reach the raise, and by drawing the ore down frequently before it has time to pack. At Monroe mine, sub-drifts were driven above the haulage level, connecting all raises and giving opportunity for barring down clogs; main-level drifts are sometimes 2 sets high at raises, to facilitate barring. At the Iroquois mine, a chain or wire rope hanging in each raise was raised by a small hoist and pulled down by men on the level, in case of a clog. High raises are more apt to clog than shorter ones; at the Jordan mine, a decrease in height from 85 to 30 or 40 ft materially reduced delays. Tapering raises have been tried, but it is difficult to design chute-gates that will prevent ore from collecting on the sides of the raise and destroying its taper. Production from milling is usually irregular, being influenced largely by the weather. Heavy rain stops work and washes out gullies on the sides of the mill, which must be filled by broken ore before resuming regular operation. Rains also block the raises with fine ore and water, which, on opening

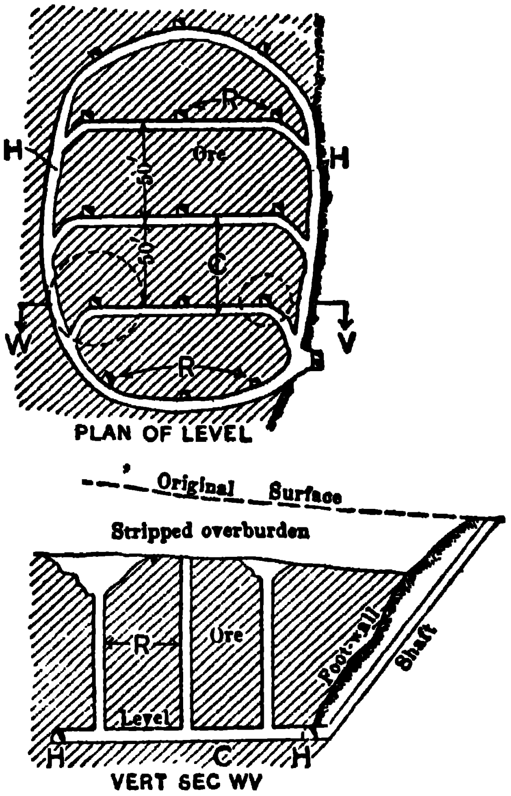

Fig 686. Milling System, Mesabi Range (Diagrammatic)

the chute-gates, often rushes into the level and obstructs tramming. When the ridges between adjacent mill-holes approach the level they are tapped by short raises. Power shovels have been used at some mines to dig this ore and drop it into the original mill-holes. **Advantages** of the milling system, compared with shovel mining: (*a*) a smaller equipment cost; (*b*) a reduction in initial investment, because a relatively small amount of stripping exposes enough ore to start production; (*c*) worked-out mills serve as dumping ground for waste stripped from adjacent areas; (*d*) the approach (Art 96), often costly in shovel mining, is eliminated. **Disadvantages:** (*a*) high cost of hoisting shaft and equipment, and the cost of raises (note, however, that many shovel pits require drainage shafts); (*b*) danger of flooding the mills with sand and slime during storms; partly controllable by surface ditching. **Cost** of mining ore by miling is higher per ton than from shovel pits of reasonable capac, and lower than from top-slicing (Art 71). Duty of labor is high, up to 25–30 tons per man-shift or more.

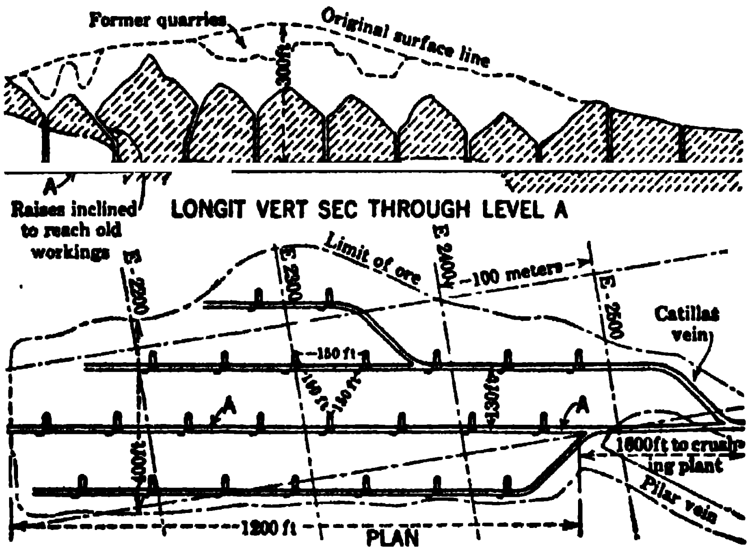

Fig 687. Glory-hole Work, Fresnillo, Mex (640)

Fresnillo mine, Zacatecas, Mex. Data from T. C. Baker in 1923 (640), with additions from A. Livingston (561) in 1932. For ore occurrence and early method, see Art 95. Glory-hole method was selected instead of power-shovel work because: (*a*) its simplicity was suited to local labor supply, foreign skilled labor being required for power shovels; (*b*) reserve of broken ore could be kept in glory-holes to insure continuous mill operation; (*c*) multiplicity of working places aided in maintaining uniform grade of mill feed. These advantages outweighed a slightly cheaper estimated mining cost and better opportunity for selective mining by power shovels. **Development.** Parallel drifts, 10 ft wide by 9.5 ft high and 130 ft apart, were driven under the orebody from adit *A* (Fig 687), which was at lowest elev that would leave room below portal for a millsite; bottom of main orebody was 20–60 ft above this level. Raises, 10 ft diam, were put up to surface (125–200 ft above) at 150-ft intervals along drifts, each having a double loading chute, 100-ton ore pocket, grizzly and bulldozing chamber (Fig 688); no timber required in raises and ore pockets. Ultimate output was 313 tons per ft of development. **Mining.** Glory-hole benches were 9 ft high. Ground broken with vert holes, drilled by dry jackhammers; spacing, 3.5–4 ft; burden, 3.5–5 ft; depth, 9–10 ft; aver speed, 120 ft per 8-hr drill-shift; contract price, 2.8–3.6¢ (U S) per ft. Aver charge per hole, 1.5 lb "Durox." About 6 tons of ore were broken per lb explosive; 0.107 cap and 1.2 ft of fuse used per ton. Comparatively close spacing and shallow depth of hole proved cheaper in total cost (including blockholing, clogged raises, etc) than deep holes and heavy charges. Best slope for sides of glory holes

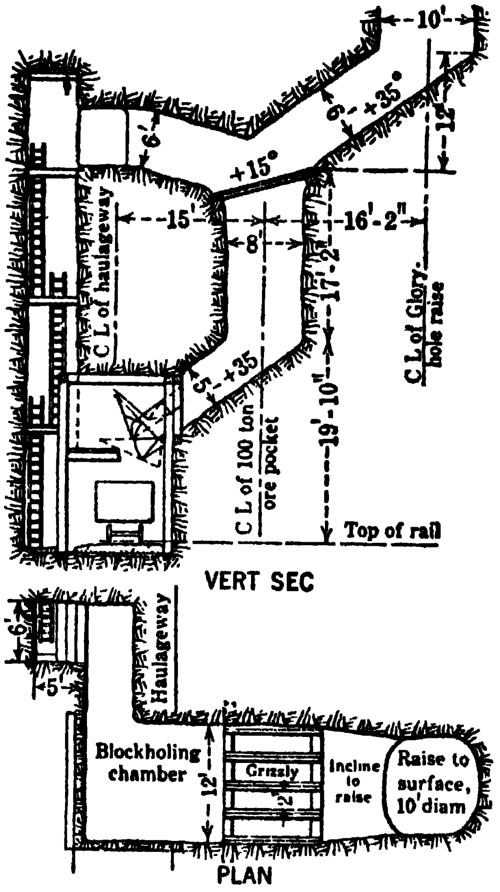

Fig 688. Bulldozing Chamber, Pocket, and Chute, Fresnillo, Mex (640)

found to be 50°–60°; ore remaining between bottoms of glory-holes, when slope decreased to 35°, was removed in horiz benches with barrows. Aver output, over whole operation, 130 tons per drill-shift, or 8 000–10 000 tons per grizzly per mo (3 shifts). HAULAGE was by elec loco, in 9-car trains of 10-cu yd cars. For mining waste, the raise affected was emptied of ore; waste was loaded from chute-gates into smaller cars. Total COST of equipment (much of it bought during high-price post-war period), and buildings for producing 3 500 tons per day was approx $140 000; this shows comparatively low initial investment for glory-hole work. See Bib (640) for comprehensive data on details.

Mt Isa, Queensland. Data from J. Kruttschnitt and V. I. Mann (500) in 1937. For ore occurrence, see Art 43. Upper and oxidized portion of Black Star lode, glory-holed to 150-ft depth, was 1 100 ft long by 200 ft wide at middle of lens, which dipped 55°–60°; narrow ridge of high ground on hanging-wall side was leveled off first. Outcrop length was about evenly divided among 7 raises, each connecting through grizzly chamber and ore pass with main haulage level on footwall 400 ft lower (Fig 689). Benching around top of raise was done with jackhammers, holes 6–16 ft deep; miners, on day shift only, had to wear safety belts; ladders provided for access. Aver slope of walls, 50°. All holes chambered; explosive producing best fragmentation was slow-acting, 25% ammonia-base dynamite. Triangular remnants between bottoms of glory-holes were mined (Fig 689) by transverse sub-level open stopes with ring-drilled pillars like those later adopted in wider parts of the sulphide orebody at lower levels (Art 43). The 15-ft pillars between stopes 30 ft wide proved inadequate to support hanging wall (weakened by undisclosed fractures) and caving occurred when about 60% of the remnant ore had been removed; drawing of crushed ore was continued until dilution by wall rock became excessive. Cost of glory-holing 270 063 tons in first half of 1933 was: labor and supervision (mining 51%, transport, 39%), 32.9¢; drills, steel, and comp air, 5.1¢; other power (mainly transp), 5.2¢; explosives, 7.4¢; timber and other supplies, 3.2¢; total, 53.8¢ per short ton.

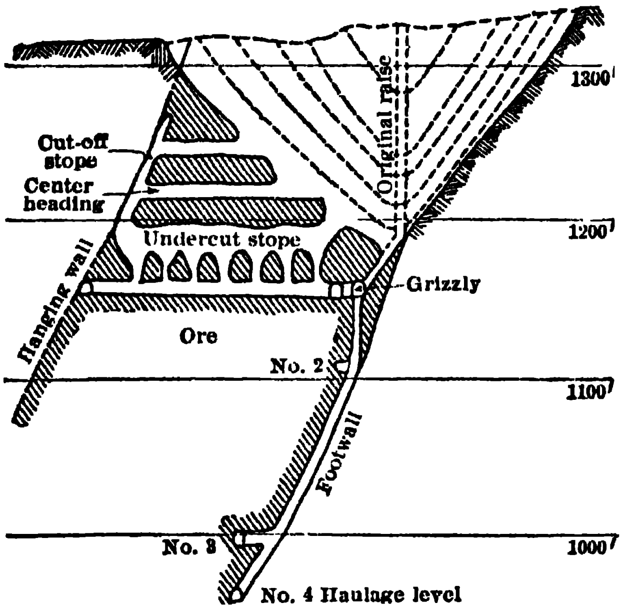

Fig 689. Vert Cross-sec through Glory-hole, Mt Isa, Queensland (500)

Round Valley tungsten mine, Bishop, Cal. Example of small-scale work described by W. O. Vanderburg (637) in 1935. Deposit of contact-metamorphic limestone, containing scheelite and averaging 0.5% WO_3, is 125 by 200 ft in area. Working level, at bottom of 75° inclined shaft 100 ft deep, has 7 raises, 5 by 6 ft, up to pit bottom. Drilling with dry jackhammers; blasting with 40% gelatin and fuse. Raises are kept full of broken ore, to hold back large blocks until they can be bulldosed; some hand shoveling required. Ore from chutes is trammed by hand and hoisted by skip. Crew of 11 men produce 120 tons per single-shift day, at total working cost of 76.3¢ per ton. Unit costs per ton: all labor (40% on breaking), 0.799 man-hr; power (@1.5¢), 1.9 kw-hr; explosives, 0.33 lb.

Tunnel method. Data from D. T. Farnham in 1914 (352). This is a variant of glory-hole work, for securing cheap loading costs in open cuts without putting up raises. A shale quarry at Renton, Wash, is illustrative (Fig 690).

The quarry face was 700 ft long by 150 ft high; output, about 700 tons per day; small output and high working face rendered power-shovel work inapplicable. Heavily timbered tunnels *T* were driven from the quarry floor into the face, and 6 by 12-in timbers, 8 in apart, were placed on the caps to form a grizzly. Hopper gates (Art 90) were built between sets. The tunnels were about 25 ft long, 5 sets being kept in the solid, and 7 or 8 sets erected outside. About 20 tunnels

were driven 20 ft apart along the face. The bank was then blasted down, the grizzlies being first covered with 3 by 12-in plank and a 2 or 3-ft layer of shale; from 2 000 to 3 000 tons were shot down in 1 blast on a group of 3 tunnels. The planks were then removed from the grizzlies, 1 or 2 at a time, starting at the outermost set; the broken shale was bulldozed as necessary and worked through into cars below. The ridges of shale between the tunnels were loaded by hand. A 3-man crew loaded 2.3-ton cars and trammed them 200 ft at an aver rate of 1.9 cars per man per hr in summer and 1.7 per hr in winter, or 4.37 tons per man-hr. Before using tunnels the duty of labor, in loading 2-ton cars by hand from the quarry floor on a 100-ft tram, was 2 tons per man-hr. Same method is still followed in shale deposits at Renton and elsewhere in Northwest, and is common practice in the steeply pitching lenticular limestone bodies (in rugged topography) characteristic of the region.

100. "STRIP MINING" OF COAL

Open-cut mining of coal is termed "strip mining," or "stripping." In U S, under suitable conditions, both hard and soft coals are thus mined; in 1937, U S Bur Mines statistics show that 7.1% of total output of bituminous (26% of that in the Mid-Western field) and 11% of Penn anthracite were obtained by stripping.

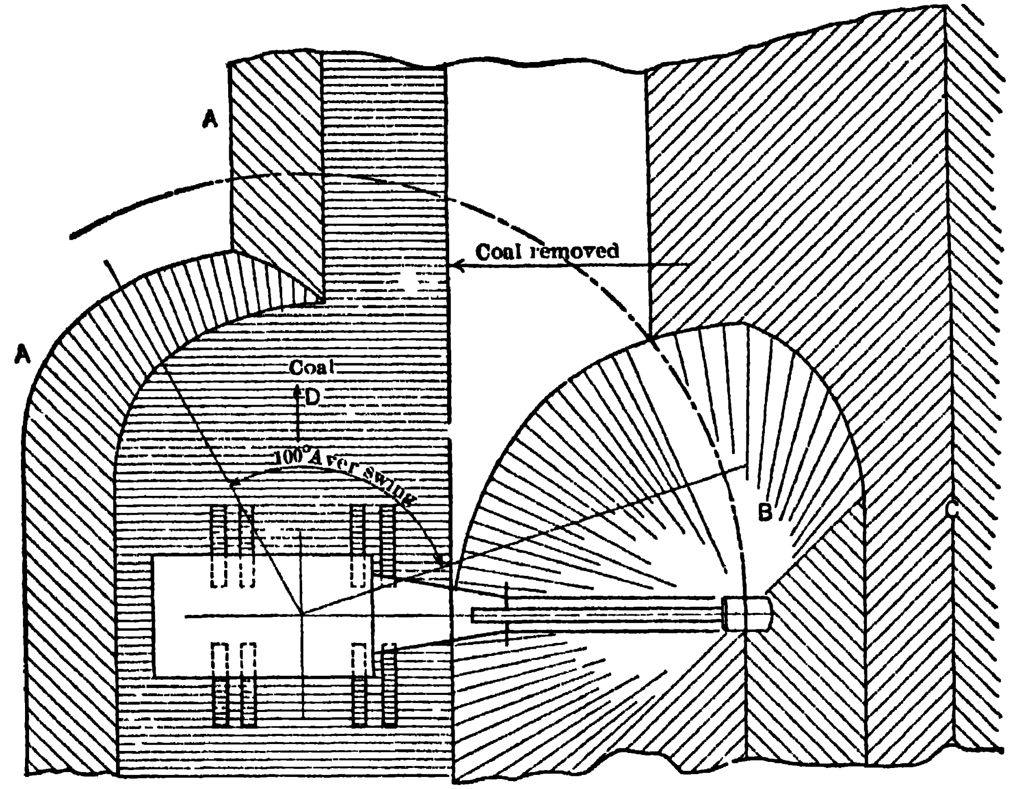
(a) Bituminous Coal

Data kindly supplied by M. M. Moser, Vice Pres, United Electric Coal Co, in 1939.

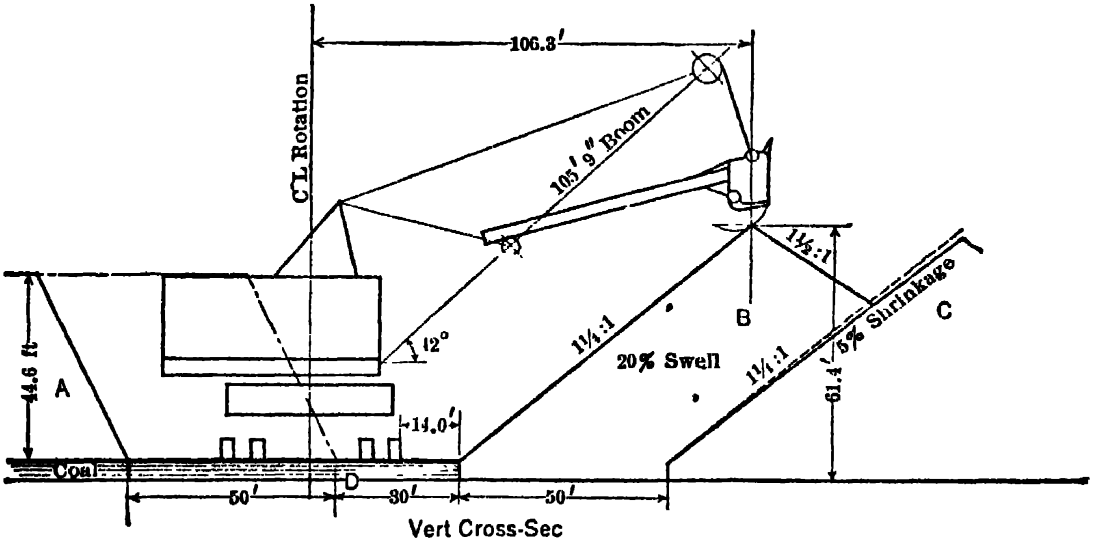
General. Production of bituminous coal by stripping has become important in recent years, especially in Mid-Western fields. Seams quite near the surface, to which underground methods are inapplicable because of thinness of seams and the roof conditions, are successfully stripped; they are from 18 in to 8 ft thick. Depth and nature of overburden are variable, but depths to 90 ft have been profitably removed. Topography of stripping areas and the coal seams are both generally fairly level. In spite of the apparent simplicity of stripping, systematic prospecting, familiarity with technique, long-range planning, proper equipment and well trained mechanical organization are essential. Quality and thickness of coal, character and depth of overburden, distance from pit to preparation plant, and freight rates to markets, are important. Costs vary widely, depending chiefly upon character of overburden and thickness of coal. In some areas, hard limestone, requiring blasting, overlies the coal; in others, overburden is mainly alluvium. The economic ratio in Mid-West fields is about 10 ft of overburden per ft of coal. Proper drainage is important in a strip mine, which is often 60–70 ft deep; heavy rainfalls can cause serious damage to equipment and completely paralyze operations.

Stripping methods. In 1939, 3 systems of stripping were practiced in Mid-West coal fields. Fig 691 shows a mine employing a SINGLE STRIPPING SHOVEL, advancing in direction of the arrow, and removing overburden *A* which, if of rock or shale, has been loosened by blasting. The shovel crawlers rest on the cleaned coal seam. Stripped material goes to a waste bank *B*, piled in the cut from which the coal has been taken. The toe of waste bank rests against edge of coal seam, and its far side lies on bank *C* of the previous cut. The cross-sec in Fig 691 shows the relation between depth of overburden *A*, width of coal seam *D*, height and slope of waste banks *B* and *C*. The largest shovel in use in 1939 has a 32-cu yd dipper; boom lengths, up to 125 ft. Stripping by shovel (as of 1939) is limited to depths of about 60 ft, depending on lengths of boom and dipper handle. Volume handled by a large 30-cu yd shovel is about 1 250 cu yd per hr. The uncovered coal is blasted and loaded by smaller shovels (0.5–6 cu yd) into trucks or R R cars.

Fig 692 shows working positions of machines in a TANDEM STRIPPING operation, using a shovel in conjunction with a dragline; the crawlers of both rest on exposed coal. Work progresses in direction of the arrow, shovel *E* removing block *C*, the top of which has been previously benched by dragline *D*. The dragline benches the cut *B*, preparing it for next trip of the shovel; the material is earth, clay, or shale. The 2 machines handle nearly equal amounts of overburden. That of the dragline is piled in a windrow *F* behind and above the rock *G*, which has been stacked by the shovel (Fig 692). The draglines have buckets up to 14 cu yd, with 160-ft booms. Overburden 90 ft deep has thus been well handled. Fig 693 shows a SINGLE DRAGLINE on a bench about one-third the depth from surface to the coal. A walking dragline is preferred because more manageable on poor footing. The loading shovel follows the dragline, as shown. When stripping



Plan



Vert Cross-Sec

Fig 691. Stripping Coal Seam with Power Shovel Alone

bench *F*, the dragline works along lines *A–B* and *C–D*; the lower material is usually the firmer and hence is put into the base of spoil bank. In stripping bench *G*, the dragline works along line *C–D* only, placing the material in the nearest windrow, as at *E*. Easy digging is a requisite, and bucket capac must be sacrificed to the reach required for success.

Haulage from the loading face to tipple or preparation plant is by trucks, rail, or a combination of these, trucks gathering from loading shovel and transferring to rail haulage at a point some distance from the working face; third method is used only where the coal face is distant from the preparation plant. Truck haulage is relatively recent, but is being adopted in most new operations. In general it is cheaper than rail haulage and promotes effic by eliminating trackage along the berm or coal surface on which the shovels must travel. Shovels are thus able to operate nearer the toe of spoil banks, and with a smaller swing angle. Truck haulage also eliminates cost of track shifting. Trucks used at strip mines are of 5- to 25-ton capac. Tractor-trailer units have handled up to 80 tons per trip. For details of equipment and methods at several mines, see Bib (680).

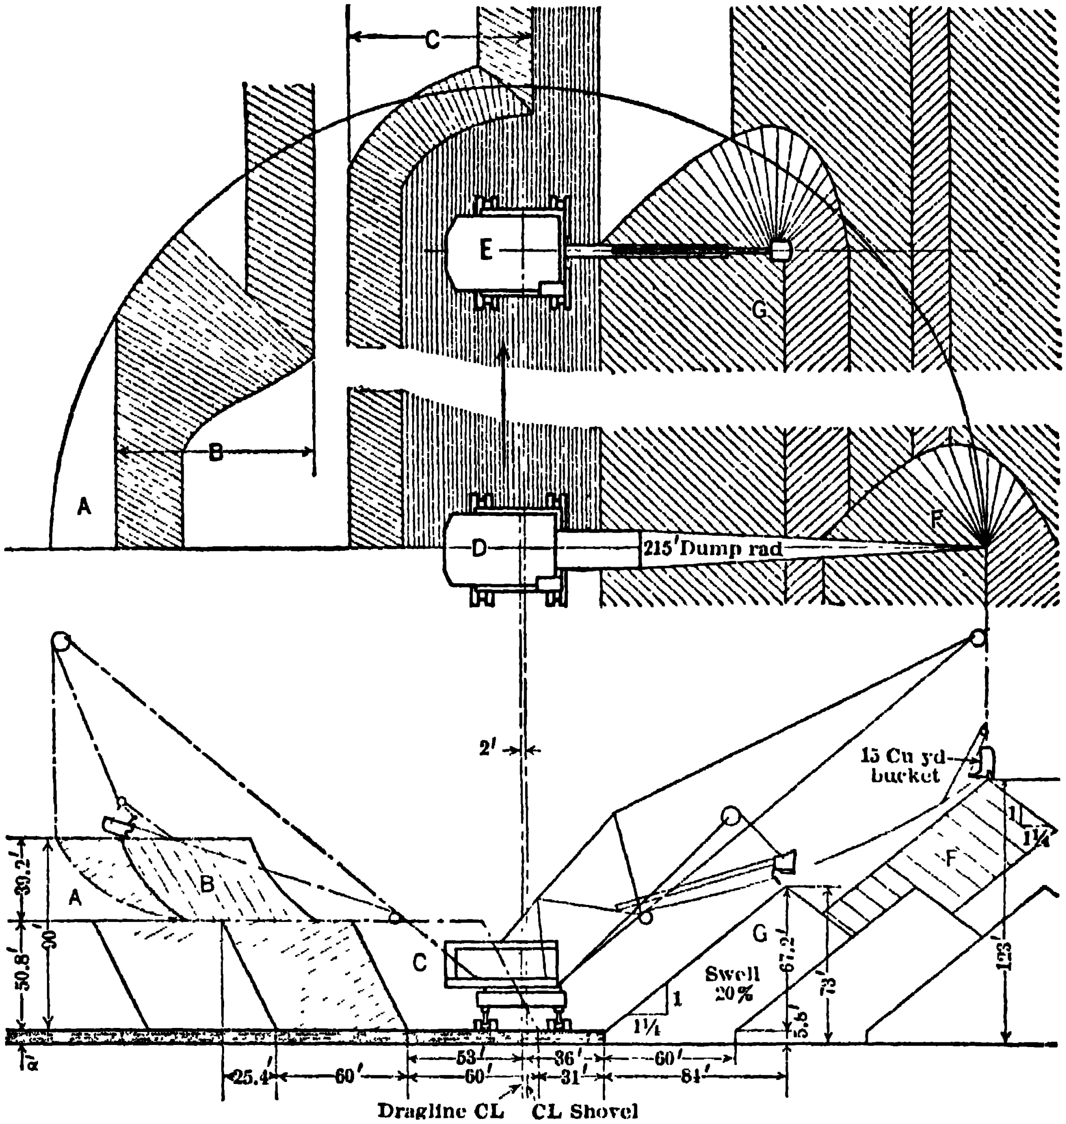


Fig 692. Stripping Coal Seam with Power Shovel and Dragline

(b) Anthracite Coal

Data from H. H. Otto in 1931, R. D. Hall in 1935, H. N. Eavenson in 1936, and others (671).

General. Strip-mining in anthracite fields has recently advanced notably in tonnage, area of individual strippings, and depth of cover removed; it is applied both to virgin coal and to outcrops where much of the coal has previously been mined from below. When steam-shovels were first applied, in 1881, max economic limit of overburden was held to be 1 ft per ft of coal; by 1911, the ratio (with 60% rock in overburden) had reached 3 : 1; in 1936, ratios were 7 : 1. Crystal Ridge stripping (begun 1925 and finished 1934), 2 700 ft long, 500 ft wide, 165 ft deep, moved 5 200 000 cu yd of overburden to recover 665 000 tons of coal; Summit Hill stripping (begun 1925) moved 7 300 000 cu yd of overburden and marketed 2 200 000 tons of coal during its first 10 yr, and will eventually have moved a total of 13 000 000 cu yd to recover 4 600 000 tons of coal.

Increase in the profitable ratio of overburden to coal has been due to cheaper excavation by draglines and power shovels, automotive haulage, and the abandonment of inclined planes for hoisting. In nearly flat seams, back-filling similar to that used in bituminous beds is practicable (see Clinton colliery, below). In steeply pitching seams, involving deep and narrow strippings, back-filling is rarely possible, except where overburden from one end can be dumped at the other end with some saving in haulage. Dragline excavators have been less rapidly adopted in the northern field, where the wider strippings make haulage of some kind unavoidable, and shovel loading more generally applicable.

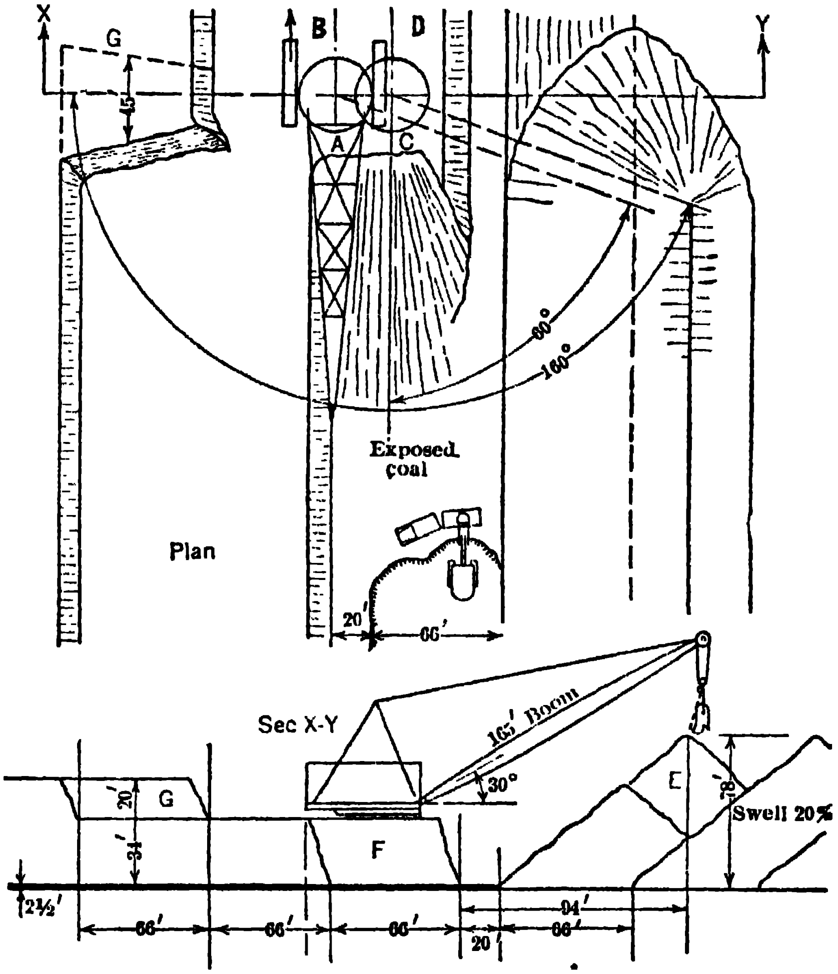

Fig 693. Stripping Coal Seam with Dragline Alone

Flat seams. Clinton colliery, in the northern field, has a nearly flat bed 65 in thick containing 50 in of coal, under aver 25 ft of overburden (half sandstone, and half earth). Stripping area, 28.3 acres; overburden, 1 112 000 cu yd; coal, 174 000 tons. A Monighan, Diesel-driven, 375-ton walking dragline excavator, with 160-ft boom and 6-yd bucket, first uncovered the outcrop by a trench 130 ft wide at top, 75 ft at bottom, depositing spoil, without other handling, in a pile 55 ft high and 70 ft back from edge. Rock was broken with jackhammer holes staggered at 8-ft spacing in parallel rows, loaded with 40% gelatin (0.5 lb per cu yd) and fired elec, 100 at a blast; broken rock removed by same excavator. Coal was loosened with black powder, and loaded into mine cars by Diesel, 50-ton Bucyrus shovel with 1.25-yd dipper. Haulage by 20-ton gasolene locos out of pit; thence by mine locos to tipple. After extracting coal from first trench, another slice was taken, depositing spoil in space just made. Max operating force (excavator working 2 shifts), 27 men, of whom 9 were on part-time. In 2 mos of 1931, 163 700 cu yd (about 1/3 rock) were moved; delays, 5% of working time; while swinging 180°, aver time was 1.5 min per cycle.

Pitching seams. For these, draglines with buckets of 5 to 12 cu yd have advantages of: (*a*) long casting reach; (*b*) permitting steep banks, since only the bucket is endangered by slides; (*c*) avoiding possibly 50% of the excavation required by a shovel for bench and loading roads; (*d*) recovering some coal not otherwise obtainable, as from partially mined outcrops. Fig 694, from R. D. Hall, shows a suppositious but typical case; Fig 695, a dragline installation where a 67° face was permissible. In some cases, the same dragline is employed on both overburden and coal; in others, coal is loaded by shovel or another dragline. Rock is generally broken with unchambered, 6-in. churn-drill holes; above a previously mined bed, holes are usually placed only over pillars. For transport, tractor-trailers, and trucks, have largely replaced locos and cars, due to (*a*) saving in track laying, moving, and maintenance; roads are quickly prepared by bulldozers, and 1 man at dump replaces a track-

moving gang; (*b*) smaller capital cost; in rush seasons, trucks can be rented; (*c*) steeper grades (to 15 or 20%) and sharper turns permissible; (*d*) less working space required around loader; (*e*) more continuous loading is usually possible; (*f*) automotives easily shifted from one job to another. Following examples illustrate strippings on pitching coal.

Summit Hill. For yardage and tonnage, see above. Coal 50–400 ft thick, latter due to folding; only upper part will be stripped. Equipment: for overburden, 1 Bucyrus 320B, elec shovel, 7.5-yd, and 2 Bucyrus 120B, elec shovels, 4-yd; for coal, 1 Link-Belt K55, gas-elec dragline, 2-yd, and 1 Marion 37, elec, convertible shovel-dragline, 1.75 and 1.5-yd; 19 6-in churn drills, 12 elec, 7 gasolene driven; 2 wagon drills; 35 standard-gage, 30-yd, side-dump cars for spoil; 10 geared locos, 50–65-ton; 5 rod locos, 38–55 ton. Coal loaded into R R cars on track at 3% max grade.

Crystal Ridge (Mammoth seam). For yardage and tonnage, see above. Stripped with Bucyrus 7.5-yd, elec shovel; waste hauled 5 900 ft up 3.5% grade to dump in 30-yd cars; coal loaded with 3-yd elec shovel. Same stripping later extended 70 ft, with dragline having 3.5-yd bucket for clay, 4-yd for rock, casting and re-casting into old pit. Totals: 27 300 cu yd clay, 73 500 yd rock, 13 500 yd caved material from old rooms, to yield 46 200 cu yd coal loaded by shovel into trucks.

Hell's Kitchen. Primrose virgin coal, 30 ft thick, dipping 30°; removing 1 300 000 cu yd overburden uncovered 514 000 tons coal. Stripped with 2 Bucyrus 70C steam shovels loading 4-yd, side-dump cars; hauled up 3% grade by 20-ton steam locos. Coal loaded by one of the above shovels, or a 1.5-yd gasolene shovel, into mine cars.

Lansford. Mammoth seam, 55 ft thick, dipping 60°, previously mined. Outcrop exposed for 6 000 ft; stripped to 65 ft deep, both walls sloping 60°. Shovels, 2.5-yd in rock, 1.5-yd in coal, load Mack trucks dumping into tops of old rooms connecting with haulage level 360 ft below.

Richards. Synclinal fold with dips of 43° and 64°; pit 130 ft deep in 1934, expecting to reach 184 ft. Coal in 3 splits, with slate and sandstone partings 4–5 and 10 ft thick. Marion 490 shovel loads trucks which climb ramps along sides and across ends of stripping.

Wm Penn, at Shenandoah. Mammoth seam in 2 splits; parting widens from 40 to 180 ft within length of stripping. As dip is in same direction as slope of hill, outcrop of top split, 14.5 ft thick, lies downhill from that of bottom split, 17.5 ft thick, and its stripping advances ahead of the other. Both strippings are overcast downhill by Bucyrus dragline with 2-yd buckets.

101. MISCELLANEOUS DATA, OPEN-CUT MINING

Economic limit of depth. Open cutting loses its advantage of cheapness where the stripping cost per ton of ore exposed exceeds the difference in cost between open-cut and underground mining. For large, flat deposits, with fairly uniform cover of moderate depth, the problem is simple, as the cost per ton of ore for excess stripping to provide safe slopes around the pit is so small that errors in its estimation are unimportant. But, on small areas and for deep overburden, the cost of stripping slopes is important. In dipping deposits, where one or both walls must often be cut back to safe slopes, the amount of stripping is not a simple function of the depth, and this complicates calculations of the economic limit of open cutting. In districts where enough underground and surface mining have been done to establish fairly accurate unit costs, close estimates can be made from borings or other data, to determine the feasibility or limits of open cuts. The max depth of profitable stripping is often expressed in terms of a ratio of cu yd of stripping per ton or cu yd of ore (or ft of overburden per ft of ore). These ratios are useful if applied intelligently; ratios applicable in a well known district may be incorrect in a new region.

Mesabi estimates (35). Sometimes a choice of method can be made by inspecting the ore estimate (Art 11). Relative costs of underground and open-pit mining are usually calculated by applying unit costs to a column 1 yd sq. EXAMPLE: a drill hole shows 50 ft of drift and paint rock, 15 ft hard taconite, and 36 ft merchantable ore; general conditions allow use of either method. Comparison of costs, using 1912 unit costs (641) which, though old, illustrate method of calculation:

Underground mining. Cost of mining a volume of ore 1 yd sq by 36 ft high @ 75¢ per ton (1 cu yd = 2 tons)		$18.00
Open-pit mining. Stripping a column of overburden 1 yd sq by 50 ft deep @ 30¢ per cu yd	$5.00	
Stripping 15 ft of taconite = 5 cu yd @ $1 per yd	5.00	
Steam-shovel mining of 36 ft of ore = 24 tons @ 15¢ per ton	3.60	13.60
Saving by open-pit work per sq yd of area		$4.40

Similar calculations are made for other drill holes, and all are combined in proportion to the tonnage represented by each. This preliminary estimate is supplemented by more exact figures when necessary. Questions of adverse topography, dumping facilities, presence of swamps, quicksand, etc, are local factors which do not permit generalization.

Pennsylvania anthracite stripping (345) (see also Art 100) is generally undertaken when it is cheaper than underground mining. But strippings yield higher extraction, cleaner coal and a higher percentage of prepared sizes (Sec 34), and allow close adjustment of output to demand; these factors may be decisive in making a choice. Strippings are often opened to recover coal otherwise not minable. Examples in determining the economic limit of depth and area of strippings: Fig 696 shows a stripping based on a ratio of 2.75 cu yd of overburden removed per ton of coal uncovered. But on resolving the operation into its component parts (see areas *A*, *B*, *C*, etc), it is found that area *A* is the lowest one within this ratio. For areas *B* and *C* the ratios are 3 : 1 and 3.5 : 1 respectively; that is, they are removed at a loss, even though a considerable profit comes from areas *D* and *E*. Hence, to justify this operation, marked advantages must be gained by removing *B* and *C*. Fig 697 shows a crop stripping common in the southern anthracite fields; either the cover must be removed, or a thick chain pillar of coal left, as shown. The coal below the pillar is minable at as low a unit cost for cutting and loading as could be realized by mining the entire upper 250 ft of seam from gangway *W* after stripping the overburden. By the latter method, development costs would be less by a few cents per ton. But, comparing the results with the case in Fig 696, the ratio here is 4 cu yd stripping per ton of coal in the chain pillar, or a ratio of 1 : 1 based on the total coal above gangway *W*. Hence, the coal strictly classed as stripping coal is mined at a loss (345).

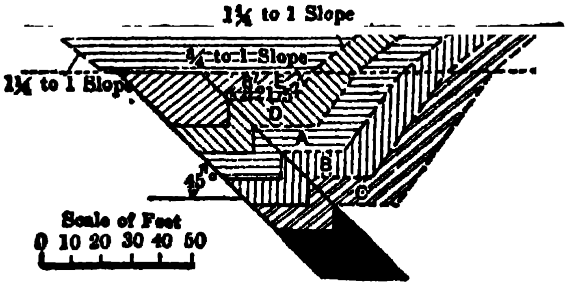

Fig 696. Pennsylvania Anthracite Stripping

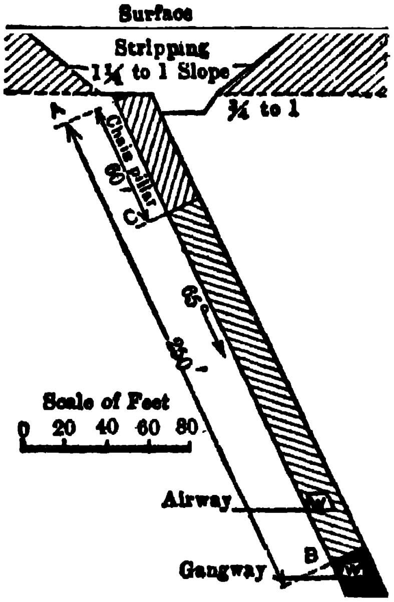

Fig 697. Pennsylvania Anthracite Stripping

Porphyry coppers. Estimates of economic stripping limits at these mines often involve problems arising from fluctuating metal prices, varying smelter contracts, differences in milling costs and recoveries, and freight rates. Parts of the overburden often contain a little copper, and when this must be mined and loaded in any case, it may sometimes be more profitable to send it to mill than to dumps. The factors involved in these problems are shown in the following formula, used at Chino mine to ascertain the lowest grade of rock that may be called minable ore (340); all costs, and the copper price, are in dollars or fractions, and percentages are expressed as decimals:

$$\frac{M + F_0 + m}{A\,2\,000pC} + \frac{f_c + S}{D\,2\,000p} + R + E + c \quad B\,\frac{100}{105}$$

transposing and simplifying:

$$A = \frac{M + F_0 + m}{2\,000pC\left[\frac{100B}{105} \quad \frac{f_c + S}{2\,000pD} - (R + E + c)\right.}$$

where

M mining cost per dry ton ore
F_0 freight per dry ton, mine to mill
m milling cost per dry ton
f_c freight per dry ton of concentrates, mill to smelter
S smelting charges per dry ton of concentrates
R refining and delivery charges per lb Cu
E = export freight and insurance per lb Cu
c = commissions, per lb Cu
p = % Cu contents paid for by smelter
B assumed price per lb Cu
C % recovery at mill
D % Cu in concentrates
A % Cu in material in question

The above formula includes an unusual refinement in using the factor 100 ÷ 105, which allows 5% interest for the period (estimated as 5 mos) between mining the ore and sale of its contained copper. For further detail, see Bib (340).

Slopes of faces in power-shovel mining. Following data from E. E. Barker in 1911 (339) are based on experience at the Nevada Consol (Art 96).

The slope at which a bank will stand depends on the depth to be excavated, as well as character of the material; hence no general rule can be formulated. Slopes steeper than

1 : 1 will not stand in the leached porphyry and fractured schist of the disseminated copper deposits. Blasting shatters harder rocks, so that banks will not stand much steeper than 0.66 horiz: 1 vert. Faults, if present, may necessitate flatter slopes. Experience with rock "flows," in deep excavations in soft rock on the Panama canal, shows that slopes suitable for ordinary work may not stand on great depths. These statements indicate the wisdom of using generous slope allowances for both estimates and operation. (See Sec 3 and 5 for data on angles of repose and safe slopes.)

The slope of a working face as a whole is affected by the height and width of benches, number of benches, and slope of each face (Fig 698). For benches of equal size, the general slope is given by: $S = \frac{a + (n-1)\,b}{nc}$, where S = general slope ratio, a = base of the bottom slope triangle, b and c = width and height of bench, n = number of benches. Fig 698 shows a layout suited to economical power-shovel work in soft porphyry ore; that is, the benches have the minimum economic width and the max economic height and slope; 50-ft benches are safe, and the shovel is seldom in danger of being buried. Width b depends largely on the slope of the broken ore which ordinarily will repose on a slope of about 1.5 : 1, but the impetus given in blasting flattens the slope to about 2 : 1. Churn-drill holes for blasting are started about 10 ft from the edge of the bank, and loosen the ground for about 10 ft back; the position of the broken ore face is indicated by dotted line fg. The remaining clear space ef (about 20 ft wide) gives ample room for the loading track, without danger of its being buried by the blasts. The general slope of the 4 benches is 1.75 : 1; a larger or smaller number of benches would increase or decrease the ratio, in accordance with the formula.

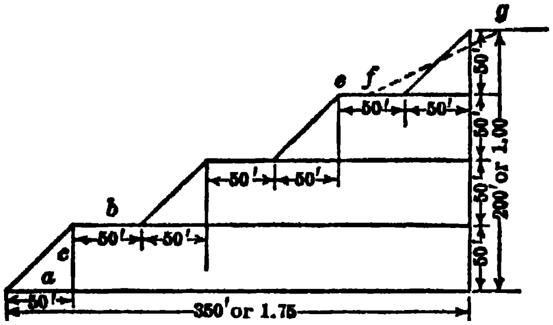

Fig 698. Ideal Layout of Power-shovel Benches, Nevada Consol Copper Co

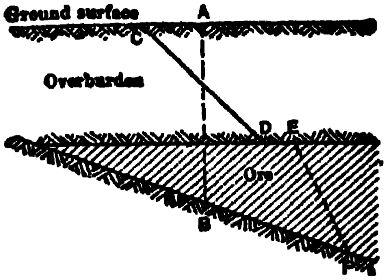

Fig 699. Limits of Power-shovel Pits, Mesabi (G. J. Young)

Examples of practice as to overall slopes in open-cuts under different conditions are given in Art 95-97. See also remarks on pit slopes in Art 113.

Pit limits for power-shovel mining in orebodies which feather out at their edges are determined as in Fig 699 (286). AB is the line along which the unit cost of underground mining equals that of power-shovel work plus stripping. Line CD, on a slope equal to the angle of repose of the overburden, fixes the crest and toe of the stripping. The top of the pit in ore is determined by width of the berm DE, usually 20 to 30 ft. Through E a line EF on a slope suited to the character of ore marks the limit of power-shovel operations; ore to the left of EF would be mined by some underground method, as top-slicing (called "scramming" on the Mesabi, Art 71). See also Fig 97, Art 11.

Advantages of open-cut mining; (*a*) Properly applied, it gives large outputs at a lower unit cost than by any other method. (*b*) After a pit is well opened, its output can be varied greatly. In self-draining pits, work may be stopped and started without trouble, though with a loss of interest on investment. (*c*) Mineral within the pit limits is completely extracted. (*d*) The large working faces allow ore to be broken with minimum drilling and explosives. (*e*) Effective sorting of ore is possible in connection with hand loading. When loading with large power shovels into dump cars, sorting is limited to concentrated areas of waste (or some particular grade or kind of ore to be kept separate), large enough to fill one or more trains; otherwise delays due to switching or breaking up trains may offset saving effected by sorting. Closer sorting is possible with small power shovels loading into automobile trucks; at United Verde pit (Art 96) such equipment handles waste, smelting ores, and milling ores separately. A close determination of values over relatively small areas is usually possible in open-pits by sampling cuttings from blast holes, especially if churn drills are used. Sorting is impossible in glory-holes. (*f*) No timbering or filling are needed, artificial lights are unnecessary for day work, and supervision is easier. Hygenic conditions are generally better than underground; open cuts also eliminate dangers peculiar to underground mining (see Table 65). Duty of labor is higher, and usually a larger daily output can be produced from a given area than by underground mining.

Disadvantages of open-cut mining: (*a*) The surface is destroyed for other purposes, though in shallow, back-filled pits, the soil may be restored for farming. (*b*) Surface rights of way and room for dumps must often be purchased. (*c*) Large-scale work, especially that involving extensive stripping, requires large capital outlay before any return is secured. (*d*) Open cuts are limited to relatively small depths. (*e*) The plant is often composed of a number of scattered units. (*f*) Work is stopped or seriously hindered by bad weather. (*g*) An open pit collects snow and rain, and tends to drain water from the surrounding surface. This may add a serious expense for pumping to the cost of subsequent mining at depth, but may be partially met by surface ditching; note also trouble with mud-rushes at the Kimberley diamond mines, Art 88. Great care must be taken in scaling loose slabs from working faces to p rotectmen at the base of the faces from injury. (*h*) Horses of waste must be mined and handled.

COAL MINING METHODS

By William Emery, Jr, of Day & Zimmerman, Inc, Philadelphia, Pa

Introduction. The preceding articles deal with the methods common to nearly all kinds of mining. Metal mining methods are more varied than those for coal, due to the greater diversity in form and occurrence of metalliferous deposits, and, to avoid repetition, the articles on coal mining are devoted chiefly to the distinctive methods employed, omitting minor variations. As coal seams are "beds," they are generally mined like bedded deposits (Art 30, 31, 32, 42). Striking exceptions exist in the pitching basins of the Pennsylvania anthracite fields, where the extreme folding and varied contours of the seams require original and complicated methods. For details of prospecting, development, breaking ground, support of excavations, and underground handling of minerals, refer to these subjects in Art 1 to 93.

102. CLASSIFICATION, DEFINITIONS, AND GENERAL CONSIDERATIONS

A distinction is sometimes made between the methods of mining anthracite and bituminous coals, but for a given case the proper method depends much less on the kind of coal than on the physical characteristics of the seam, roof, and floor. For example, similar methods are employed in the flat seams of the northern anthracite field of Penna and in the bituminous mines of the same state; likewise, some of the "pitch-mining" methods of Penna resemble those used in the pitching bituminous seams of Colo. Standard underground methods, with their modifications, fall into two groups:

Pillar methods (Art 105, 106), known as room-and-pillar, pillar-and-breast, pillar-and-stall, bord-and-pillar, are those in which, from haulageways (gangways, roads, entries, or headings), comparatively wide openings (breasts, rooms, stalls, chambers, or bords) are driven. These openings correspond to stopes of metal mines. PILLARS, between rooms and other openings, support the roof. Nearly all coal in the U S is mined by room-and-pillar. Aver recovery in FIRST MINING, that is, with no attempt to rob pillars, is 30%–50%. Final ROBBING increases the yield. U S Bur of Mines in 1923 stated extraction in U S anthracite mines was 49–69%, aver 65%; in 10 states, producing 90% of the bituminous coal, extraction was 55–92%, aver 65%. J. D. Sisler in 1931 (620) estimated total losses in mining bituminous coal at: 40% in Ohio, 27% in Penna, and 22% in W Va; or approx same losses as in 1922.

Longwall methods (Art 108), divided into ADVANCING and RETREATING longwall, are used extensively abroad, but, until recently, have found little favor in the U S. Instead of opening rooms with intervening pillars, coal is mined from a continuous face. As work advances or retreats, the roof is allowed to cave, haulageways and airways being kept open by packwalls of waste (gob). Recovery is approx 100%.

Development openings, corresponding to the levels and drifts in metal mines, are locally called ENTRIES, HEADINGS, or ROADS (bituminous mines, U S), or GANGWAYS (anthracite mines). Openings for ventilation are termed AIRWAYS or AIR COURSES, also MONKEYS or MONKEY WAYS in anthracite mines. The mode of entry, by tunnels, drifts, or vertical or inclined shafts (slopes), depends primarily on the conditions governing the development of any mineral deposit, viz: topography, together with the pitch and physical characteristics of the seam (Art 14–20). For modifications in development to provide the special ventilation needed in coal mining, see Art 104, 108.

Stripping (open-cut mining) is sometimes adopted for coal seams, or parts of seams, near the surface (Art 100).

103. CHOICE OF METHOD

The best method in any case is that which will yield a max recovery at a min cost per ton, in the best marketable condition, and with least danger to the miner.

General factors influencing choice and details of method are as follows: ROOF PRESSURE is an indeterminate quantity varying with thickness of overburden. In longwall mining, a roof that hangs over moderate areas and settles gradually may help break down the face, but in general, where longwall is used, a roof that breaks "clean" at a moderate distance from the face is of greater advantage, as it relieves the pressure and simplifies roof control. Much attention is now being given to roof control in connection with long faces and mechanical loading, and much of the success so far obtained from mechanical loading and the methods devised for it is attributable to control of the roof and roof pressure. In pillar-mining in general, heavy roof pressure requires larger pillars and smaller openings; this is especially true in thick seams, or in soft, friable coal. Failure to recognize roof pressure in working out a room-and-pillar system may cause a squeeze or general crushing of pillars, and loss of coal over large areas. This may occur during first mining, but oftener during robbing, where removal of even one pillar may transfer to adjacent pillars a wt exceeding their supporting power. Pillar methods are used in most American mines, under all conditions of roof pressure in both flat and pitching seams; but greater attention is now given to the adaptability of longwall and modified longwall methods to flat seams, where heretofore roof pressure and other conditions were considered unfavorable. CHARACTER OF ROOF AND FLOOR. The roof is the stratum directly above the seam. A good roof is self-supporting over moderate areas; other conditions being favorable, a greater recovery may be obtained in the first mining and less timber is required. These advantages disappear when the roof is self-supporting over large areas, because during robbing excessive pressure may be transmitted to pillars. The roof may be weak, as in the case of draw slate, with a stronger stratum above. If the weak stratum is thick enough to choke the room when it falls, equalization of press may be obtained, which is advantageous during robbing. Control of such a roof is difficult and dangerous, requiring much timber. In some regions, roof conditions are greatly improved by leaving a thin layer of coal unmined under the roof stratum; especially true where air and moisture cause flaking and disintegration. Character of floor also influences size of openings. Soft bottom requires narrow openings and large pillars, especially where firm coal is mined under strong roof. Pressure on pillars tends to force them into the floor, causing floor to bulge, known as "heaving bottom." A firm floor is always desirable. CHARACTER OF COAL. Strong coal may be mined by pillar or longwall. Mining soft, friable coal is always difficult, and in pillar methods requires large pillars. Flat seams of friable coal under heavy cover are best mined by longwall, if character of roof permits. INCLINATION AND THICKNESS OF SEAM. In general, the max allowable size of opening decreases with increasing pitch and thickness of seam. Friable coal in a pitching seam sometimes tends to run; this emphasizes the requirement of large pillars and small openings. Practice abroad favors longwall for pitching seams of moderate thickness; in U S practically all pitch-mining is done by pillar methods. PRESENCE OF EXPLOSIVE GAS AND DUST indirectly influences choice of method, but has a direct effect on details of all methods. Advancing longwall in a gassy seam involves constant danger of gob fires; hence, retreating longwall is preferable. In pitching seams containing occluded gas, coal often tends to break away from face and pillars (called "bumpy" coal), and requires narrow openings and large pillars (for discussion of this subject, see Sec 23). If there is danger from explosions of gas or more especially of dust, it is best to use a panel system (Fig 722), to confine explosions to small areas. Explosive dust also makes low-velocity air currents desirable and influences cross-section of airways (see Sec 23). PRODUCT DESIRED. Generally, the best method is that which will produce largest amount of lump coal; coal for coking is an exception (see Sec 34, 35). Wide faces produce the most lump coal; from this point of view under favorable conditions longwall methods are best. Excessive use of explosives should be avoided, and systems of loading and haulage carefully designed to avoid breakage. LABOR AND MARKET. In longwall, there must be a steady market and a steady class of labor; even a short stoppage may result in serious damage to the working face. In pillar methods, this is less important. ESTABLISHED WAGE SCALES AND WORKING CONDITIONS. Where, by agreement or custom, extra pay is required for certain types of work, as yardage for narrow work in entries or rooms less than

10 ft wide, brushing (breaking down) of top or lifting of bottom, gobbing (packing) of waste in the seam, or of draw-slate above the seam, timbering, and other items generally mentioned in wage agreements, it may not be possible to adopt the method most suitable for the physical conditions on account of its excessive cost. Freight rates. R R rates (and more recently trucking rates) are generally the factors governing shipments into market zones (except for special-purpose coals). These rates may directly affect choice of method; a mine having a favorable freight rate to a given market may be able to use a method giving greater recovery per acre than a competing mine without this advantage. Specification purchases. Large tonnages are purchased on certain standards of ash, sulphur, volatile matter, ash fusion, and Btu content. A system designed for mechanical loading, without auxiliary cleaning, may so alter the quality of shipped product, as compared with hand loading without auxiliary cleaning, as to eliminate the coal from a desirable market. Size of property (its available tonnage) may bear directly on choice of method, by limiting the equipment investment. Thus, a relatively small property, physically capable of development by a system employing mechanical loading, may be unable to employ the system if, to produce a marketable product, additional investment in a cleaning plant is required (Sec 34, 35).

104. ROOM-AND-PILLAR METHODS

General. Because of the frequent presence of explosive dust and gas (Sec 14), thorough ventilation is more important for coal than for metal mines. This requires driving development openings in sets. Fresh air enters by one or more openings, the intake, and after passing through the workings the foul air leaves the mine by other openings, the return.

Development in flat or slightly pitching seams. Single-entry (rarely used, see Sec 14). A single opening is driven, from which rooms are turned off in one or both directions (Fig 700). The entry acts both as a main haulageway and an intake airway. The ventilating current circulates as shown. A fall of roof may cut off the flow of air. Fig 701 shows a typical double-entry layout. Main entries are driven from the shaft, or from the surface; from these, cross or butt entries are opened. Rooms are turned off the cross entries. The cut shows the split system of exhaust ventilation (Sec 14), the main haulageways being intakes. Advantages: (*a*) in case of accident in one entry, the other affords an escape; (*b*) the mine is divided into separately ventilated sections, so that a fall of roof or complete closure of any pair of butt entries will not affect ventilation in other parts of the mine; (*c*) main or cross entries may be driven ahead as far as desired and ventilation maintained without turning off rooms. Fig 702 shows triple-entry applied to main entries, with double-entry in cross entries. The middle entry is the main intake and haulageway; the outer ones form the return. While involving more narrow work than double-entry, this system is well adapted to gaseous mines of large working area; it is also used where local conditions (bad roof, etc) prohibit driving a single entry of sufficient width for double-track haulage; the middle entry is then used as the return and the outer entries as intakes and haulageways. In quadruple-entry, 4 main entries are driven in parallel (Fig 703), each side of the mine being served by a separate intake and return. One intake entry may be used as a traveling way, and the other as a haulageway, or both as haulageways. This system facilitates circulation of large volumes of air and is well adapted to high-speed endless-rope haulage (Sec 11). By leaving the center pillar intact, *i e*, eliminating the break-throughs *B*, the two sides of the mine become wholly independent of each other, and may be considered as distinct mines, each opened by double-entry. Quintuple-entry is the same as the preceding, with addition of one more entry, used as a traveling way.

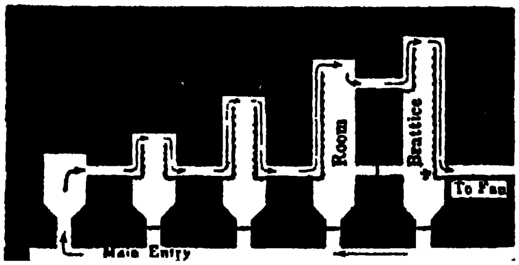

Fig 700. Single-entry System in Flat Seam

Entries in flat or slightly pitching seams. Size of entry depends on two factors: (*a*) Entries must be large enough to insure adequate ventilation. State laws prescribe a minimum quantity of fresh air per man or animal, and a max velocity of current (Sec 14). Airways should have the min perimeter for a given sectional area; a square entry is preferable to a rectangular one. In haulageways, height and width are influenced by size of car and mode of haulage. (*b*) Cost of maintaining wide openings may be prohibitive if roof is bad, or the floor has a tendency to heave, or the coal is friable or easily crushed; in such cases, narrow entries, while costly to drive, are in the end an economy. In seams containing more or less waste, or in thin seams, where floor or roof must be blasted to secure headroom, entries are usually driven 16 to 20 ft wide and then narrowed to 6 to 10 ft by building the waste into a packwall along one of the RIBS (Fig 704). (Rib is the face of solid coal along the side of a working.) Extra cost of driving is partly or wholly paid for by the coal taken out and transport of waste is eliminated. DISTANCE BETWEEN ENTRIES. Main entries in flat seams are commonly driven on 30–60-ft centers, leaving, for a 10-ft entry, a 20–50-ft pillar. Large pillars are required to protect main entries during life of mine. Cross entries need not remain open after the area served is exhausted; they are on about 30-ft centers, leaving a 20-ft pillar for 10-ft entry. For economy in driving, entries should be as close together as possible to reduce cost of breakthroughs. Distance between sets of cross entries depends on length of room and method of mining; length of room depends on character of roof, floor, and coal, system of haulage and ventilation. Rooms are commonly 300–350 ft long and, where turned in one direction only, give a gross entry spacing of 350–400 ft. Where turned in both directions, spacing of cross entries is 700–800 ft, or twice the length of rooms, plus suitable pillars if desired. DIRECTION AND LOCATION depend largely on size and shape of the property, surface conditions, cleavage or CLEAT of the coal (in bituminous mines), dip, amount of water, etc.

Fig 702. Triple-entry System (Coal Miners' Pocketbook

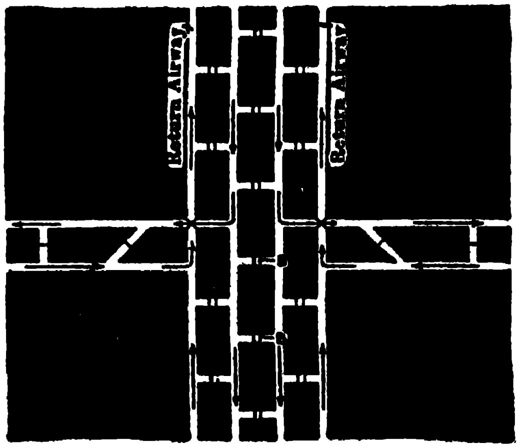

Fig 703.' Quadruple-entry System

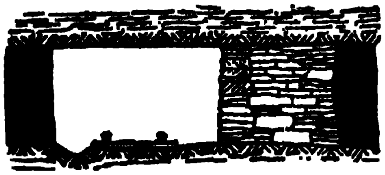

Fig 704.

Main entries should be located approx to bisect the property. In mines opened by drifts, this allows development in 3 directions, reduces length of cross entries and permits final robbing at an earlier date, decreases cost of protracted maintenance of long haulageways, facilitates haulage, and permits material increase in output on shorter notice. To favor haulage and drainage in slightly pitching seams, main entries are driven directly on the pitch and cross entries approx parallel to strike. In bituminous coal, the cleat may alter this plan, as the cost of driving is often increased if entries are not parallel to one of the pronounced cleavage planes. ALINEMENT AND GRADE should be uniform. Curves increase frictional resistance and wear and tear on track and rolling stock. Bends in airways increase friction and hence reduce efficiency of ventilation. Uniform grade is essential for efficient haulage and drainage. Cross-entry haulageways usually have a slight grade (0.75 to 1.5%) favoring the load. To obtain this it may be necessary to blast top or bottom rock and to fill local depressions. Cross entries in slightly pitching seams may be driven at an angle to the strike to secure any desired grade. The following formula (355) is useful: *sin A* = *tan X* ÷ *tan Y*, where *A* = angle between cross entry or rooms (if on a grade) and strike line; *X* and *Y* = pitches of cross entry and seam, degrees (Tables 88, 89). Angle between rooms and cross entry = angle between rooms and strike line + angle between main entry and strike line. Sharp curves from main to cross entries should be avoided; sometimes done by driving diagonal CUT-OFFS.

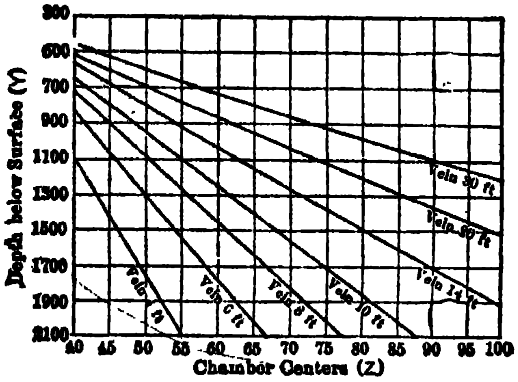

Fig 705. Relation between Depths and Room Centers for Different Thicknesses of Seam for 20-ft Rooms

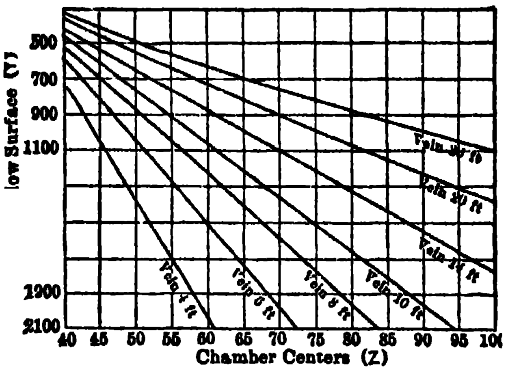

Fig 705*a*. Relation between Depths and Room Centers for Different Thicknesses of Seam for 24-ft Rooms

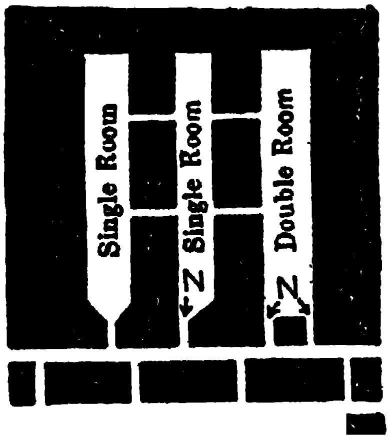

Fig 706

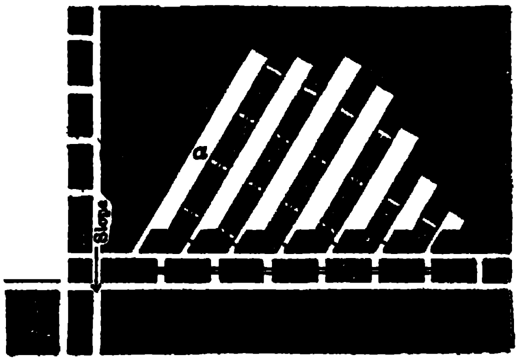

Fig 707

Rooms and pillars in flat or slightly pitching seams. Rooms are usually turned off at right-angles to the entry in one or both directions, depending on system of mining and dip of seam. From the NECK *N*, Fig 706, of about the same width as the entry and 10 to 30 ft long, the room is widened on one or both sides. Aver width of rooms in the U S is 24 ft; their length varies with local conditions, custom, and method of working. Table 89 (355) is useful in laying out rooms driven at an angle to the entry.

D. Bunting (368) gives the following formula for proportioning pillars in deep Penna anthracite seams of flat pitch: $yz = 1\,000 \times \left(0.70 + 0.30\frac{b}{h}\right) b$, where y = depth below surface, ft: z = distance center to center of rooms, ft; b = width of pillar, ft; h = total thickness of seam, ft.' It is assumed that the weight of the overlying strata is 144 lb per cu ft and that the safe load on a cube of anthracite is 1 000 lb per sq in. Fig 705, 705a, platted from this formula, gives results corresponding with practice in Penna.

Bunting states that, in the application of any formula to the calculation of the size of pillars necessary to resist the press of overlying strata, consideration must be given to the nature of the seam and its contiguous strata, and to the dip. Moreover, the proper factor of safety varies with local conditions, such as the relative location and extent of workings, and the seriousness of possible disturbance to the overlying strata and surface.

Where conditions permit wide openings, double rooms may be used; they have 2 necks and are usually served by a track on each rib, gob being stored in the middle. Fig 706 shows types of single and double rooms. Haulage in rooms, unless mechanical, becomes difficult on pitches of 6° to 8°; rooms may then be turned off obliquely (Fig 707); this means of reducing haulage grades in rooms is feasible in seams pitching to 12°; calculations for grade are made as for oblique entries (see above). This practice increases the difficulty of robbing pillars.

Influence of cleat. Bituminous coals usually contain two cleavage planes or cleats, running approx at right-angles to each other. Advantage is taken of them to facilitate breaking down the coal and to release occluded gas by driving the rooms at different angles to the more pronounced cleat. Face cleats are longer and more regular than end cleats. Fig 708 shows methods of driving. In driving face-on, the face of the room is parallel to the face cleats. This is the general method where conditions permit; it requires less powder and undercutting than the others, and yields more lump coal. In long-horn work, the room face makes an angle less than 45° with the face cleats. Coal breaks in long slabs and with well placed shots there is a fair yield of lump coal. In half-on work, the room face is at 45° to the cleats; adapted to coals breaking equally well on face and end cleats. In short-horn work, the room face is between 45° and 90° to the face cleats; adapted to cases where pronounced end cleats require that added support be given to the coal face and bears the same relation to end-on work that long-horn does to face-on. In end-on work, the room face is parallel to the end cleats; this, with short-horn, is adapted to withstand strong roof pressures, but yields less lump coal than other methods. In coals containing occluded gas at high pressure, face-on methods may cause violent

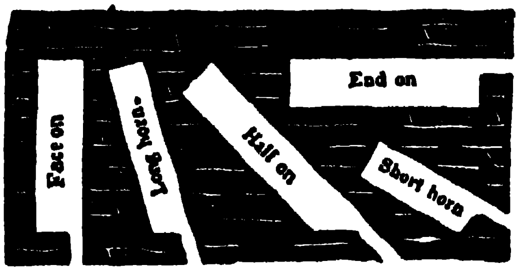

Fig 708. (Coal Miners' Pocketbook)

outbursts of gas, whereas end-on rooms cut the face cleats and allow gas to escape gradually. Under these conditions, by using long-horn or short-horn methods, the pressure of gas may be controlled and utilized to assist in breaking down the face.

Development in pitching seams. The following notes describe Penna anthracite practice, which may be considered standard for the U S. As in flat mining, development openings are driven in pairs, consisting of a haulageway or GANGWAY, and an airway or MONKEY. These openings are connected by CHUTES, corresponding to the breakthroughs of flat mining. In thick, gassy seams, an extra monkey may be added, to provide a separate split of air in each working place. Fig 709 shows typical development for moderately thick seams; for variations, see Art 106. SIZE OF GANGWAYS depends more on size of car and method of haulage than on character of coal, roof, or floor, and thickness of seam. Gangways for mule haulage are commonly 7 ft high by 10 to 12 ft wide in the clear. For mechanical haulage the height may be less, though good practice leaves at least 2 ft clearance above top of car. DIMENSIONS OF MONKEYS depend primarily on air requirements (Sec 14); thus, if an area of 36 sq ft is required to pass the air needed in a

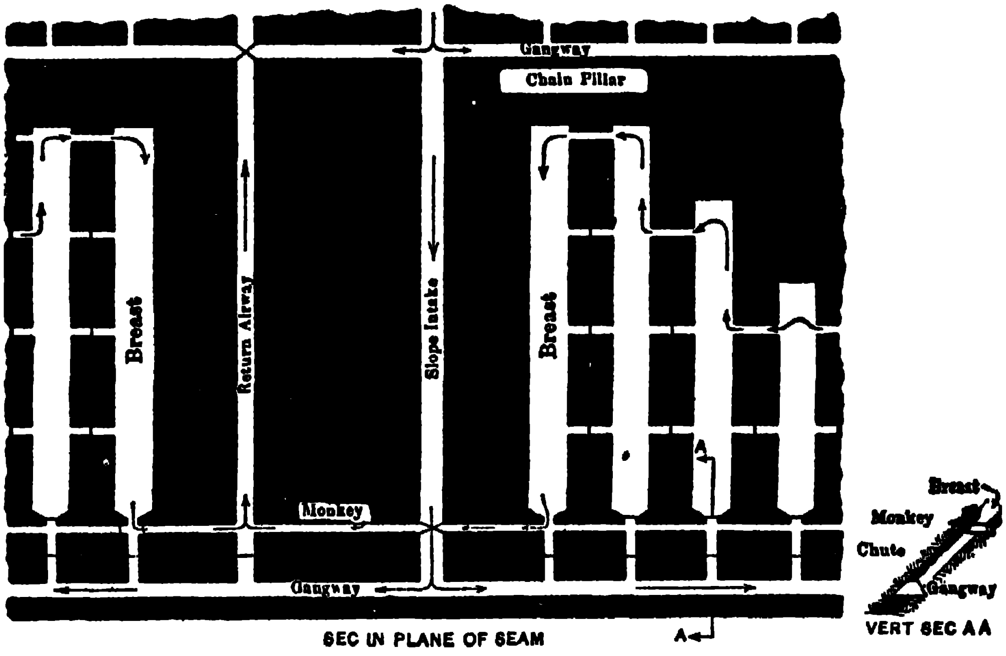

Fig 709. Typical Development of a Pitching Anthracite Seam, Penna

split without undue friction, a monkey in a 6-ft seam would be 6 ft high. DISTANCE BETWEEN DEVELOPMENT OPENINGS. In Penna, the distance between gangway and monkey in moderately thick seams is commonly 30 ft. In thick seams, this distance depends largely on whether the monkey and gangway are on the same or opposite walls of the seam. It is customary to space gangways 300 ft apart along the pitch, leaving a CHAIN PILLAR 20 to 50 ft wide (along the pitch) underneath each gangway (Fig 709). This allows a breast length, including the chute, of 250 to 280 ft. In thick-seam mining, on pitches over 40°, it may be advantageous to divide a lift of 300 ft in half by driving a COUNTER OR BUGGY gangway. In many cases small mine cars, "buggies," are used on counter gangways; if so, the coal is lowered to the main gangway through COUNTER CHUTES (Art 106). Standard cars on counter gangways may be lowered by gravity planes (Sec 11), or the coal handled in counter chutes. Advantages of counter gangways are increased safety and better facilities for ventilation and handling timber. DIRECTION, LOCATION, AND GRADE OF GANGWAYS. Gangways are driven in the seam, following its contours along one wall, and are on a grade of 0.75 to 1.5% in favor of loaded cars; they are usually turned in both directions from the main openings. BREASTS correspond to rooms in flat mining. Experience shows that moderately thick seams may be worked most economically by driving breasts 24 ft wide, on 50-ft centers, and not exceeding 300 ft long. Variations in dimensions, due to character of roof and floor, and texture and thickness of coal, are much the same as in flat seams. Friable coal in a pitching seam is

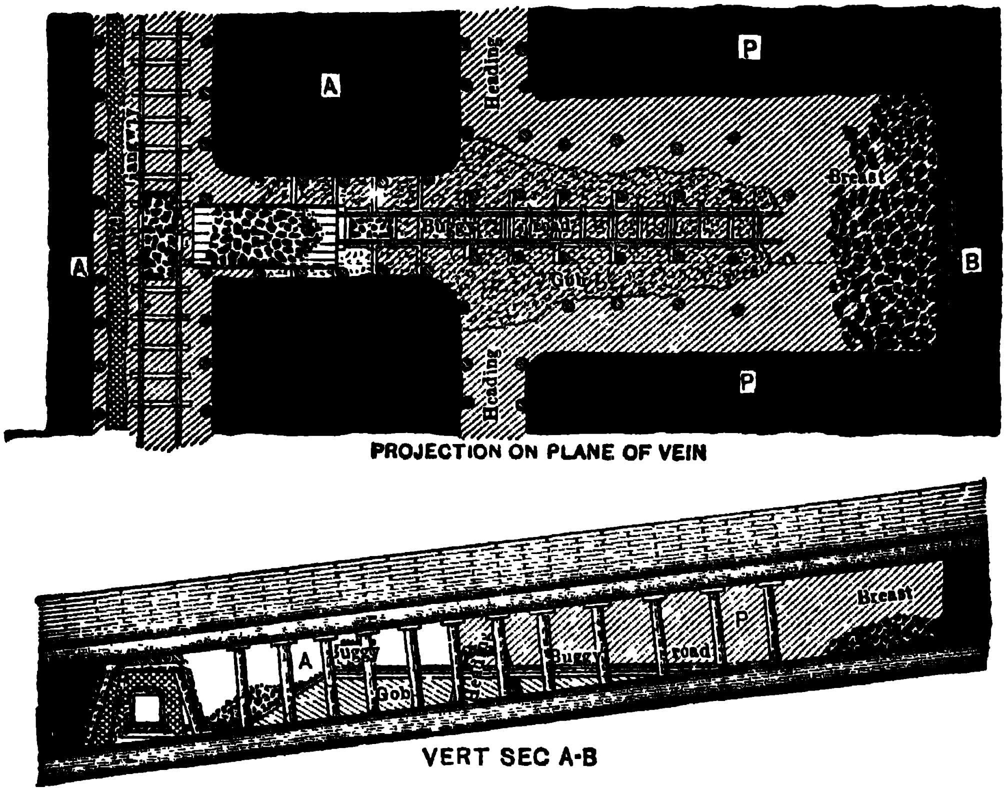

Fig 710. Buggy Breast (after Chance, Vol AC, 2nd Geol Surv Penna)

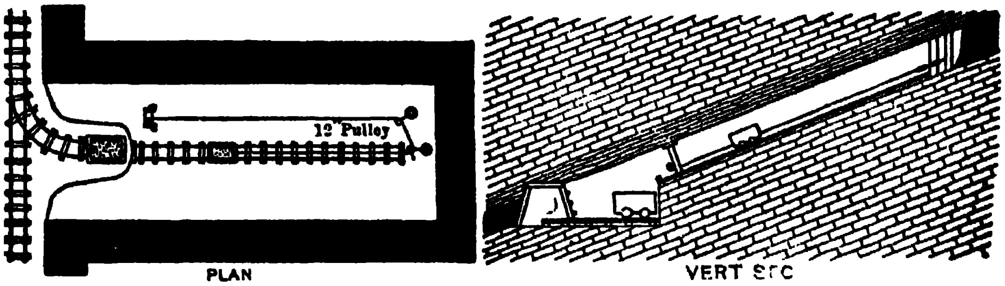

Fig 711. Buggy Breast (Coal Miners' Pocketbook. Pitch exaggerated)

apt to break away from the face and ribs, causing a "run-away" with more or less disastrous results; in such coal, narrow, well timbered breasts are essential.

Classification of breasts according to their pitch. Wagon breasts correspond to rooms in flat mining and are used where pitch is less than 12°. Full-size mine cars are run to the face and loaded by hand or conveyers; shaking chutes or scrapers may be used to transport coal from the face to cars placed on the gangway. Buggy breasts (Fig 710, 711) dip 10°–18°; small cars (buggies) transport coal from face to cars on the gangway. Buggies have been largely replaced by conveyers, shaking chutes, or scrapers (Sec 27). Chute breasts. For pitches over 15° and less than 30° to 35°, a chute lined with sheet iron (usually No 16 gage) conveys coal from the face to a loading platform at the gangway (Fig 712). On dips less than 20°, the coal must be pushed along the chute, or mechanical drags may be used. Rock and refuse are gobbed on the sides of the chute. When the pitch exceeds 35°, coal will generally slide on the bottom rock; the sheet iron is then eliminated and planks set against the two rows of props guide the coal to gangway. Steep breasts worked empty. As the dip increases, the working of empty breasts becomes increasingly difficult and dangerous, and the breakage of coal a serious item. Dips of 40° to 45° are probably the limit for safe and economical empty work. Breasts pitching

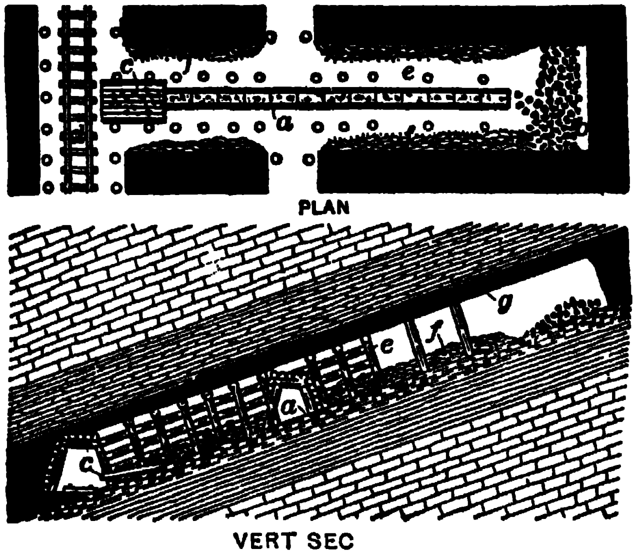

Fig 712. Chute Breast (Coal Miners' Pocketbook). *a*, Sheet-iron chute. *c*, Loading platform. *e*, Props. *f*, Gob. *g*, Top coal

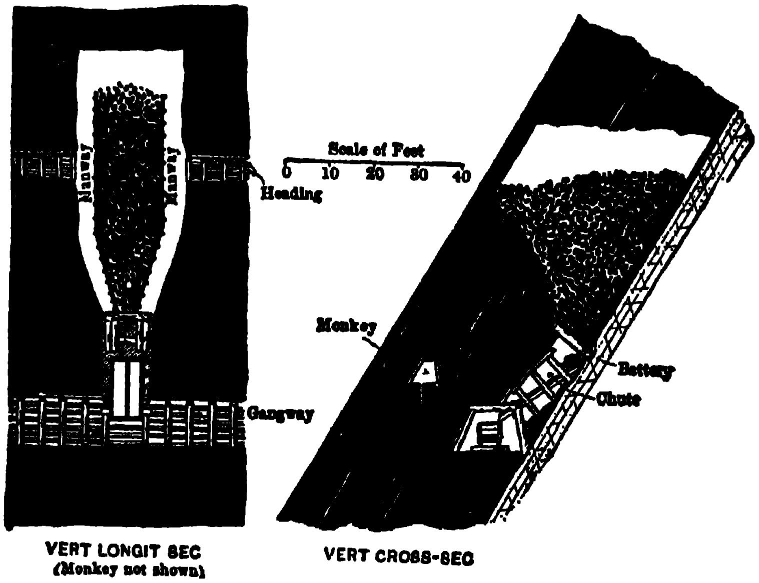

Fig 713. Battery Breast, Mammoth Seam, Hazleton, Penna (after Chance)

55° to 60° have been worked by a staggered battery method (Art 106), but the practice is bad and should be avoided. Battery breasts, used in steep pitching seams, resemble shrinkage stopes in metal mines (Art 68). At the head of the chute (Fig 713) is a battery or gate, consisting of props heavily lagged or planked. From this point the breast is widened as required; manways are carried up each side and the broken coal is retained in the middle by lagged or planked props. The broken coal supports the miners; it occupies approx 50% more volume than solid coal. To give headroom at the face, excess broken coal is thrown down one of the manways and drawn off daily at the gangway.

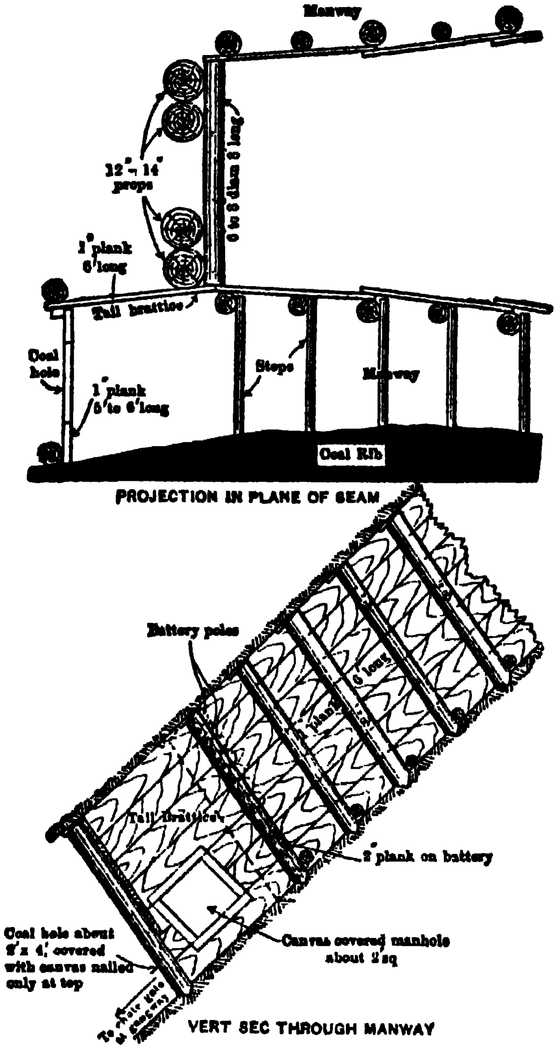

Fig 714. Battery Construction

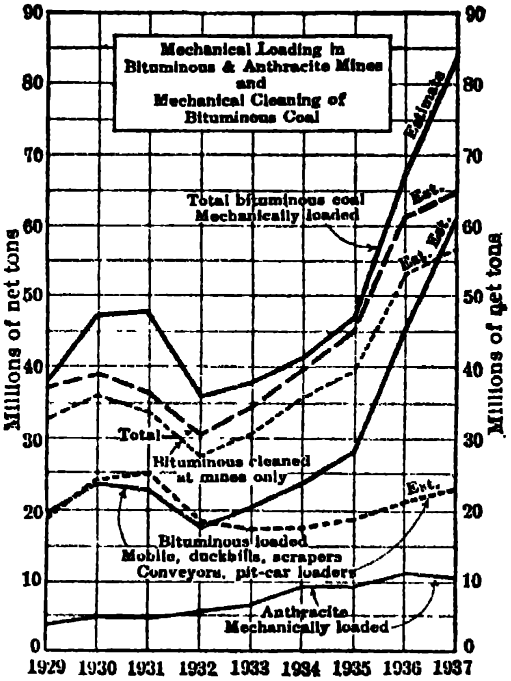

Fig 715

When the breast is finished, the broken coal is drawn through the battery as desired. Fig 714, by W. L. Cross, Jr, shows typical construction.

Mechanization of coal mines. Like all other mass-production industries, coal mining seeks to eliminate hand labor. In hand-loading mines in the U S, the labor cost probably exceeds 60% of total cost of production. As wage scales increase, this percentage increases, and the cost of production puts coal at a disadvantage compared with oil, gas, and elec power, in the production of which the percentage of labor cost to the total is relatively small. Coal operators are therefore adapting the established methods of room-and-pillar, panel, longwall and modified longwall, to the use of mobile loaders, conveyors, shaking chutes, and scrapers (Sec 27). Besides mechanical loaders, elec coal drills, hand-held, post- or track-mounted, and track-mounted cutting and shearing machines of large capac are being installed.

From statistics of the National Bituminous Coal Comm (672) Fig 715 shows tonnage of anthracite and bituminous coal mechanically loaded in U S mines from 1929 to 1937, and tonnages of bituminous coal mechanically cleaned in the same period. Table 90 shows equipment used in bituminous mines in 1936. N B C C estimates percentage of U S coal production mechanically loaded at 12% in 1933 and 16.4% in 1936, exclusive of coal from strippings.

105. EXAMPLES OF ROOM-AND-PILLAR MINING IN FLAT SEAMS

(See also Tables 87, 88)

Georges Creek district, Md. Data from H. V. Hesse in 1909 (357). Fig 716 shows unsystematic methods employed in 1850 for a bituminous seam 6–9 ft thick. All workings were at random, with no attempt to recover pillars; 55% of total coal, not including top coal left standing for a roof, remains and makes reworking or robbing difficult and costly. This old example shows necessity for systematic mining to secure max recovery. In this seam, narrow rooms and wide pillars are required by the character of roof and coal. Fig 717 shows a recent systematic plan of working, evolved after numerous experiments. Most of the coal is obtained by robbing (Art 107); total recovery of 94% is claimed.

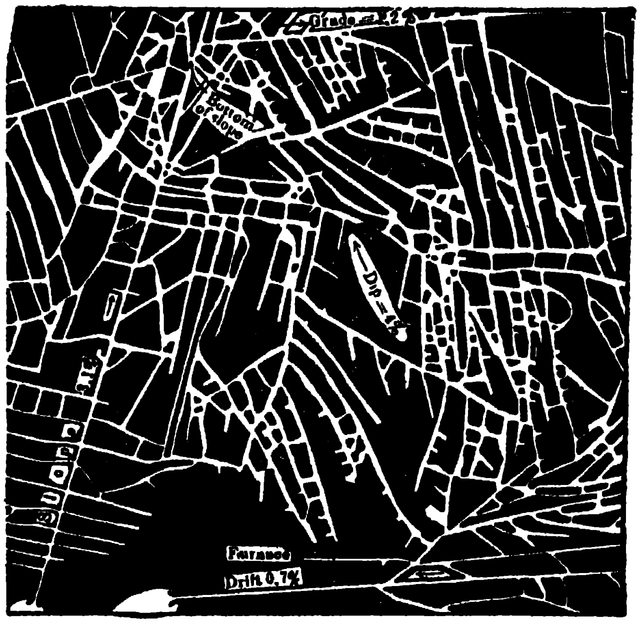

Fig 716. Unsystematic Mining, Georges Creek, Md

Pittsburgh region. Data from F. Z. Schellenberg in 1910 (358) and Pittsburgh District Committee on Coal, of the A I M E, in 1926 (606). Seams are regular, permitting systematic development; a pronounced cleat in the Pittsburgh seam is an important factor in laying out workings. Where pillars are not drawn, rooms are 20–25 ft wide and 200–300 ft long, with 8 to 10-ft pillars. Rooms are often turned off butt entries, and driven with their faces on the face cleats. With pillar-drawing, panel systems are used, most of the faces being at right-angles to the butt face cleats. Standard length of rooms, 200–300 ft; width, 10–20 ft; headings, 8-10 ft wide, are 2 to 6 in number, spaced 35–50-ft centers, according to the ventilation and haulage requirements, the overburden, and life of the entry in question.

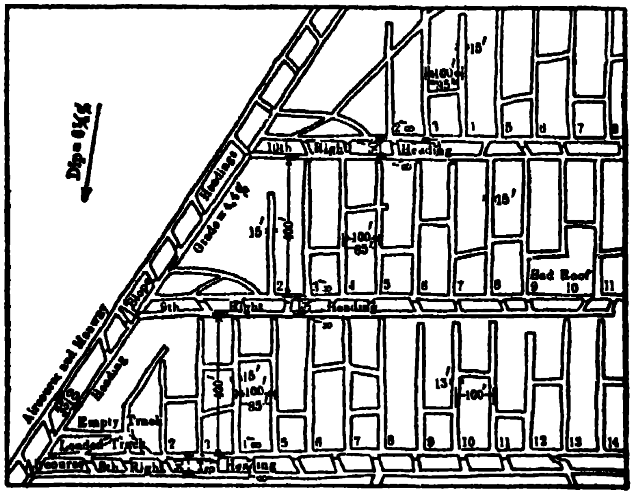

Fig 717. Systematic Mining, Georges Creek, Md

Pittsburgh seam throughout this district is 4.5–9 ft thick; dip, 0°–6°; recoveries from mining, 55–90%. Fig 718 shows standard method in the Connellsville region; Fig 719, Fairmont district, northern W Va; Fig 720, Pittsburgh Coal Co; Fig 721, 722, general method of Monongahela River Consol Coal and Coke Co. Panels are 500–600 ft wide by 1 400 ft long; rooms are usually turned in both directions from the butt entries. Pillars are robbed during either advance or retreat; faces of robbing operations are at 45° to the butt entries.

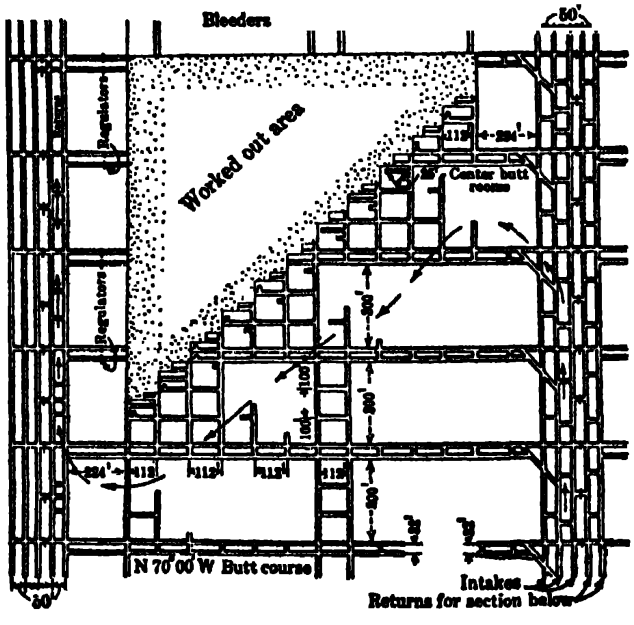

Fig. 718. Standard Mining Method of Advancing and Retreating, Pittsburgh Seam, Connellsville Region, Penna (606)

West Virginia. Due to the regularity of the seams, definite systems of mining are planned and carried out with only slight variations to meet local conditions. Main entries are triple or quadruple; section entries, triple or double; cross entries, double. Panel systems are common. Usual dimensions are as follows, with exceptions noted below. Main and section entries are at 40–60-ft centers and 8–12 ft wide; cross entries, 30–50-ft centers, 8–12 ft wide; interval between pairs of cross entries, 400–600 ft; rooms, on 40–80-ft centers, are 15–30 ft wide and 200–400 ft long; interval

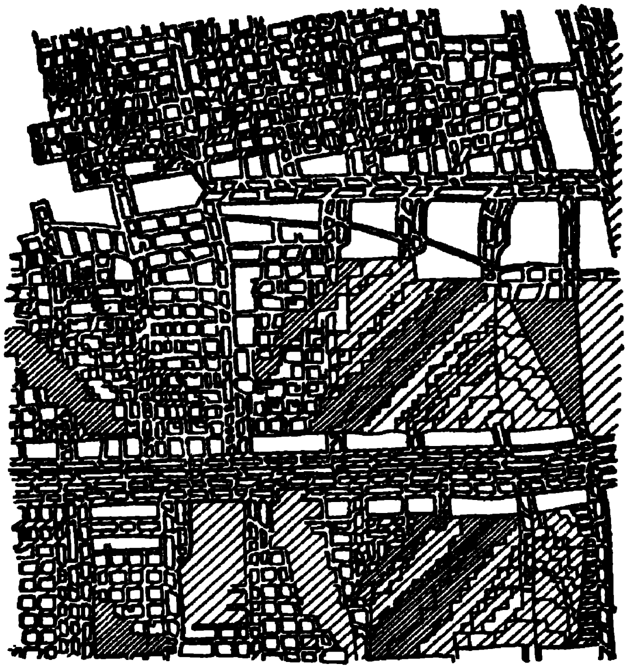

Fig 719. Mining in Fairmont District, W Va

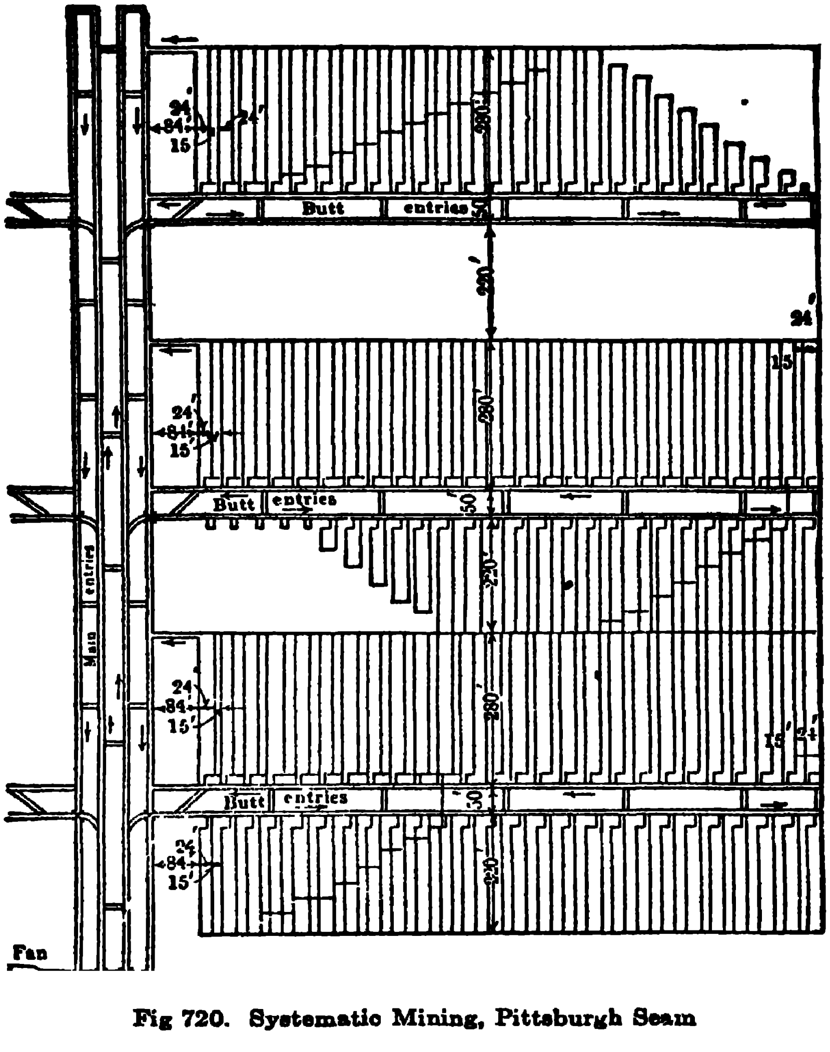

Fig 720. Systematic Mining, Pittsburgh Seam

between crosscuts in entries, 75–100 ft, in rooms, 100 ft; barrier pillars, 100–200 ft wide. **Mona mine**, Arkwright Coal Co, Morgantown, W Va (359). Pittsburgh seam, 8 ft thick, of which 7 ft is mined and 1 ft left on top to support draw slate 3 to 6 ft thick. Productive territory is developed by pairs of butt entries on 60-ft centers, at intervals of 300 ft. Butt entries, 11 ft wide, are driven

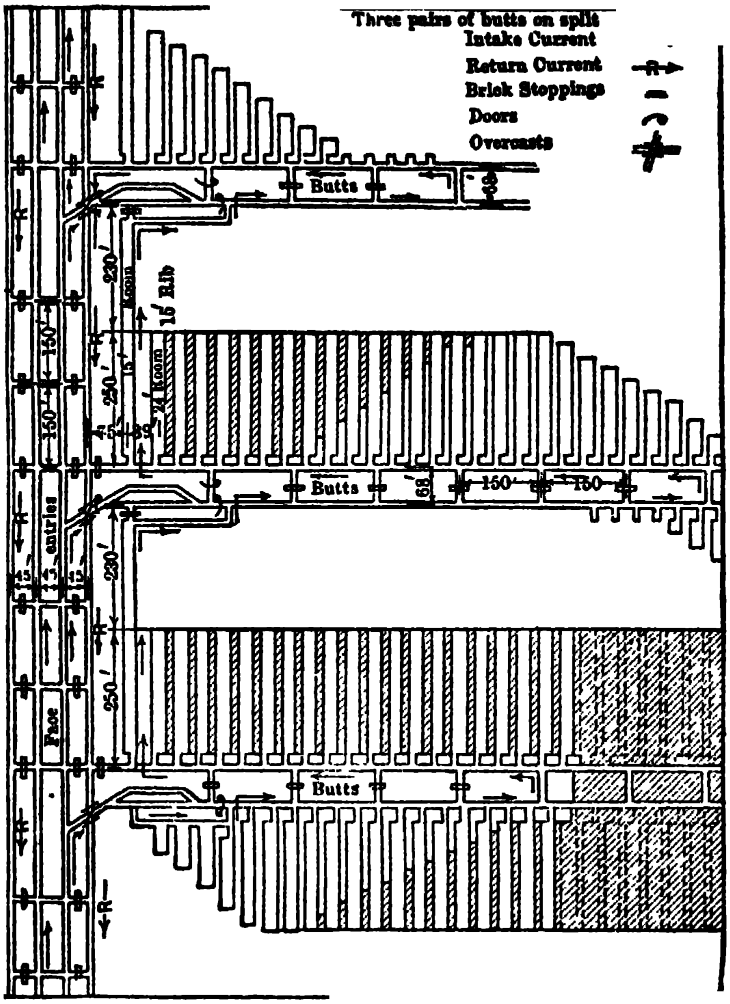

Fig 721. Systematic Mining, Pittsburgh Region

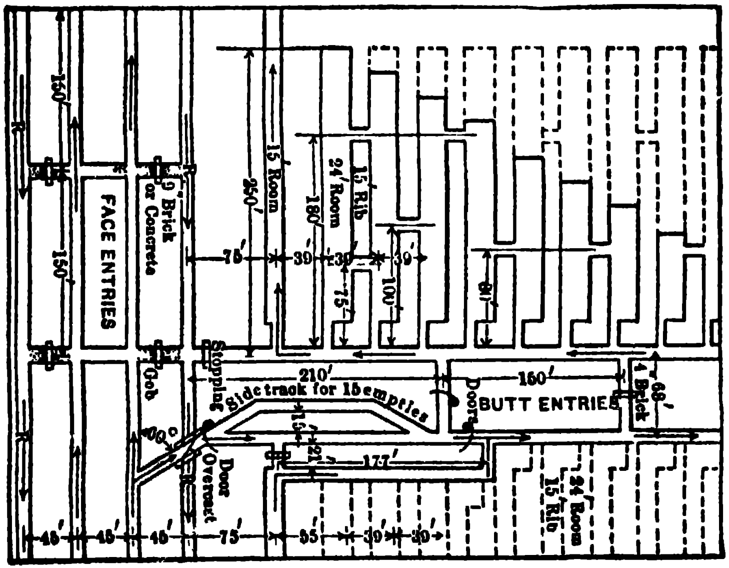

Fig 722. Detail of Fig 721

950 ft to accommodate 14 rooms on 60-ft centers, leaving a 150-ft barrier pillar between face entries and first room. Rooms are turned off the inby butt entry only, and are driven to the outby entry of the next pair of butt entries; rooms 11 ft wide; pillars, 49 ft. Most of tonnage is recovered on retreat, and roof control is successfully accomplished by maintaining a 45° pillar line Coal faces, both on advance and retreat, are top-cut and sheared by a Universal-type, track-mounted machine cutting a 6-in kerf. Drilling is by track-mounted, elec auger drill; loading by a track-mounted, elec loader. In retreat, room pillars are extracted by a series of 15-ft cuts, leaving small "fender" blocks of coal next to the gob (Fig 723), which keep the gob from rolling into the fall of coal. Fig 724 shows method of breaking ground in advance and retreat. Pocahontas field. **Seams, 3 to 10 ft thick. Fig 725 shows the general development plan of the Pocahontas Coal and Coke Co,**

providing for quadruple main entries, triple cross entries, and double panel entries; alternative methods are shown in panels 1, 2, 3. The following directions, issued by the company, indicate the distinctions between these methods. Panel no 1. Drive the rooms on the 3rd cross entry as soon as they are reached. Begin robbing (Art 107) when the second room is completed, and rob advancing on the 2nd and 3rd cross entries to within 100 ft of the 2nd cross entry. On the

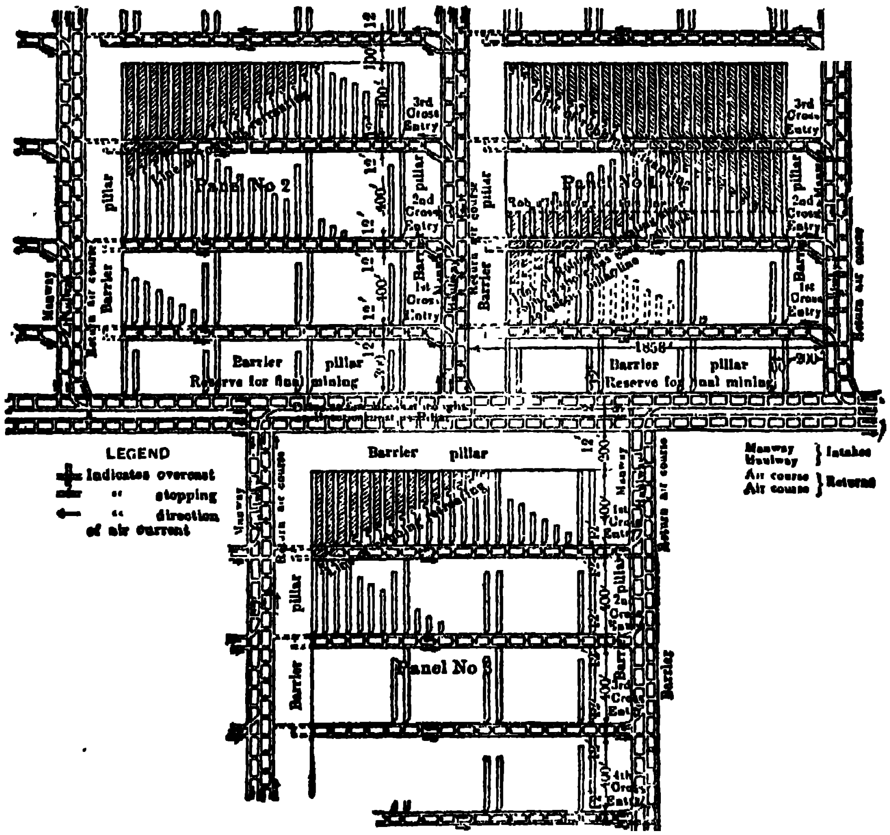

Fig 725. Mining in Pocahontas Field, W Va

1st cross entry drive the last room first and rob retreating, taking out the barrier pillar left on the 2nd cross entry. Panel no 2. Drive entries to the limit before turning rooms, except as shown. Turn last room and 3rd cross entry first. Begin robbing at inside corner of panel; develop rooms only fast enough to keep in advance of robbing and bring robbing back with a uniform "break-line," until completed to barrier pillars. Panel no 3 illustrates a continuous panel. Drive

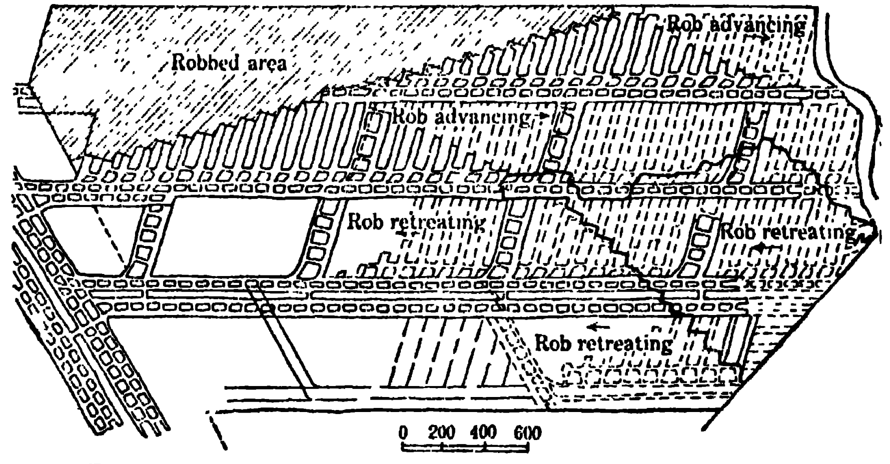

Fig 726. Room and Pillar, Mine No 6, U S Coal & Coke Co (607)

entries to the limit before turning rooms, except as shown. Turn last room on 1st cross entry first, and begin robbing as soon as the second room is completed. Develop rooms only fast enough to keep in advance of robbing, and bring robbing back with a uniform break-line until the limit of mining is reached. With uniform conditions, such plans can be quite closely followed (360). Mine No 6, U S Coal and Coke Co. Data from E. O'Toole in 1923 (607). The method (Fig 726) is

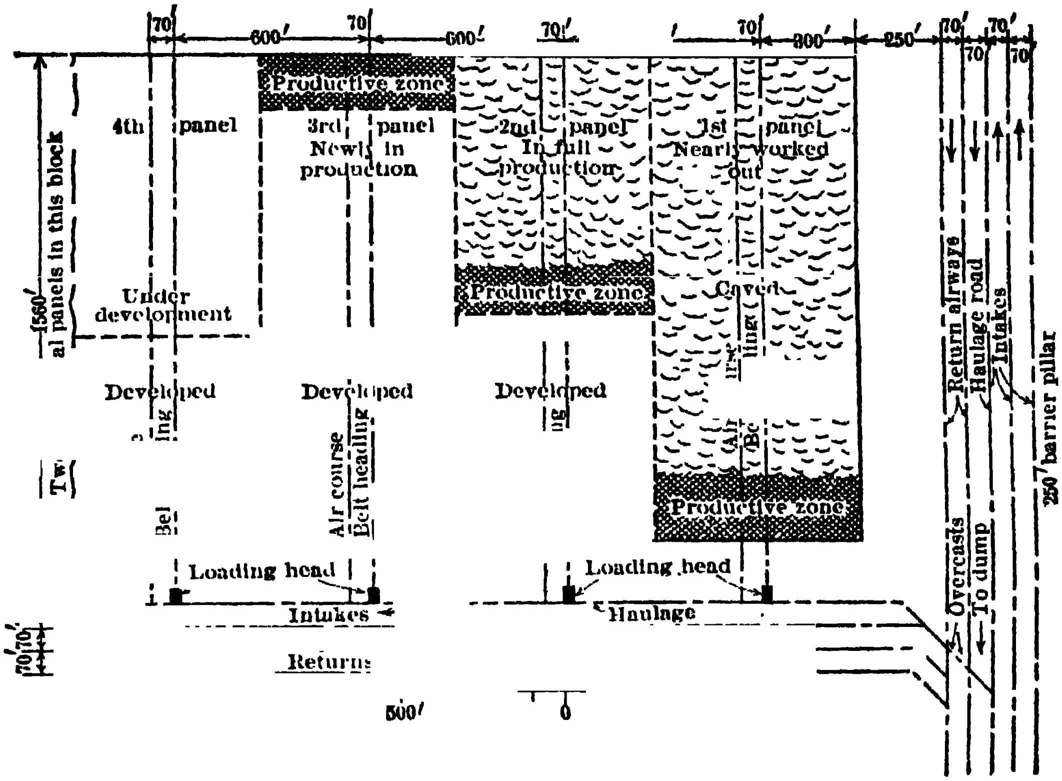

Fig 727. Mining System, MacAlpin Coal Co (490)

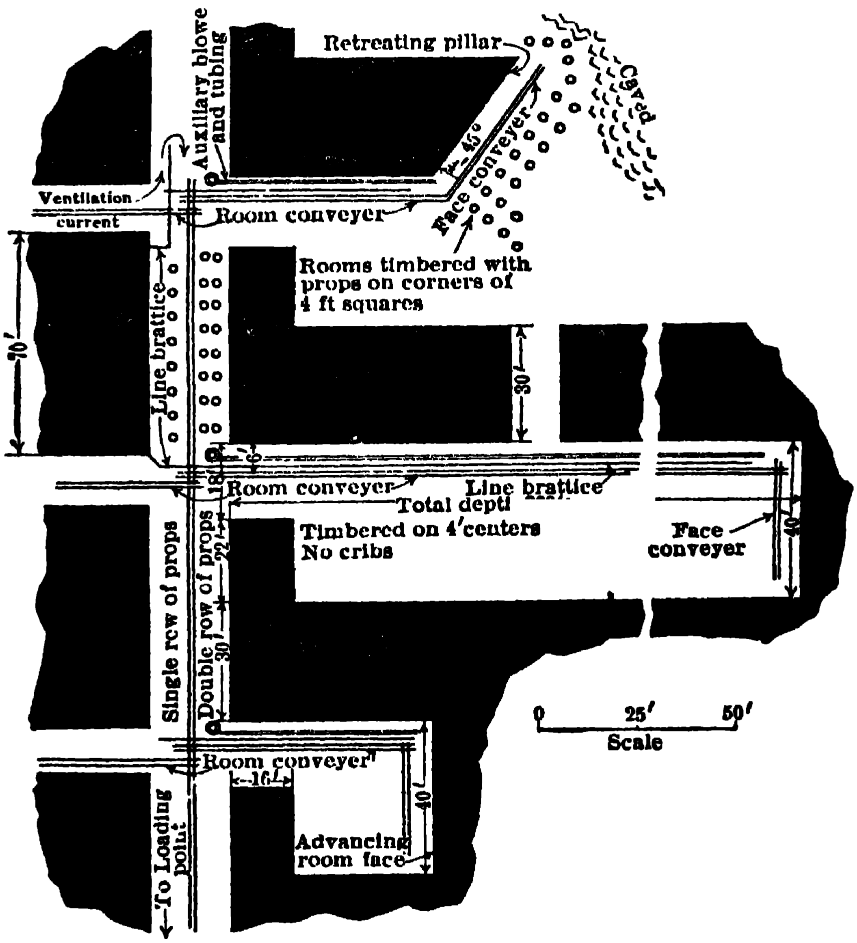

Fig 728. Typical Room Diagram, MacAlpin Coal Co (490)

a room-and-pillar continuous advancing and retreating system. While advancing, room ribs, heading stumps and heading chain pillars are extracted. During advancing period, headings are continually progressing, rooms being driven on the inby side. When the rooms reach their limits the pillars are withdrawn, resulting in complete extraction of the section. When robbing cuts a cross heading off from the main headings, haulage proceeds to another heading through a room. Each section is planned for 1 000 tons per shift. This method aims to give full production soon after beginning operations and maintain it until the mine is practically exhausted. Life of a section is 10–40 yr. The method affords simple ventilation, transport and drainage; it concentrates operations and permits max supervision. MACALPIN COAL CO, Mine No 4 (490). Pocahontas No 4 seam, 3 ft thick. System is room-and-pillar retreat; pillar drawing using chain-flight face and room conveyers and belt mother conveyers on panel entries; cars to slope and belt conveyers to tipple. As in Fig 727, main headings are in sets of 5; cross headings in sets of 4, and panel or room headings in pairs. Cross headings are on 2 200-ft centers; panel or room headings, 600-ft centers. All headings are 16 to 20 ft wide. Room necks, 18 ft wide, 16 ft deep. Rooms, 40 ft wide on 70-ft centers. Each panel contains 40 rooms, 20 driven from each heading. A cycle of mining is maintained on each panel heading, whereby the inby pillar is drawn as the 2 adjacent outby rooms are advancing. Heading pillars are also drawn. Fig 728 shows detail of room and pillar mining.

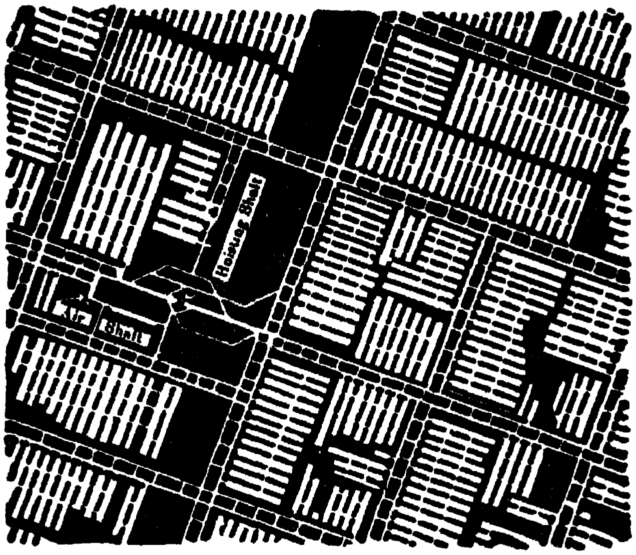

Fig 729. Block Room-and-pillar System, Ill

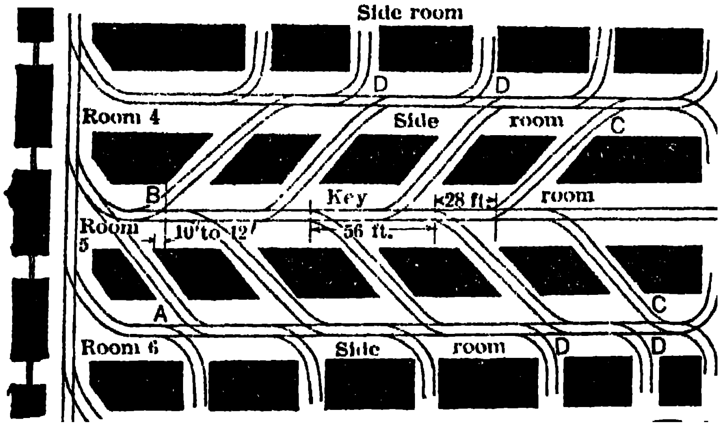

Fig 730. Room System, Peabody Coal Co Mine No 8, Ill (491)

Illinois. Seams are generally flat; aver depth, 200 ft. The coal is firm, with partings of varying widths; seams, 2.5–9 ft thick. Roof characteristics vary; floor is generally fire clay, likely to heave when wet. Straight room-and-pillar panel systems, and a modified panel system known as the "block room-and-pillar" or "semi-panel" (Fig 729), are all in use. For dimensions of openings see Table 91 (361). Some longwall mining is also done (Art 108). **Peabody Coal Co, Mine No 8, Christian County, Ill (491).** No 6 seam, 6 to 7.5 ft thick; 370 ft of overburden. Panel system of 30-ft rooms at 50-ft centers, 256 ft long. Panel entries are in pairs 12 to 14 ft wide on 42-ft centers; 21 to 37 rooms are turned from each pair of panel entries, every 7th room being omitted, to leave

† Minimum for district. * Max for district.
(*a*) Small section, worked by room-and-pillar.

a 70-ft pillar for roof control. Track-mounted horiz cutting machines and caterpillar loaders are used. To facilitate car change and loading, every third room is driven as a "key" room. As shown in Fig 730, the first crosscut in the key room is driven through into the side room, making sure there is enough pillar left between entry and crosscut *A*. Then the first crosscut to the left from key room is turned when the outside rib of crosscut is 10 or 12 ft past the inside rib of opposite crosscut *B*. This procedure, which staggers the crosscuts for roof protection, is carried out until the room is nearly finished. The last crosscuts are driven from the side rooms *C*, because the back switches in the side rooms make the car change much quicker. Each back switch has a switch directly behind it, *D*, to speed up the car change. Crosscuts in the key rooms aver about 56-ft centers, with 40-ft pillars. This makes the switches 56 ft apart on each side, but only 28 ft from switch to switch, counting both sides. MINE No 57, of same company, uses nearly the same system of panel mining and "key" rooms, but shear-cuts room faces and advances them as in Fig 731. Increased yield of lump is claimed. MOFFAT MINE, Moffat Coal Co, Sparta, Ill (634), is in the No 6 seam and was originally developed for hand loading. Rooms are 30 ft wide on 70-ft centers, with max length of 300 ft; breakthroughs on 50-ft centers. Gathering was first done by mules. Later, caterpillar loading machines were installed, as in Fig 732. The system was further modified, as in Fig 733, by using tractor-trailer (storage-battery) gathering units mounted on rubber tires. These are of 5-ton capac, bottom-dumping, and are run directly over the conveyer hopper when discharging. Another modification is planned, as follows: The 300-ft rooms will be lengthened indefinitely. Every 300 ft, 3 lines of crosscuts will be driven across a panel of 18 rooms, for haulage and air, with a line of stoppings outby the first line of crosscuts to advance the air supply. Each 18-room panel will have a hopper-conveyer unit, located centrally along the tractor-trailer haulageway. This will limit the max gathering haul to about 1 000 ft, and the aver haul to less than 600 ft. As two gathering units can then serve a loading machine, the territory will be subdivided into

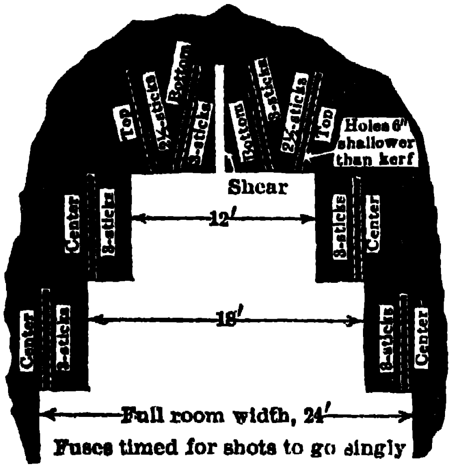

Fig 731. Breaking Coal in Peabody Coal Co Mine No 57, Ill (491)

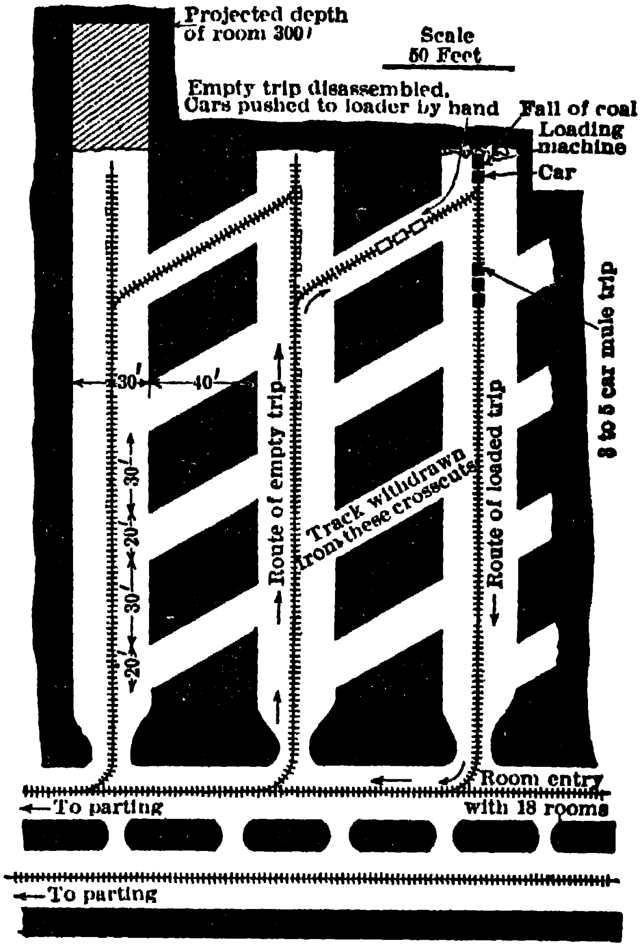

Fig 732. Mine-car Gathering Cycle, Moffat Mine, Ill (634)

2 sections, of 9 rooms each, on each side of the hopper-conveyer. Each section will have a loading machine, with auxiliary equipment. Thus the single conveyer will serve 2 loading machines and 4 tractor-trailers. Panel entries, parallel to the rooms, will be advanced by gang work as usual. Fig 735 shows the proposed method; Fig 734, the method of timbering.

Indiana. Panel systems of room-and-pillar work with double-entry development are in universal use. The following figures of practice of the Brazil Block Coal Co are fairly representative; seams are 4.7–10 ft thick; depths, 80–600 ft. Roof is sandstone or shale; floor, fire clay. Rooms, 18–30 ft wide, usually 21 ft; necks, commonly 9 ft wide and 12–20 ft long. Width of main-entry pillars, 18–40 ft; cross-entry pillars, 15–30 ft; room pillars, usually 9 or 10 ft wide, occasionally, 20 ft (362). SAXTON MINE, Saxton Coal Mining Co, Terre Haute, Ind (635). Seam No IV, 5 ft thick. Fig 736 shows typical production panel. Main entries are 11 ft wide, on 33-ft centers; room entries, 11 ft wide, 25-ft centers. While panel entries are advancing, the middle entry serves as haulageway; when a panel has been driven full distance, track is removed from middle entry, which then serves as return airway only. In each panel, 24 rooms are turned at 45° along each side entry. Rooms are 21 ft wide on 33-ft centers, and are driven to max length of 350 ft. Six subsidiary rooms are turned at 45° from the first room. Room panels, 594 ft wide, are separated from one another by barrier pillars 25 to 50 ft wide, thus making room-panel entries on 619 to 644-ft centers. By using wide rooms and narrow pillars, a recovery of approx 66% is claimed. In development work, the coal face is

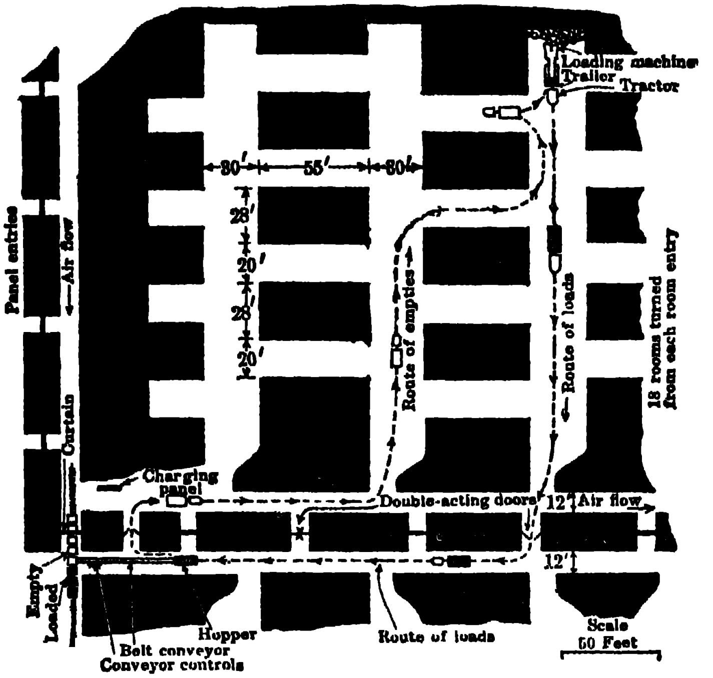

Fig 733. Tractor-trailer Cycle, Moffat Mine, Ill (634)

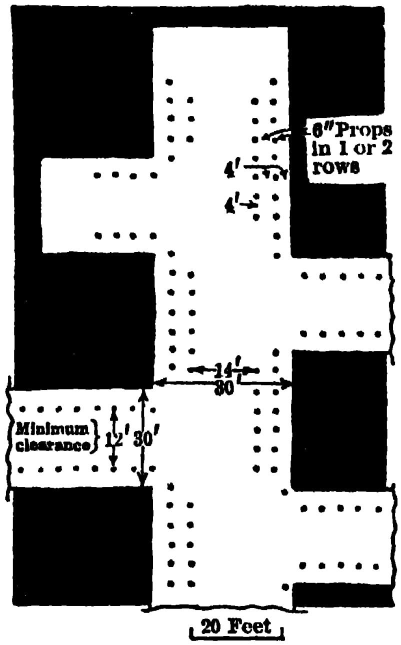

Fig 734. Timbering Diagram, Moffat Mine, Ill (634)

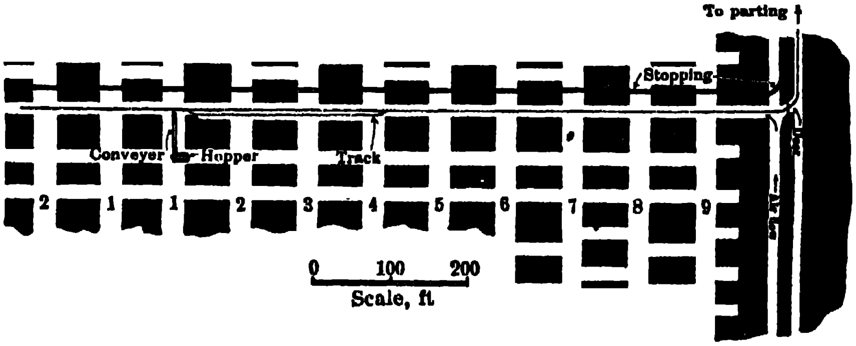

Fig 735. Mining System, Moffat Mine, Ill (634)

undercut its entire width and sheared from top to bottom above the right-hand rail. Depth of cut, 8.5 ft with 6-in kerf. Fig 737 shows mode of cutting and placing shots in rooms. Equipment includes track-mounted cutting and shearing machines, elec post-mounted auger drills, track-mounted shovel loaders in development entries, and track-mounted flight loading machines.

Ohio. Wheeling Township Coal Mining Co, Mine No 2, Adena, Ohio (639). Pittsburgh No 8 seam, 54–60 in thick. Draw slate, 11 to 14-in, is taken down, leaving a 12-in seam of coal as roof. Mine opened by drift under cover of 30 to 260 ft. Quadruple main and face entries are driven as 2 pairs, connected for haulage purposes every 600 ft. One pair serves as intake, other as return. Butt entries 8.5 ft wide are in pairs on 32-ft centers, turned on 484-ft centers at right-angles to face entries. Driving butt entries 1 635 ft allows for turning of 48 rooms 26 ft wide, 225 ft deep, on 34-ft centers,

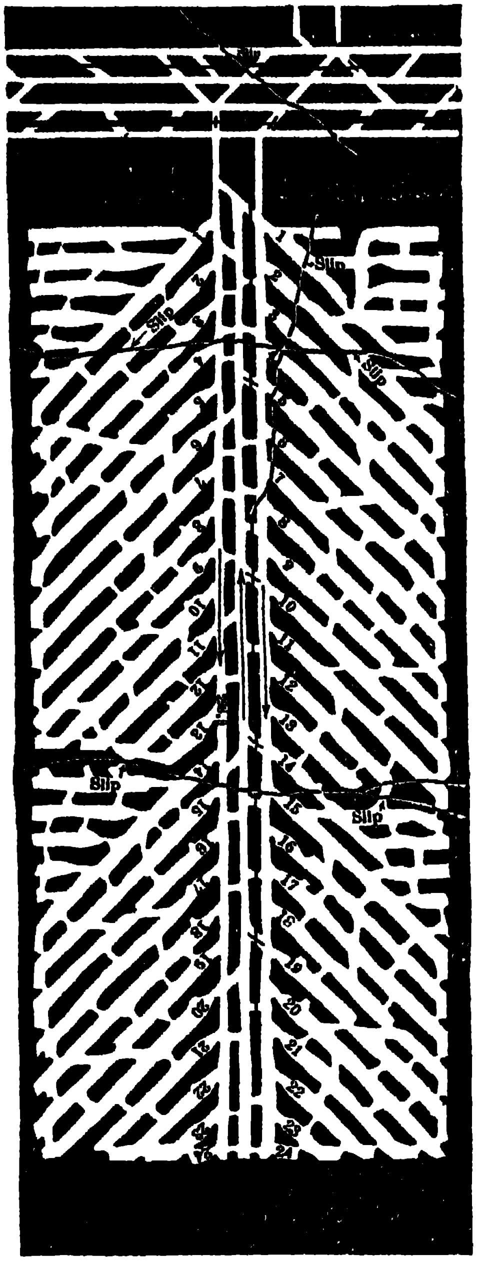

Fig 736. Panel in Saxton Mine, Ind (635)

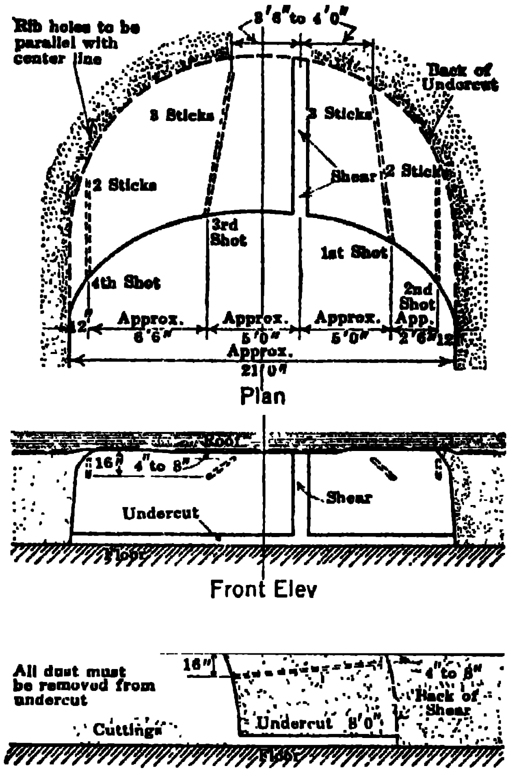

Fig 737. Breaking Coal in Rooms, Saxton Mine, Ind (635)

leaving a 136-ft pillar between first room and the face entry. Room necks are turned off butt entries at 55° and deflected to full 90° after 4 cuts. Necks are 12 ft wide to accommodate track-mounted cutting and loading machines. Every eighth room is omitted, giving 7-room panels separated by 42-ft pillars to control roof. After the butt entries have been driven the required 1 635 ft, production is obtained by simultaneously advancing blocks of 7 rooms off each entry. These rooms are completed before production starts on the next 2 blocks of 7 rooms each. No pillar recovery is attempted. Coal is loaded by caterpillar loading machines directly into 3-ton cars. Room face is undercut and sheared near its center by track-mounted cutting machine, making a 9-ft cut, 6 in wide. Four holes are drilled in the face with post-mounted elec auger drill of 1.5-in diam; 1 hole on each rib and 1 hole between each rib and the shear cut; all holes are horiz and 6 in below the draw slate. The hole to left of the shear cut is shot first and the broken coal loaded out; then the left rib hole is fired, and its coal loaded; same system is repeated on the right side. Pellet powder is used; 3 sticks per shot. Draw slate is shot down after coal has been loaded out. Entries are undercut and sheared on both ribs. One 1.5-in hole is drilled with hand-held elec auger in the center and 6 in below the draw slate and loaded with 2.5 sticks of pellet powder. Crew of 6 men, working a pair of entries, under normal conditions makes seven 9-ft cuts per shift, or about 30 ft advance in each heading. Standard room timbering comprises a row of road posts on 3-ft centers 4 ft to the left of center line of room; another row on 3-ft centers 4.5 ft to right of center line (extra 6 in to allow clearance for loading-machine operator); 2 rows of gob posts on 6-ft centers, between road posts and ribs. All posts are hardwood, in lengths of 5.5 or 6 ft, secured by sawed wedges driven between roof and top of post.

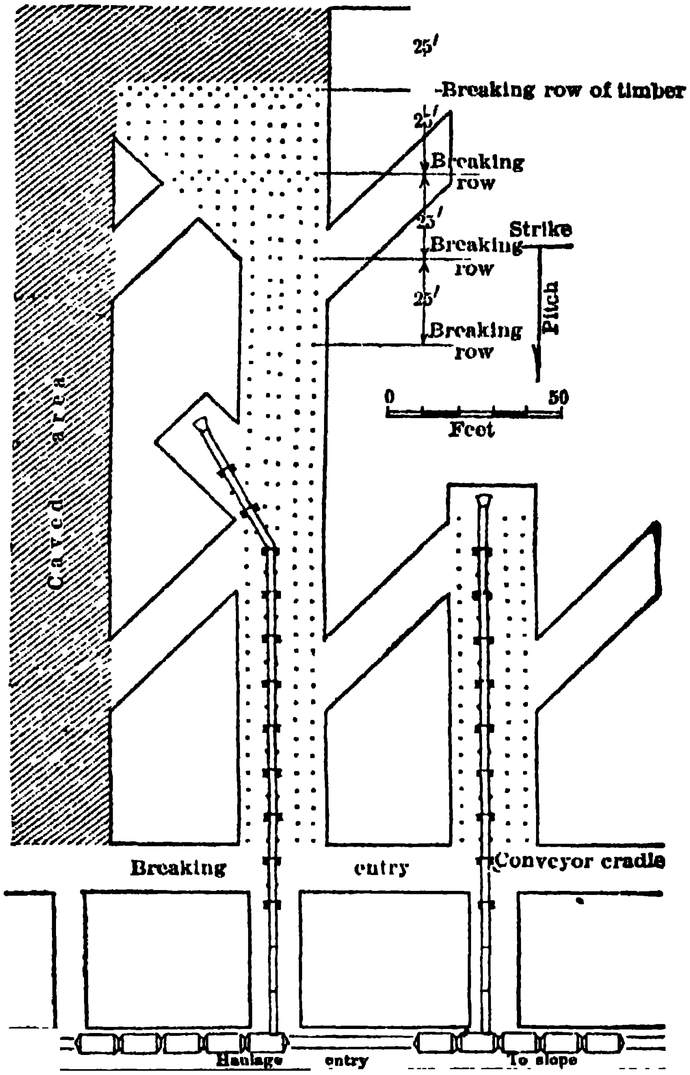

Fig 738. Room Work, D. O. Clark Mine, Wyo(636)

Wyoming. Fig 738 shows typical room-and-pillar operation in the D. O. Clark mine of the Union Pacific Coal Co, Sou Wyo, where self-loading shaking conveyers (duckbills) are in use (636). Distinguishing feature is that one pillar is being mined on retreat while an adjacent room is advancing.

British practice. Room-and-pillar methods in England (bord-and-pillar, post-and-stall, pillar-and-stall), and in Scotland (stoop-and-room), resemble those in the U S, except in dimensions of openings and percentage of recovery on first mining (Fig 739). Common dimensions (363): entries (walls), 6 ft wide; rooms (stalls), 12–15 ft wide; room pillars, as large as 132–198 ft square. Recoveries are about 30–35% in first mining; first-mining recoveries of 40–50% are considered dangerous. Most of the coal is won during robbing (Art 107).

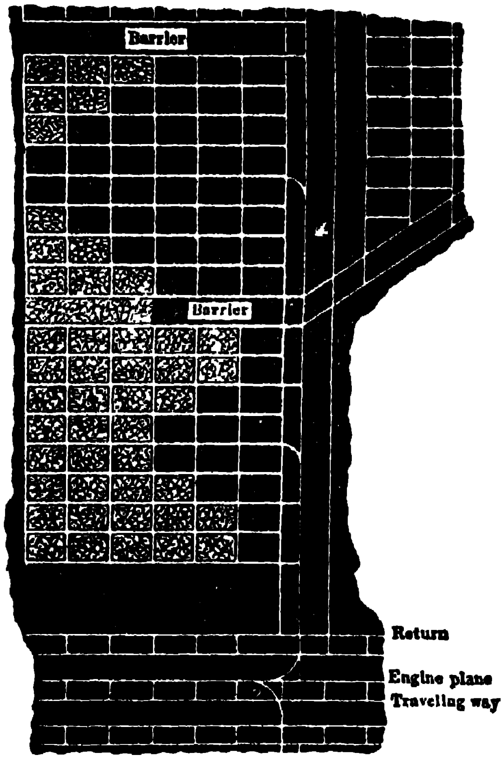

Fig 739. British Practice, Bord-and-pillar or Panel System (Hughes)

106. EXAMPLES OF ROOM-AND-PILLAR MINING IN PITCHING SEAMS

General. Pitch-mining practice has been developed most extensively in the anthracite basins of Pennsylvania; Fig 740 (364) shows the relative positions of several seams and indicates a wide variety of local conditions. Virgin seams of moderate thickness are mined with buggy, chute, or battery breasts (Art 104), the pillars being subsequently robbed (Art 107); the Natalie Colliery illustrates such work. Other examples outline more complex methods for special conditions.

Natalie Colliery, Western Middle field, Penna. The Lykens seam occurs here in 2 splits, separated by 60–80 ft hard conglomerate. Seams are very irregular; pinches, faults, and sudden changes in the texture of the coal are common. The underlying split (Lykens No 1) averages about 4 ft of shelly, friable, badly crushed coal, with bands of slate and dirt to 1 ft thick; it contains a little gas. Roof and floor are hard conglomerate. The overlying split (Lykens No 2) averages 4–5 ft of very hard clean coal, with no gas; roof and floor, conglomerate. Aver pitch of both splits, 25°; vert depth of workings, 410 ft. Main opening is a double-track slope, driven on pitch in Lykens No 1; cars hoisted to surface. Gangways, 7 by 12 ft and about 300 ft apart along the pitch, are driven on the strike against the top rock, on grade of 0.75% favoring the load. The monkey, 30 ft above the gangway, has an area of 36 sq ft, dimensions varying with thickness of seam. Chutes, 6–8 ft wide by thickness of seam, are turned off at right-angles to the gangway on 50-ft centers. Breasts are 24 ft wide and 270–290 ft long, leaving a 10 to 30-ft chain pillar to support the gangway above. Headings, turned on 60-ft centers, have an area of 36 sq ft. Coal is conveyed from the face to the gangway by sheet-iron chutes. Lykens No 2, opened by a tunnel from No 1, is mined similarly. Forced ventilation is used; interruptions of air current, due to opening of doors for gangway traffic, are not serious because of small quantity of gas.

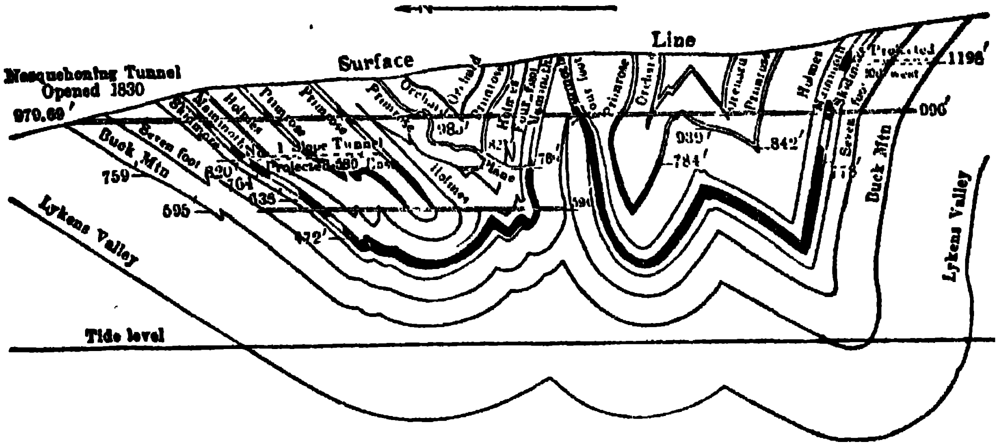

Fig 740. Workings from Nesquehoning Tunnel, Southern Anthracite Field (Whildin)

Staggered battery breasts. At a mine in the Middle Western anthracite field of Penna, the seams have an aver dip of 20°. Coal is firm and hard and 5 ft thick; roof and floor, good. Breasts are 24 ft wide on 50-ft centers and worked with sheet-iron chutes. Coal is paid for by the car, miners doing their own loading. As the faces of the breasts advanced in one section, the dip increased gradually from 20° to 60°. Due to the small area in which this occurred, and because the whole mine was worked on a car basis of payment, it was deemed inadvisable to drive a counter gangway and work battery breasts from it. Instead, and to provide safety and support for the miners and decrease breakage of coal, staggered batteries were used when the pitch reached 40° (Fig 741). This shows poor mining, but illustrates variations of practice to meet local economic and geological conditions. Many other variations are in use.

Rock-holes (rock-chutes) are widely employed in mining contiguous seams. Development openings are driven in the underlying seam and rock-holes (inclined raises similar to chute-raises, Art 67) are driven to the overlying seam from the gangways or breasts, or both. Breasts may be opened in the overlying seam directly from the rock-holes, or from small gangways driven to connect tops of rock-holes. This often effects large economies in development; especially in reworking the thick Mammoth seam, which contains large amounts of coal left by crude early methods. Reopening old gangways in Mammoth seam is dangerous and costly; it is often impossible even to drive new gangways near worked-over areas.

One or more contiguous seams may be opened by tunnels run across the strata from a main haulageway in one seam. This presupposes possibility of driving and maintaining gangways in the other seams. Where a series of short tunnels is driven to reach an adjacent seam they are known as SECTIONAL TUNNELS, and are spaced at intervals depending on their length, speed of development desired, and condition of the seam to be opened They avoid breakage of coal in rock-holes, provide numerous working faces and hence allow rapid development. Examples follow.

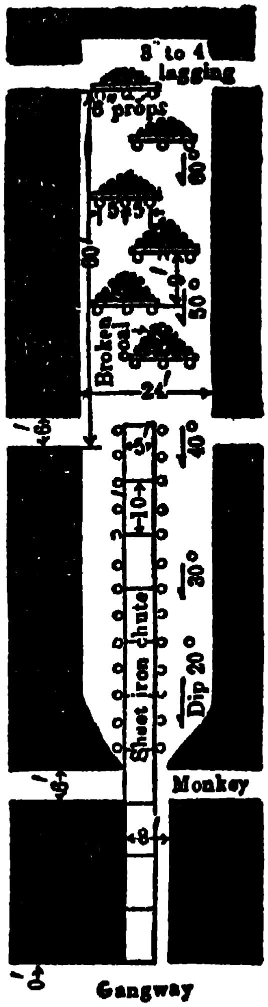

Fig 741. Staggered Batteries

Lawrence Colliery, Schuylkill region, Penna (H. H. Morris). Holmes seam, averaging 8–10 ft of firm coal, is mined by rock-holes from development openings and breasts in the Four-Foot seam; the seams are separated by about 10 ft of rock; pitch, about 60°. Gangways and monkeys are driven on 80-ft centers in the Four-Foot seam, with chutes on 50-ft centers. A few feet above high side of the monkey, a battery is built, and enough coal blasted to allow a 6 by 8-ft rock-hole to be driven at about 40° through the top-rock to Holmes seam. The rock-hole is partitioned to make a manway and a coal chute. On entering Holmes seam, a battery breast is driven 24 ft wide up the pitch. For ventilation, 2 or more rock-holes, breasts and headings must be opened in the Holmes; a split of air from the Four-Foot monkey is carried up the manway of one rock-hole, through the workings in the Holmes and down another rock-hole manway into the Four-Foot monkey. After the Holmes breasts have been driven and drawn, breasts of same width are driven in Four-Foot seam directly under those in the Holmes. Pillars must all be of same size. Sometimes the mined coal in the Holmes breasts is held in reserve and not drawn when a breast is finished, in which case an extra battery is built in the rock-hole, for opening the breast in the Four-Foot. In this part of the mine, surface conditions prohibit robbing; pillars in the Holmes seam, however, could be robbed before driving breasts in the Four-Foot. In another part, several seams, pitching 65° and 1.5–30 ft thick, are mined by counter-gangways, counter-chutes and rock-holes (Fig 742). The colliery is opened by a "gun-boat" slope in the Seven-Foot seam. Main level is at 634 ft elev; counter-levels at 820 ft, 920 ft, and 1 000 ft; surface at outcrop, 1 200 ft elev. (In Penna anthracite mines, elev of gangways is given in ft above sea level.) The method in the thinner seams is about the same as at the Natalie Colliery (above), except that all breasts are of battery type and worked full. It was impossible to drive gangways in Mammoth seam, due to condition of its old workings; hence, rock-holes (6 by 6 ft) are driven from Skidmore or Leader seam at 60-ft centers on the gangways and 60-ft centers on the pitch from Skidmore breasts. Distance between Skidmore and Mammoth seams, 20–60 ft. All coal mined on the counter-levels goes to a counter-chute in Leader seam (a 12 to 18-in split of Mammoth appearing at irregular intervals between the Skidmore and Mammoth). This counter-chute extends in the Leader from the 1 000-ft counter-gangway to a point above the 634-ft level, where a rock-chute is turned back to the loading pit slightly below 634-ft level. Batteries are built in the counter-chute above each counter-gangway, to regulate the flow of coal and maintain dump room on the gangways. Breakage is minimized by keeping the chute as full as possible and by careful drawing; this gives a "prepared yield" (Sec 34) as high as 60%. A successful rock-hole system, more elaborate than the above, is used by the Lehigh Navigation Coal Co; for this, and for details of various intricate methods of re-working the Mammoth seam, see Bib (364).

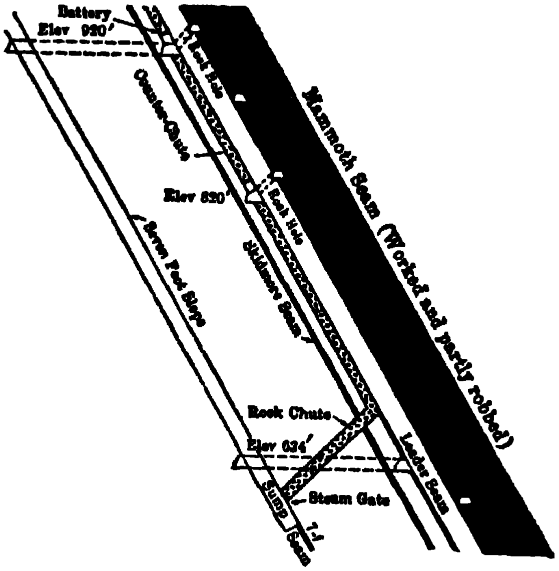

Fig 742. Counter-chute Method (Lawrence Colliery)

Rock-holes and buggy gangways are used at one mine in the Southern field for working the Mammoth seam; development openings are driven in the underlying Skidmore seam, which is 90 to 100 ft away. Rock-holes are driven at intervals of 300 to 600 ft from the Skidmore gangways and connected at their tops by buggy gangways in the Mammoth. Breasts are then turned off the buggy gangways, and the coal is mined and dumped down the rock-holes, which in reality are rock counter-chutes. By driving buggy gangways in both directions, the haul is halved and speed of development doubled. The rock-holes furnish convenient points to which to retreat in robbing; the method avoids maintenance of expensive main gangways in the Mammoth.

Lehigh Navigation Coal Co, Lansford, Penna. Data from W. G. Whildin in 1914 (364). Battery breasts and "cut-backs" are used for mining the Mammoth seam. Where the pitch is 60° to 90°, gangways and airways are driven along the top rock, so that the loading chutes can be driven back on a 30° pitch; this provides a safe working place for loaders, and allows better control in drawing broken coal. In flatter seams, gangways are driven on bottom-rock, and airways either along the bottom or top rock; distance between gangway and monkey, 20–50 ft. The larger interval results in a lower maintenance cost of gangways.

The method of opening a breast is shown in Fig 743, 744. Chutes 6 by 6 ft, partitioned to make a manway and a loading chute, are driven from the gangway on a slope of 22° to the bottom rock and then up the pitch to the height for opening the stump heading. Here a jugular battery is put in and a 4 by 6-ft stump heading driven to the next chute. This is used both for ventilation and access, and is known as the "bottom-breast crosscut." From it, a "front" manway (dog-hole) is driven on one side of the breast 20 ft up the pitch, and a "back" manway on the other side. The breast is started 10 ft wide by 8 ft high next to the back manway and is gradually widened to 18 ft at top of the dog-hole, leaving a stump pillar (Fig 743). Mining then proceeds by advancing a battery breast, 18 ft wide by 15 ft high, on the bottom rock for a distance of 21 ft above the bottom-breast crosscut. At this point a cut-back, 10 ft wide along the pitch, is carried up to the top rock from rib to rib. After the first cut-back is finished, the breast is driven 30 ft farther up the pitch, where a second cut-back is made. Where the pitch is 45°, the loose coal does not fill the whole space, in which case the miners carry a "path" along each rib of the cut-back. Two miners blast the coal, each traveling his own path, until the top rock is reached and all the coal taken out between the cut-backs. The breast is again driven up the pitch 15 ft, where a third cut-back is made. If the breast does not run away, or the top coal does not fall, a cut-back is made every 15 ft to the limit of the breast. In steep-pitching veins, no paths are necessary, the miners standing on the loose coal. For further detail, see Bib (364). Note that prices quoted in Fig 743 are as of 1914.

Fig 743. Cut-back in Breast 62, E Mammoth Seam, No 10 Shaft, L N C Co

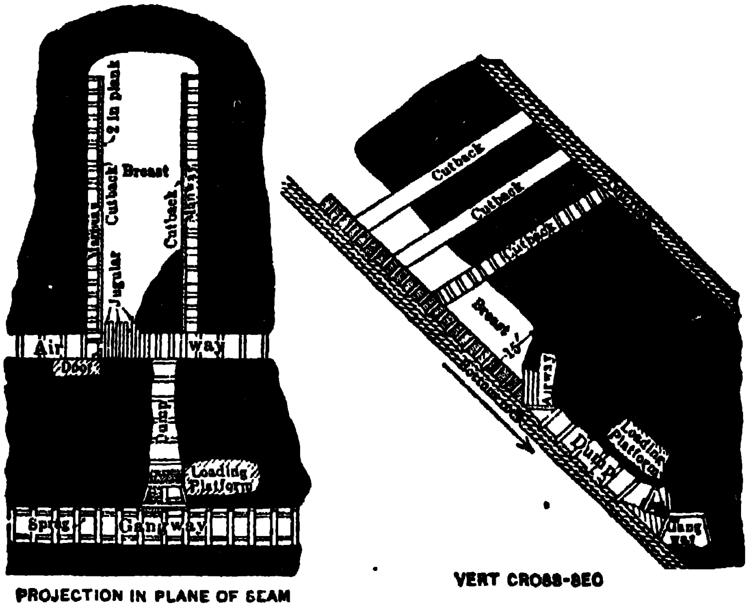

Fig 744. Cut-back System, Mammoth Seam, Penna

Orchard seam, Nesquehoning District, Penna. Data from J. S. Miller in 1925 (609). Dip, 65°–70°; coal is hard; roof fairly strong; width at surface 8 ft, increasing to 15 ft at first gangway. Fig 745 shows method used by Lehigh Nav Coal Co, instead of the usual battery-breast and pillar method, with subsequent robbing by one of the plans in Fig 750, 751 and 752. Mining is done from a series of main chutes *C* (Fig 745), driven at an angle to the dip on a slope of 30°–35°. Loading chutes *L* are first put up from the gangway at 130-ft centers; air connections *A* are next driven and then the main chutes. Until

the latter hole through to surface they are ventilated by an elec fan. Main chutes, 300 ft long, require little upkeep compared with a chute driven up the pitch.

Mining starts near top of a main chute; a breast *B*, about 50 ft long is opened, with its upper manway 25–30 ft down the chute from the surface. While driving the breast, the auxiliary chute *X*, and the crosscut *B*, are driven. Chute *X* is 20 ft below the lower manway of the breast and about 25 ft long; a check battery is erected in it. When the breast is completed, a skip (No 1 skip, Fig 745) is taken beginning at the top of *X*; crosscut *B* provides ventilation for this work. Successive skips are taken in same way. When work has passed the point *Y*, the pillars below the breast and skips are robbed, starting with stump *S*, and working downward to *Y*, below which the stumps are left standing to maintain ventilation for succeeding work and to protect the gangway; 7 to 8 skips are taken on each main chute and usually 2 skips and a stump on each airway *A*.

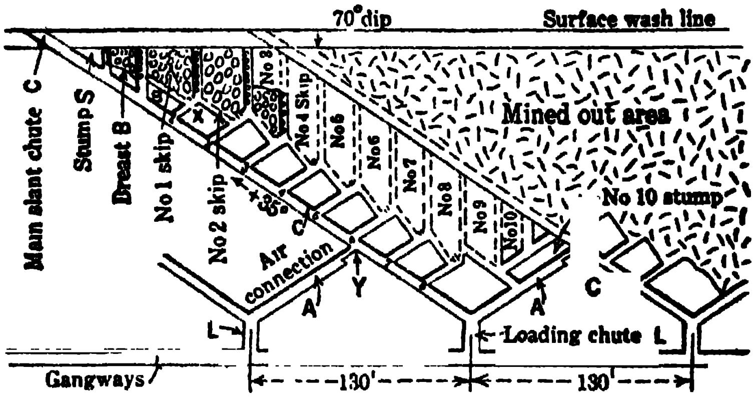

Fig 745. Orchard Seam, Lehigh Nav Coal Co, Penna (609)

Driving and robbing a main chute takes 11–12 months; 4 or 5 chutes are worked simultaneously. The method extracts 68% of the coal; gives a high percent of prepared sizes; concentrates the area of operations for a given output as compared with pillar and breast work; eliminates objectionable features of pillar-breast, pillar-skip, and pillar-chute robbing (Art 107). In this property, the method increased output 40–90 cars per day and about halved the cost per car. As the seam is free from gas and the workings reach the surface, natural ventilation is used. Deeper work with forced ventilation would require more airways.

Tesla, Calif (Fig 746). The seam averages 7 ft of clear coal; pitch, 60° (376). The system was devised to get coal rapidly in a part of the mine where a short-grained, slate cap rock came in over the coal, making it difficult to keep props in place. The floor is slate, with a decided heaving tendency; roof is good sandstone; there is a small but troublesome amount of gas. Two double-compt chutes are driven up the pitch and connected by crosscuts. Small gangways are driven from chutes parallel to main gangways at intervals of 36 ft along the pitch. These are continued 300 ft from each chute if conditions warrant. The end of pillar between the highest small gangways is then attacked, the coal being worked on the cleavage planes. Resulting breast consists of a 36-ft face, including the drift or gangway through which the coal is carried to the chutes. A 2 or 3-ft pillar is left between breasts to keep rocks from falling on breast below. Working face in each breast, 45–48 ft. Light iron chutes, to load coal into cars on the small gangways, are moved along as the face advances; loading is cheap, loss from breakage, small. Coal is dumped from cars into angle chutes, connecting with main chutes on slopes of about 45°; these keep main chute full, so that each breast can deliver coal continuously, and so reduce breakage. The breast gangways are 5 ft wide,

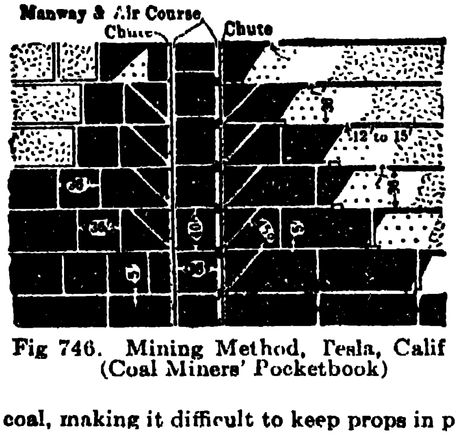

Fig 746. Mining Method, Tesla, Calif (Coal Miners' Pocketbook)

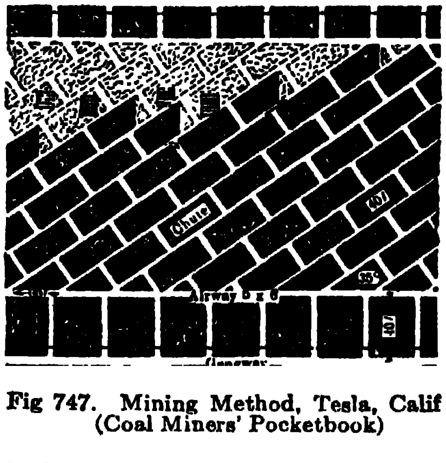

Fig 747. Mining Method, Tesla, Calif (Coal Miners' Pocketbook)

untimbered. The small pillar left over the tops of breasts is maintained until the face has advanced 12–15 ft, when it is cut out. The roof caves and fills the opening. Ventilation at faces is by chutes driven between gangways at 36-ft intervals.

Fig 747 shows another system in a 7-ft seam. As roof is shelly and breaks quickly, mining must proceed rapidly. A gangway and airway, 40 ft apart, are connected by chutes every 30 ft, which are driven up the pitch at about 35°; they are connected by crosscuts 40 ft apart. This divides the seam into pillars, which are then worked out from top downward. Rows of cogs are built about 80 ft apart, to delay roof settlement and prevent remaining pillars from crushing; little other timber is required.

Pierce County, Wash. Data from S. H. Ash in 1925 (610). Steeply pitching seams are 3–25 ft thick; coal often gassy; roof and floor bad, precluding wide breasts; hence mining is by a chute-and-pillar system. Fig 748 shows general plan on pitches to 65°; in steeper seams, slant chutes are driven on pitches of 45°–60°. Gangways are 200 ft apart.

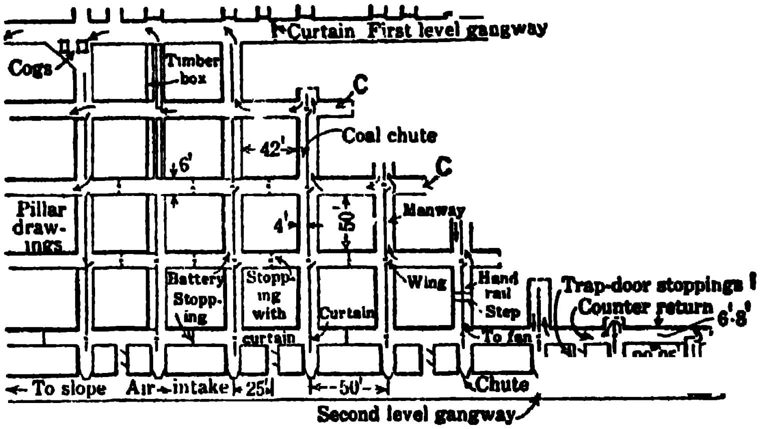

Fig 748. Development by Chute-and-pillar, with Ventilation Details, Pierce County, Wash (610)

A counter gangway (monkey or airway in Penna mines) is driven 20–25 ft above the gangway. Chutes are on 50-ft centers; 6 ft wide between gangway and counter gangway, above which they are 8–10 ft wide. Half chutes, for traveling ways, are put up to the counter-gangway between alternate main chutes. Crosscuts *C* (Fig 748) vary from a small hole to 6 ft wide. This work comprises the first mining (see Art 107 for pillar robbing). Brattices are carried through the chutes; the inby compartment is used as a manway, the outby as a coal chute. Fig 748 shows path of air currents.

107. ROBBING PILLARS

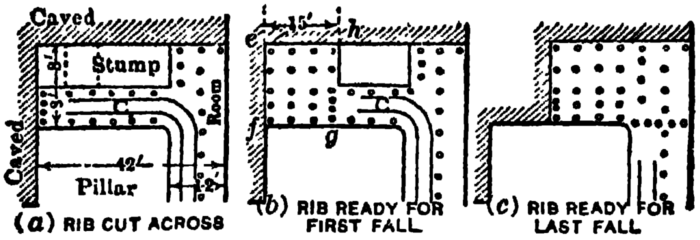
General. Robbing or drawing pillars consists in removing the coal left for roof support after first-mining has been completed. The character of roof and floor, texture of coal, thickness and dip of seam, presence of gas and other local conditions, all influence the method of work and the time at which it should be done.

Systems of robbing. There are 2 general systems: robbing during the ADVANCE and robbing on the RETREAT. A further distinction may be made between PRELIMINARY and COMPLETE or FINAL robbing.

Advance system. Fig 701 shows its application in a flat seam with rooms turned in one direction only. First-mining is followed closely by preliminary robbing, which removes the room pillars; stump pillars are left to support the haulageways, and, with the entry pillars, are removed on the retreat system after first-mining and preliminary robbing are completed to the limit of the entry and the section abandoned. Pillars must be drawn uniformly, keeping working faces in a straight line; this avoids throwing excessive press on any one pillar and secures a uniform line of break in the roof. Direction of line of retreat depends chiefly on character of roof, which should break as robbing proceeds; otherwise the press on stump, entry, and remaining room pillars may crush them or cause a general squeeze. ADVANTAGES: (*a*) max production per unit area of development; (*b*) reduction of loss caused by deterioration of pillar coal on long exposure to air; (*c*) increased yield of lump coal in soft or friable seams, because pillars are removed before roof press can cause extensive crushing; (*d*) improved ventilation in non-gaseous mines; (*e*) room pillars are smaller, due to short life and limited area of support. DISADVANTAGES: (*a*) gas is apt to accumulate in caved areas, which can not be ventilated, and there is always danger from fire; (*b*) where roof strata are water-bearing, breakage of the roof increases amount of inflow; (*c*) comparatively large stump and entry pillars are necessary to prevent squeezes and avoid excessive cost of maintenance of entries.

Retreat system is the reverse of the advance. Development entries are driven to their limit, rooms turned, and first-mining is completed throughout the entire area before robbing begins. Robbing is begun at the inside limit of the area and retreats toward the main or sectional entries; robbing is complete, *i e*, room, stump, and entry pillars are extracted in one operation. A combination system known as ADVANCE AND RETREAT is sometimes used where rooms are turned in both directions (Fig 721). Rooms are turned in one direction only as the development entries advance, and room-pillar robbing is carried on during advance. When the limit of the entry is reached, rooms are turned in opposite direction and work retreats toward main entries, final robbing being carried on during retreat.

Examples of American practice. Details vary widely with underground and surface conditions and quality of labor; many cases require special methods. CONNELLSVILLE REGION, Penna. Fig 749 shows pillar-drawing in flat seams. Robbing in any pillar begins at face of the room and retreats toward the entry. A cut *C*, 8 ft wide, is driven through the pillar, leaving an 8-ft stump next to caved area. Cut *C* is timbered with props. Cuts are then made across the stump, as indicated by dotted lines in (*a*), and the roof is picked up by props until work reaches stage (*b*). Props in area *efgh* are next drawn or shot out, forcing the roof to fall. The rest of the stump is then mined and caved, and the process repeated until the whole pillar is drawn back to the entry pillars, which are removed by similar methods (358). This plan, with modifications of detail, is in universal use in the U S for drawing pillars in flat seams. Loading may be done mechanically with scrapers (Sec 27). ANTHRACITE MINES, Penna. Methods are unsystematic and often left to the miners. In flat or slightly pitching seams, pillars are usually robbed by taking slices ("skips") off the ribs, the roof being temporarily supported by props. In steep-pitching seams one of the following methods is used, with variations to suit local conditions: (*A*) Pillar-breast (Fig 750). A battery is placed at one corner of the pillar; manways on each side of pillar are connected at intervals, as at *AB*; pillar is then mined as a breast. This method, though practically abandoned, is used to some extent in modified form by leaving wider pillars on first-mining. Then a full-width breast is driven in middle



(*a*) RIB CUT ACROSS (*b*) RIB READY FOR FIRST FALL (*c*) RIB READY FOR LAST FALL

Fig 749. Robbing Pillars, Connelsville Region, Penna

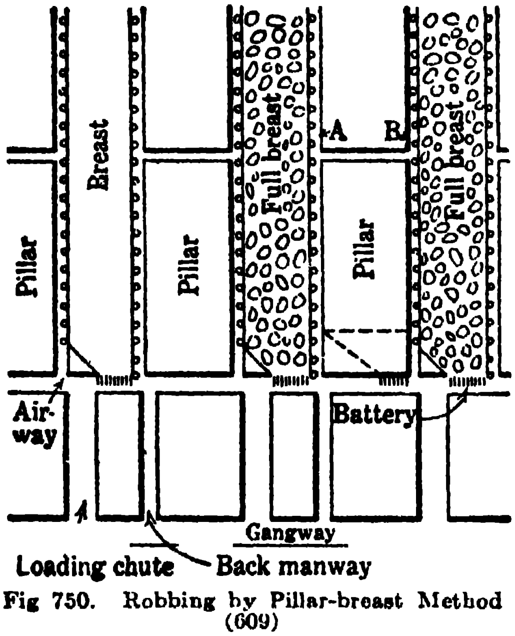


Fig 750. Robbing by Pillar-breast Method (609)

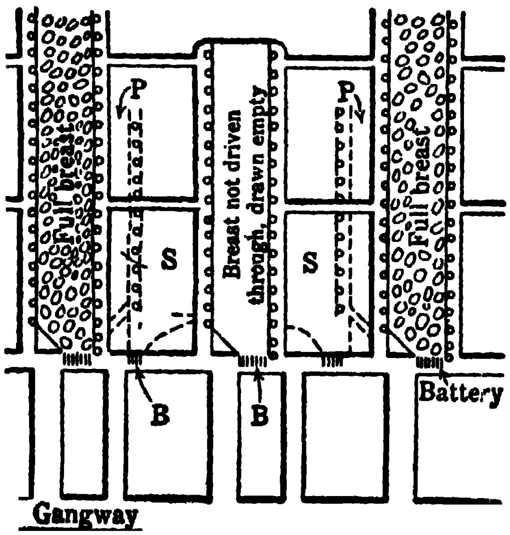

Fig 751. Robbing by Pillar-skipping Method (609)

of the pillar, and the remaining narrow ribs are drilled full of holes and blasted in one operation (609). (*B*) Pillar-skipping (Fig 751). Middle breast of a group of 3 is not driven through; it is drawn empty; the 2 adjacent breasts are left full of broken coal. A skip *S* is taken off the inside of each pillar, much of the coal being blasted into the central empty breast. Small pillars *P* are left between skip manways and full breasts; they are drilled and blasted after the skips are completed (609). (*C*) Pillar-chute method (Fig 752) is most used, either of necessity or because of its safety. The pillar is first split by a chute *P*, 4–6 ft wide, driven from the gangway. Robbing begins at the top and is carried on by inclined skips (*a*), or by driving heading *H* and then blasting out the small pillars *L* with long shots (*b*), or by running skips up the pitch from a heading (*c*). Only experienced miners should be employed for robbing; danger increases with steepness of pitch and thickness of seam. Liberal use of props is essential to support "flakes" of roof-rock, and give warning of impending falls. No props are drawn; they crush down as the roof comes in, and aid in keeping rocks from rolling onto the working face. Pierce County, Wash. Data from S. H. Ash in 1925 (610). First-mining by chute-and-pillar system is shown in Fig 748. Three adjacent pillars formed by 4 chutes and 2 gangways are usually drawn in one operation (Fig 753), in which robbing is starting at the upper inby corner of pillar No 33; work is finished in pillar 30 and is in intermediate stages in pillars 31, 32. Sequence of operations: crosscuts in the pillars to be robbed are well timbered.

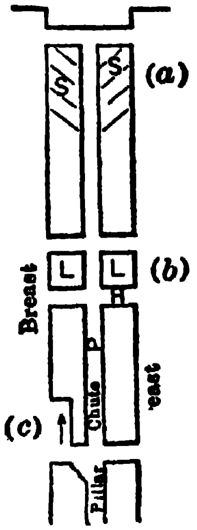

Fig 752. Robbing Pillars, Thick Steeply Pitching Seams

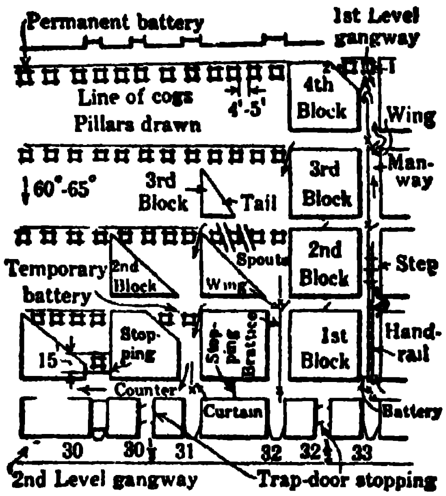

Fig 753. Pillar Drawing in Chute-and-pillar System, Pierce County, Wash (610)

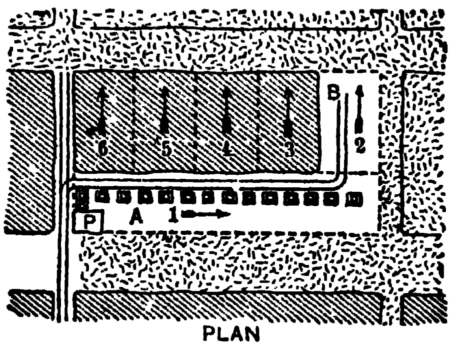

Fig 754. Robbing Pillars, Northumberland

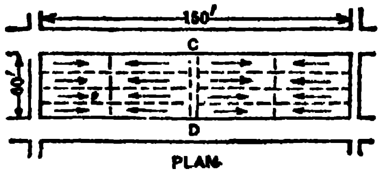

Fig 755. Robbing Pillars, West Durham

A cog (1 in pillar 30) is built under the upper gangway as close as possible to the inby rib of the chute. A corner pillar 30 is then worked off until space is gained to build another cog 4 or 5 ft from the first. A temporary battery of props above this cog protects men from injury by falls from above and provides a traveling way on the gangway. Work proceeds by "taking off the angles," until half the top block of pillar 33 is mined; remainder of block is the "tail." The upper inby corner of 3rd block in pillar 33 is next robbed in same way, and the tail of 4th block is then drawn. Broken coal from the tails is run out through spouts between the cogs below (see 3rd block of pillar 32), after which a permanent battery is built above the cogs. Pillars are drawn back to the 1st block, as in pillar 30, and a permanent cog stopping placed in the chute neck. Roof breaks above

the cog lines and broken material is held on the pitch by the cogs. With a good roof 90% of the coal is often recovered.

Foreign practice. H. F. Bulman and R. A. S. Redmayne give the following examples in England (365). Seaton Burn colliery, Northumberland. Fig 754 shows robbing in a flat seam, averaging 4 ft thick, at a depth of 360 ft; pillars are 30 yd long, 16 yd wide. A "way" *A* (skip) is driven 6 yd wide the length of the pillar. A small pillar *P* 2 yd square (a "stook") is left to support the haulageway; a track is run along the solid rib and cogs are built on the open or caved side 3 ft apart. When the "way" has been driven the length of the pillar, a "lift" *B*, 6 yd wide, is driven across the pillar. Five lifts complete the robbing of the pillar. This seam yields more lump coal when worked end-on. Marley Hill colliery, West Durham. Fig 755 shows method used in a flat seam, which averages 5 ft thick and contains a 4-in and a 1.5-in parting in the middle. Depth of seam, 432 ft. Pillars are 50 by 20 yd. The pillar is first split on its short dimension by a "sliding-over" or "half-pillar wall" *CD*. From this and from the haulageways 5-yd lifts are turned and the work completed as at Seaton Burn colliery. Murton colliery, Durham. Fig 756 shows the method in a 46-in flat seam, at depth of 1 470 ft. Lifts 6 yd wide are driven at right-angles to and toward each other, in sequence shown. This retains the square shape of pillar, considered best for withstanding heavy press, throughout the entire operation.

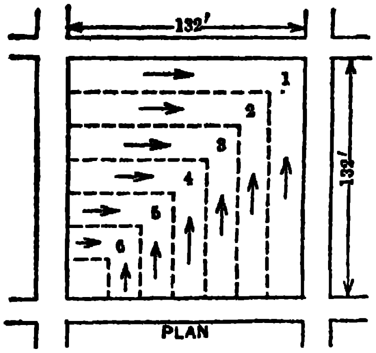

Fig 756. Robbing Pillars, Durham

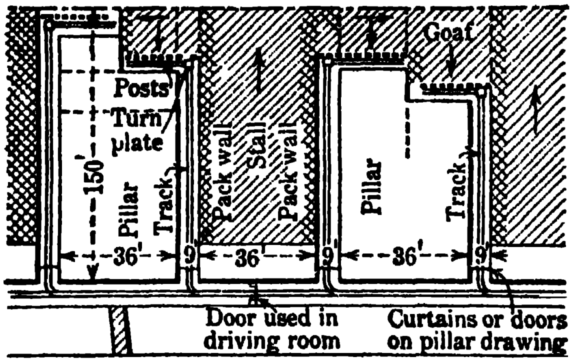

Fig 757. Robbing Pillars, Pillar-and-stall Method, Wales (611)

G. S. Rice in 1921 gave following examples of foreign practice (611). Pillar and double stall (Fig 757) was formerly used in Scotland, and in 1911 in a Welsh anthracite bed 7–8.5 ft thick. Stalls are 42–48 ft wide, with 2 entrances and tracks along each rib; area between tracks is gobbed; pillars, 36–42 ft wide. When a stall reaches next entry, it is widened on either side and the adjacent pillar robbed retreating by taking cross slices 10–18 ft wide (Fig 757). Sometimes a thin pillar is left between stalls; if so, this pillar is not recovered. A recovery of 90% is claimed; the method is being supplanted by longwall (Art 108). Square-chamber method, South Staffordshire. Fig 758 shows its use in a nearly flat seam, 24–30 ft thick. Chambers, separated by thick pillars, are 46 yd wide and 200 ft long; they are opened off the level with 2 narrow gate roads connected by a "lane"

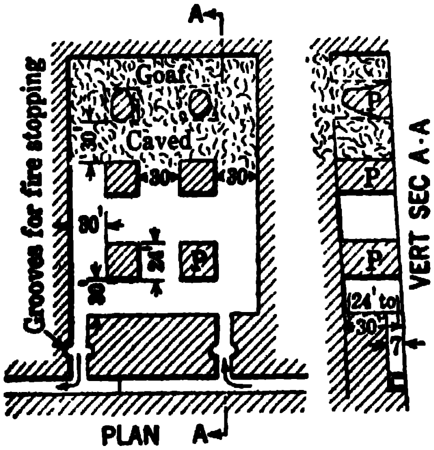

Fig 758. Square-chamber Method, South Staffordshire

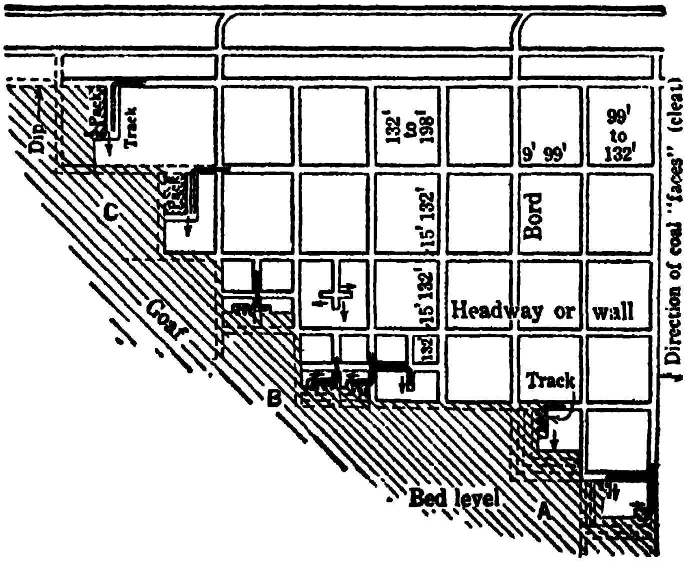

Fig 759. Robbing Pillars, Bord-and-pillar Method (611)

10 yd wide. Stalls, 10 yd wide, are driven 8 yd apart from the lane; cross lanes, 10 yd wide, connect stalls every 8 yd, leaving 4-6 pillars, 8 yd square, in a chamber. This work is done in the bottom bench, 7-8 ft thick. After the chamber is formed, the top coal is taken down in sections, by cutting vert grooves in it 6 ft apart, separated by "spurns," or narrow webs, which are reduced by pick and finally knocked out with a "picker" (like a boathook). The mass falls as a whole, and is loaded out. On reaching the roof, the internal pillars are sliced as much as possible before the roof falls. Some coal is necessarily buried. Pillars between chambers are mined after the ground has settled. This method requires skilled work. BORD-AND-PILLAR or STOOP-AND-ROOM (Fig 759) is the most important European pillar system. It is considered especially applicable where: (*a*) coal bed is horiz or not dipping over 1 in 3; (*b*) bed is 4–10 ft thick; (*c*) roof is strong, not flexible or bending; (*d*) bed free from thick partings. LONGWALL has supplanted it where: (*a*) roof is weak or flexible; (*b*) bed is under 4 ft thick; (*c*) seam is thick, but has a soft underlying clay; (*d*) bed has thick partings suitable for packwalls. In typical bord-and-pillar, narrow openings are driven at right-angles to each other, forming rectangular pillars which are extracted when workings reach the boundary; it is essentially longwall retreating (Art 108). In a typical application, Eppleton Colliery, Durham, England, there are 3 horiz seams, 3.7–7.3 ft thick, at depths of 1 008–1 170 ft. Pillars are 33 by 44 yd to 66 yd square. "Headways" or walls (driven on the butts) are 3 yd wide; bords at right-angles, 5 yd wide. In forming the pillars only 10–17% of the coal is extracted. Generally, on reaching the boundaries, pillar-robbing retreats along a stepped diagonal line (Fig 759). Pillars to be drawn are split by a headway and a narrow bord into 4 small pillars, which are either split again or successively sliced off on the goaf side; or, where the roof breaks short, sides of the headings are sliced, working toward the goaf. Small corner stumps, left for protection under a poor roof, are sometimes lost. Most timber used in mining pillars is recovered. Total recovery of coal, 95%. Objections to method: large amount of costly, narrow first work, which produces much small coal. For further detail, see Bib (611).

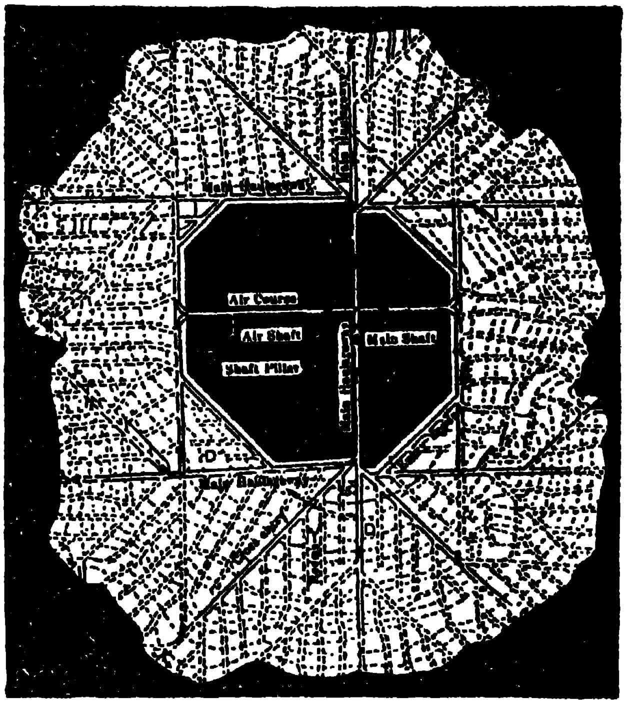

Fig 760. Longwall Advancing (after Swift)

108. LONGWALL METHODS

The fundamental principle is the complete removal of the entire seam in one operation, by carrying a continuous working face (hence the name longwall), leaving no pillars and allowing the roof to cave behind the face.

General plan of work in a flat seam is shown by Fig 760 (366). A large pillar maintains the hoisting and air shafts; successive positions of the face, as advanced outward from the shaft pillar, are indicated by dotted lines. As face or breast is advanced, the roof between it and the shaft pillar caves. Packwalls on each side of the numerous haulageways must be maintained through the caved area (GOB or GOAF) to reach and ventilate the working face. Weight of roof often causes the packwalls to settle; headroom is maintained by breaking down (brushing) the roof over haulageways; the waste thus produced, with that from mining, is utilized in packwalls, the excess being thrown back into the gob. Haulage roads are known as MAIN and BRANCH or CROSS ROADS, haulageways or entries (Fig 760). From branch roads, short openings called STALL ROADS or ROOMS are kept open at intervals; they are approx perpendicular to the face. As the face advances, new branch and stall roads are started and old ones abandoned; this keeps the stall roads short and saves maintenance. Haulage tracks may be turned from the stall roads and run along the face, so that coal may be shoveled

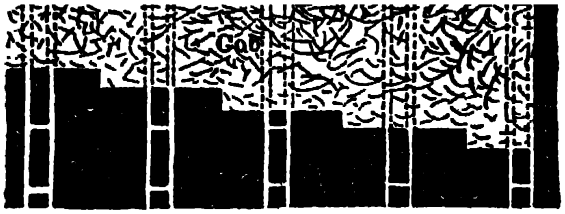

Fig 761. Longwall Retreating

directly into cars; various forms of conveyer and scraper (Sec 27) may also be used for transporting coal along the face (369).

This plan of work is known as LONGWALL ADVANCING or LONGWALL WORKING OUTWARD. Fig 761 shows another form called LONGWALL RETREATING, in which the seam is first developed by a series of haulage and airways, which are driven to the property lines before any mining is done. The ends of these openings are then joined, forming a long face which is worked back toward the shaft; the roads and airways are in solid coal and the mined-out area is allowed to cave a short distance back from the face.

Advancing *vs* retreating systems. CAPITAL OUTLAY. Longwall advancing requires smaller outlay for development than any other coal mining method. Narrow work in driving haulage and airways is eliminated, with the exception of the development openings in shaft pillars, etc. The mine begins to produce coal in a relatively short time. Longwall retreating requires a larger initial outlay with no immediate return. Extensive development openings must be maintained during life of the mine; capital requirements are in direct proportion to area of the property. In advancing systems, MAINTENANCE of haulage and airways is an increasing deadwork charge; these openings pass through caved ground and the packwalls supporting them often give trouble from settlement. Longwall retreating entirely avoids cost of building and maintaining packwalls; all haulage and airways are in solid ground. VENTILATION is more efficient in retreating than in the advancing system. Caved or gobbed areas are difficult to ventilate. Gas if present may accumulate in the gob, and cause explosions and gob fires seriously affecting the active workings. Retreating systems eliminate the necessity for ventilating the gob. Nevertheless, longwall retreating is rarely used, chiefly because of the large investment required; what follows refers to longwall advancing.

Longwall *vs* room-and-pillar methods. ADVANTAGES of longwall, aside from those connected with investment and quick return: (*a*) smaller powder consumption and greater yield of lump coal; (*b*) ample storage underground for waste; (*c*) fewer roadways per unit length of face, thus reducing first and maintenance costs; (*d*) easier and cheaper ventilation; (*e*) less liability to accident from roof falls; (*f*) requires less timber; (*g*) surface subsidence is more uniform and causes less damage; (*h*) duty of labor is greater; supervision is easier. DISADVANTAGES of longwall: (*a*) labor must be experienced; (*b*) market demand must permit uniform production at all times (Art 103); (*c*) danger from gob fires in advancing systems; it is difficult to divide working places into small districts to localize effects of gas or dust explosions; (*d*) cost of packwalls; (*e*) requirements for successful application of longwall are quite rigid. Roof must come down gradually behind the face; a very strong roof or one that breaks short at the face prohibits use of longwall. Faulty ground makes it difficult to maintain a continuous working face. Waste for packwalls must be cheap, whether obtained from the seam or by brushing the roof or floor (see Art 103).

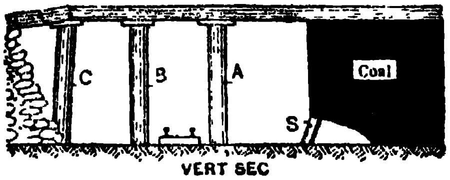

Fig 762. Longwall Face

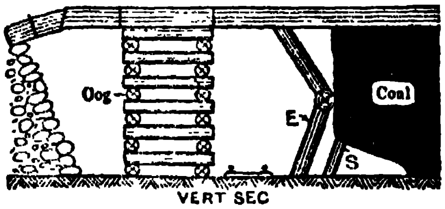

Fig 763. Longwall Face

Work at the face. The pressure caused by settling of the roof is utilized in breaking coal at the face. Fig 762, 763 show sections through typical faces. The roof between gob and face is supported partly by props on about 5-ft centers along the face and partly by the stall-road packwalls; the distance between gob and face is commonly 10 to 12 ft. With bad roof, collars are placed between props *A* and *B*, or every 3rd or 4th prop *B* may be replaced by a timber crib 3 to 4 ft sq (cog or chock). The face is undercut by hand or machine, and is generally supported by sprags *S*, set on 4 to 6-ft centers. Sometimes lateral support in the form of "cockermegs" *E*, Fig 763, is also required. When undercutting is completed, the sprags are knocked out and the face is allowed to fall. Under ideal conditions the roof pressure breaks the coal down; frequently the coal must be wedged or blasted. The broken coal is then loaded, the fresh face dressed, a new row of props set near the new face, packwalls are extended, the excess waste is gobbed, and the tracks are shifted. Props *C* are pulled if possible and if sound are reused. For further detail, see Practice in Illinois, below.

Distance between stall roads is from 36 to 150 ft. Hughes (363) summarizes the factors determining this dimension as follows: (*a*) the face between 2 stall roads must be advanced regularly and rapidly, which is difficult with very long faces; (*b*) stall roads spaced too closely involve excessive first and maintenance costs; (*c*) seams too thin for cars to run along the face require close spacing of stall roads; (*d*) the number of stall roads depends somewhat on the output required; only 2 cars at a time can be run into a section of working face between 2 roads, *i e*, one from each end; (*e*) number of men working at one section determines its length and hence the distance between stall roads.

Modifications of longwall for inclined seams are chiefly to secure a working face and haulage roads, directions of which allow convenient handling of coal. On DIPS TO 5° the stall roads are run to the rise, the working face being parallel to the strike and therefore horiz. On DIPS OF 5° TO 12° OR 15° the roads may be at an angle to the dip, thus keeping grades within the limit of hand tramming. Pitches to 30° are sometimes worked to the dip instead of to the rise; cars run down the stall roads by gravity, pulling a hoisting rope after them. The limit for such work is about 30°, where packwalls begin to slide. ON STEEP DIPS, filled flatback (longwall) or stepped-face stopes may be used (Art 60); stall-roads then become chutes or mill-holes. See also Miller mine near end of this Art. See Bib (355, 363, 367, 370) for details and variations of foreign longwall practice.

Practice in Illinois. Data from S. O. Andros in 1914 (366). This is one of the few American regions where longwall has been successful. Table 92 shows size and characteristics of the seams and dimensions of workings in 11 mines.

(*a*) Slope. (*b*) No pillar. (*c*) Protects 3 hoisting shafts. * Stall roads.

Note.—Immediate roof is shale, except for small areas of mine No 5, where roof is sandstone. Floor is fireclay, hard, sandy or soft. Mine No 1 has sandstone floor grading into fireclay; in mine No 3 a hard sandy shale underlies coal in places. Coal in all mines contains lenses or bands of clay, pyrite, or sulphur balls, 2 to 21 in thick.

All of the mines are worked by longwall advancing and with one exception have vert shafts. The greatest difficulty in starting operations is to form the shaft pillar and establish the working face. Usually in this district, after the hoisting shaft and air shaft have reached coal, a main entry is driven about 225 ft from each side of the hoisting shaft. From the air shaft 2 entries are driven in opposite directions at right-angles to the main entry, to the edges of the proposed shaft pillar. The latter is usually blocked out by driving around it a 9-ft entry *E* (Fig 764), called the "entry-around-pillar" (Fig 760). Large pillars are desirable, to protect the shaft and provide a long working face. Another 9-ft entry is then driven around the shaft pillar, parallel to *E*, leaving a 15-ft pillar between the two; breakthroughs between the entries are about 42 ft apart. Fig 765 shows an alternative method, used where the coal in the shaft pillar spalls off; the pillar face is protected by a 15-ft packwall; the 15-ft space between the 2 entries of Fig 764 is also packed with gob. Sometimes an entry 27 ft wide is driven around the pillar and 2 packwalls are built as the entry advances. One packwall 12 ft wide is built alongside the shaft pillar, and one 6 ft wide on the future longwall face, leaving a haulage road 9 ft wide between the two walls and the necessary openings through them for haulage.

The subsidence following the first break of the roof, as the workings extend outward from the shaft pillar, is very violent and will destroy the entry-around-pillar unless the latter is well protected. Seven to 10 months are required for driving entries through the shaft pillar and blocking it out after the hoisting and air shafts reach the coal. Actual mining is rarely begun until the entries-around-pillar are connected and direct ventilation established. In some older mines, no pillar was left to support the roof around the shaft; the coal was extracted, allowing the roof to settle gradually till it rested on the floor. In such case, the shaft timbers are supported on soft-wood 12 by 12-in posts, and the coal is removed from all sides of the shaft. The space thus left is filled with soft-wood cogs (shanties), and with packs of brushing and mining rock. Through the gob a 7-ft roadway is opened from each side and end of the shaft. As the roof settles the packs are compressed and squeezed into the fireclay bottom till roof and floor meet. The shaft bottom is then widened and timbered. Advantages claimed: the expense of timbering the shaft bottom is reduced, and the roof weight begins sooner to ride on the working face. Operators using shaft pillars state that these advantages are offset by the uncertainty of being able to control subsidence sufficiently to prevent the shaft from being thrown out of plumb. Fig 760 and Table 92 show the usual arrangement of entries and stall roads. For an alternative arrangement used in 1 mine see Fig 766. In pitching seams of La Salle anticline (dips to 50°), working faces are kept parallel to the dip and coal is handled to an entry below in light sheet-iron chutes.

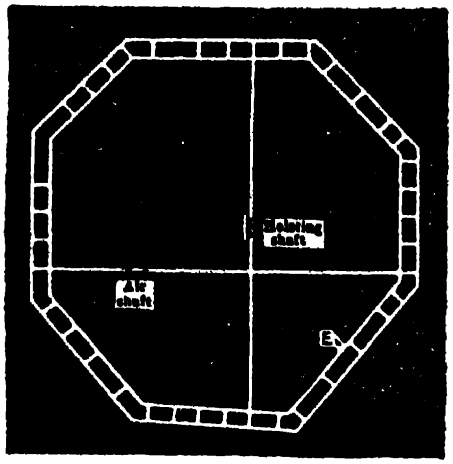

Fig 764. Blocking-out Shaft Pillar, Ill

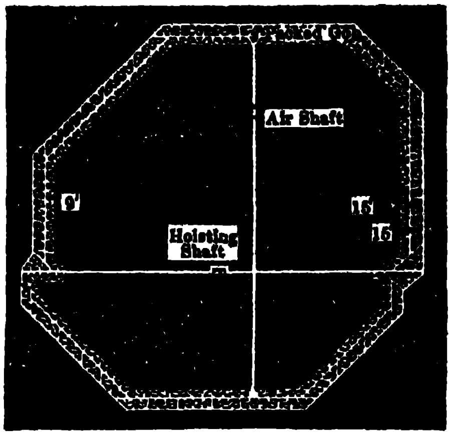

Fig 765

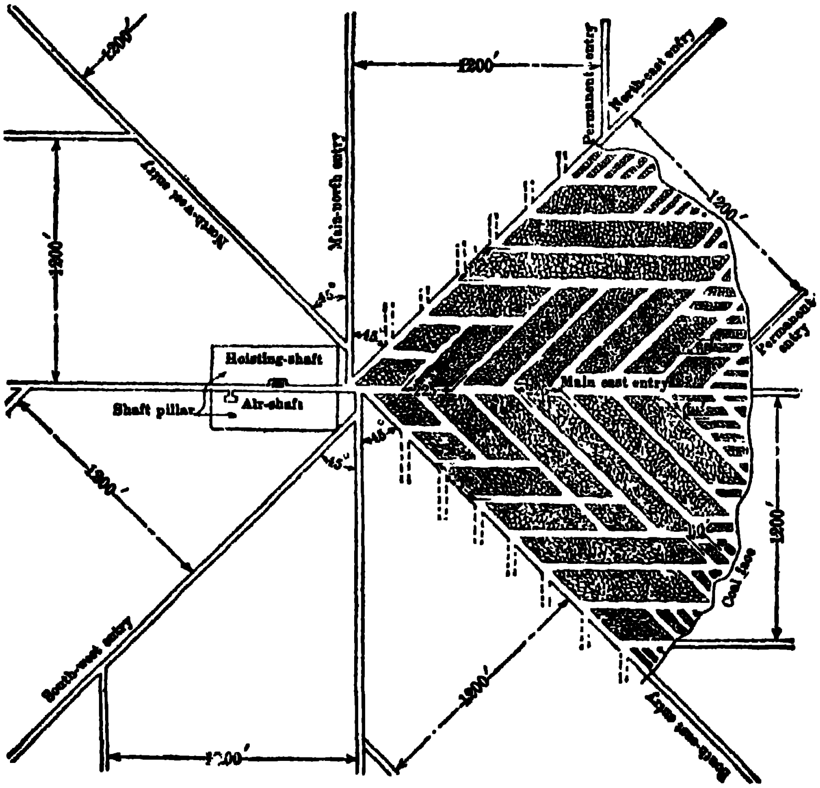

Fig 766. Longwall Mine

Fig 767 shows a flat working face. The " places " are 42 ft long; their limits are marked by " march props," as shown. Due to scarcity of labor, about 50% of the " places " are worked by 1 miner; the rest by 2 miners. The crew on a " place " is responsible for building packwalls and for gobbing as well as for mining. Where possible, an undercut 8–12 in high and 2–2.5 ft deep is made by picking in the fireclay floor. Sprags are 6–8 ft apart; props are set 2–5 ft from the face and 6–8 ft apart. With an aver depth of undermining, a good miner can undercut about 20 ft of face a day when working in soft clay 8–12 in thick. For loading a car, that portion of the coal is taken which has been standing longest on sprags. These are knocked out, and if the gob has been properly filled, so that the roof weight rides on the face, the coal breaks from the roof and is ready for loading; otherwise, the coal is wedged down. Under fairly good conditions about 80% of the coal exceeds 1.25-in size.

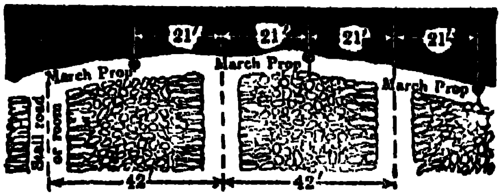

Fig 767. A Longwall Face (Plan)

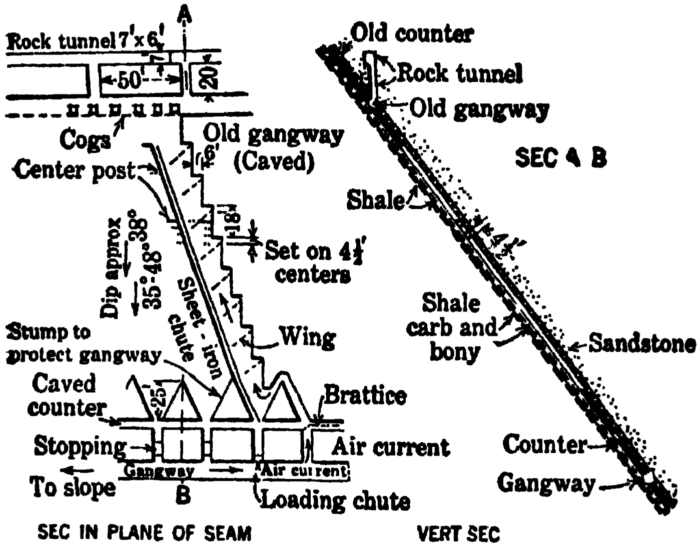
If the floor is sandstone, or if the fireclay is much over 18 in thick, undercutting is done in the coal itself; this produces much slack and increases the number of gob fires, because more fine coal goes into the gob with the waste. To save time and labor the miner often neglects to support the coal on sprags until the usual 2 ft of undermining is completed; instead, he makes a cut 4–8 in deep and pries down the coal. This does not utilize the slow breaking power of the roof; more accidents occur, and more slack and smaller coal result than when full undermining is insisted upon. For blasting, black powder is used where necessary. Practically all undercutting is done by hand.

The rock obtained from brushing the roof, that remaining after building the packwalls, and the clay obtained from undermining the coal, are piled in the gob area between the packwalls lining the roads, to help support the roof and control its pressure on the face. After the first break at the shaft pillar and face, if the gob area has been properly filled, so that the roof weight " rides " on the coal, subsequent roof breaks occur every 2 to 6 ft; they parallel the face and extend upward and backward from it at angles of 50° or more; cracks are more nearly vert on faces which are worked slowly. The distance between breaks depends chiefly upon the character of roof and the packing of the gob; with proper packing it should correspond to the width of coal brought down. The distance to which breaks extend into the roof rarely exceeds 15 ft. Squeezes which fill a working place with roof material occur when a room is driven ahead of adjacent rooms, or more commonly when packwalls are defective and the gob area is not sufficiently filled. There should be enough filling for the roof to come down gradually without breaking off short at the face of packwalls, but not so much that insufficient weight is thrown on the face of coal. The better the gob is packed, the better the coal "works." When part of the working face squeezes, the face is usually diverted to pass around the squeezed area, sometimes leaving a small block of coal in the gob.



SEC IN PLANE OF SEAM VERT SEC

Fig 768. Longwall Mining, Miller Mine, Wash (610).

The necessity for artificial humidification to prevent coal-dust explosions has not been apparent in these mines. Since all the coal is removed from the seam as the face advances and the excavation is filled with waste rock, the only sources of dust are the working face and the spillings from cars. Dust from the face is covered with shale and clay within a few days after it is made and does not accumulate. As the aver temp of the air in these mines is higher than in room-and-pillar mines, the relative humidity is decreased and moisture is absorbed from the dust of ribs and roads. In a few mines, the haulage ways are sprinkled at intervals of 1 week to 3 months (Sec 23).

Miller mine, Wash. Data from S. H. Ash in 1925. A modified longwall method was substituted for breast-and-pillar and chute-and-pillar systems (see Pierce County, Wash, Art 106, 107) in a seam 4–4.5 ft thick; aver dip 38°, which is considered slightly flat for best results. Fig 768 (diagrammatic) shows general plan of work. The coal is worked in 6-ft "skips," about 18 ft apart. On one face, 500 ft long, 30 miners produced 250 short tons per 8 hr. Coal is loaded to a sheet-iron chute, never more than 24 ft from the face; a wing, kept under each miner, protects man below from falling objects and guides coal to the chute. Fig 769 shows timbering; props are on 4.5-ft centers along the pitch. Bib (610) gives more detail.

Anthracite district, Pa. Use of longwall has increased with development of mechanical loading (Sec 27) and need for mining thin seams. H. D. Kynor, in 1921, describes method for flat or slightly pitching seams, Fig 770 (612). Gangways are 200 ft apart. A chamber is driven from lower to upper gangway; a line of "break props" is set; lines of timber cogs are built parallel to face and 10–16 ft apart; cogs in a line are 6–8 ft apart. In seams under 30 in thick, rock-packed roads 10 ft wide are made parallel to gangways and 60 ft apart; 2–3 ft of top rock broken down supplies rock for 12-ft walls on each side of road. In seams over 3 ft thick, timber cogs support the roof. Fig 770 indicates ease of applying scraper loading.

Fig 771. "V" System, Norton Mine, West Va Coal & Coke Co (608)

"V" system, Norton mine, West Va. Data from G. B. Southward in 1924 (608). Modified longwall is used under roof conditions prohibiting regular longwall. It is applied in Lower Kittanning seam; aver thickness, 6 ft; roof is slate and shale 20–30 ft thick, overlain by a sandstone bed 40 ft or more thick; total cover, 25-250 ft. Seam is worked in panels 300 ft wide (Fig 771); face is a series of V's, with sides 85 ft long and points 80 ft apart; angle of V, 45°. Roof over each V is considered as a beam supported by the coal; hence character of roof determines max length of span, and depth of cover determines amount of coal necessary for support, which in turn fixes the angle of the V. Panel development comprises lateral entries 200 ft apart, with cross entries 80 ft c-c. Slab cuts are made on the faces; machine cuts are taken to keep the V-angles constant and the points in line. Advance cross entries are driven at same speed as faces retreat; hence, when face reaches a lateral entry, cross entries have reached the next lateral, through which coal goes to haulageway. Only a small amount of advance work is required in this combination of longwall advancing and retreating.

Coal is loaded by hand to elec-driven, steel-pan, belt conveyers, which parallel the faces (see heavy dotted lines in Fig 771); similar conveyers take coal without rehandling through cross and lateral entries into cars in the haulageway. Props, set behind the face conveyers after each cut, and in the area between faces, support the slate; at intervals, timbers are removed near caved area and the roof falls. Aver production from 8 faces, besides coal from development, is about 750 tons per day of 2 8-hr shifts, by an aver of 60 men between faces and tipple. The method gives a 600-ft working face in a 300-ft panel; it simplifies supervision, drainage and ventilation; accidents few and output per man high (608).

109. BREAKING GROUND IN COAL MINES

General. Breaking ground (Art 26) is, in coal mines, sometimes called CUTTING COAL. Principles are the same as those of breaking ore or rock, except that coal is relatively soft and brittle, and, as a lump product is generally desired, the explosives are of low power and number of holes in a given face a minimum. No definite rules can be laid down as to location of drill holes and charge of explosive, for the following reasons: WIDELY VARYING LOCAL CONDITIONS occur in different seams, or successive cuts in the same seam. Slate partings, " blowing benches," pinches or faults, rolls, slips, cleat, and character of the coal itself, demand experience for properly locating and charging holes. CONTRACT WORK is usual, miners being paid by the car of coal or yard driven; they purchase their tools, explosives, fuse and caps, and pay their laborers. Since a misplaced or improperly charged hole will reduce his earnings, both by increasing his supply account and decreasing output, the miner is prompted to take advantage of every possible condition which will break most coal with least effort and explosive.

For example, miners applying for work in the Southern Anthracite Field of Penna often state that they are Mammoth, Buck Mountain, or Lykens miners, as the case may be. Observing their work, it is apparent that they have studied their particular seam and in locating a drill hole are quick to recognize advantages or disadvantages which no rules can cover. Men must work for some time as helpers and pass a state examination before becoming miners and allowed to "cut coal."

Drilling. The miner plans his work to suit the conditions and keep his laborers busy. Drilling is done chiefly with hand or power augers, mounted on bars or posts. The various small and light jackhammer drills (Sec 15) have been successful in driving gangways, especially in the Southern Anthracite Field, where work in thin seams requires the breaking of considerable top or bottom rock. To facilitate blasting and obtain a max lump product, coal cutters (Sec 16) are widely used in bituminous mining and to some extent in the Northern Anthracite Field. Chain machines are limited to pitches less than 20° to 25°; those of the " post-puncher " type are successful in the semi-bituminous coals of Washington on pitches up to 38° (371, 612).

Explosives used are black powder, low-power Ngl or ammonia dynamites, and, in gaseous or dusty mines, the permissible explosives (Sec 4). The rending effect required to produce a large proportion of lump coal is secured by black powder or 15% to 20% dynamite; practice tends toward the latter. For modes of charging and firing, see Sec 4.

Examples of practice. SOUTHERN ANTHRACITE FIELD, Penna W. L. Cross, Jr, furnishes following data on driving gangways, monkeys, chutes, headings, and breasts, in Skidmore and Buck Mountain seams at Buck Run Colliery. Fig 772, 773 show methods of driving gangways. Holes in coal are drilled and fired first, the broken coal is removed and the face dressed. Then the rock holes are fired, bottom rock being lifted in each case. Aver advance per round, 5 ft, with an aver consumption of 25 lb of 35% dynamite. Fig 774 shows driving a monkey in firm and hard coal, drilling with hand augers. When near the chute an advance of 1 cut or 5 ft is made in 8 hr. As distance from chute increases, advance is slower, because the coal must be reshoveled. Fig 775

NOTES TO ACCOMPANY TABLE 93

* Numbers are same as diagram numbers in Bib (613). † Where not stated, method is probably elec blasting. # Lb. *AD* = Adobe. *BP* = Black powder FFF in Ex 5, fine grained in Ex 12. *CD* = Clay dummies put in loosely. *CA* = Cartridges. *EL* = Elec blasting. *FC* = Fire clay. *IN* = Inches. *MC* = Center-cut. *PE* = Permissible $1\frac{1}{4}$-in by 8-in cartridges. *RD* = Rock dust. *SN* = Snubbed *SO* = Shot from solid. *SQ* = Squibs. *TC* = Top cut. *UC* = Undercut. *A* = Soft, high volatile, low sulphur and ash. Definite cleavage, but coal tends to stick to roof Contains $\frac{1}{4}$-in sticker near bottom and 2-in binder near middle. *B* = Medium hard, containing sulphur balls and slate bands. Coal breaks badly from roof, hence top cut. *C* = Very soft, 14-in slate band near middle. *D* = Semi-bit coal, limestone bottom, roof of soapstone 1–18 in thick and coal underlying limestone; 1-in black band and 2-in copper rock in lower part of face. *E* = 1 ft 4 in coal, $3\frac{1}{2}$ ft slate, 3 ft of coal at top, 45° pitch. *F* = 5 ft of coal, 14 in slate and 3 ft 4 in of coal on top, lower coal hard. *G* = 2 ft 6 in coal, 3 in slate, 2 ft 7 in coal, 5 in slate, 1 ft coal, 2 in dirt, 8 in coal on top. Bottom bench medium hard with slips. Slate seams brittle or soft. Top coal hard and solid. *H* = Medium hard with many slips, parting 4.5 ft from floor. *I* = 6 in bony coal near middle *J* = 11 in of tough bone and bony coal near middle. Top 8 in of seam is hard. *K* = Range of thickness, 4 ft 7 in–2.5 ft. Coal breaks from top bench easily. *L* = 7 in bony coal near middle of face, cannel coal at top. *M* = 7-in sulphur band near bottom. *N* = Soft, high-volatile dry seam. Holes 1 ft from ribs and 6 in from top. *O* = 1 ft of draw slate left in roof, 1-in slate band near bottom. *P* = Coal soft but firm. $\frac{1}{2}$-in binder near middle. *Q* = 4-in clay band about one-third from bottom. *R* = 6–8-in blue band about one-third up face. *S* = $\frac{1}{2}$-in and $\frac{3}{4}$-in slate band below center; 9 in of extra soft coal at top. *T* = Coal rather hard, elec drills. *U* = Sulphur bands in lower part. *V* = 3 ft 10 in–2.5 ft thick. Coal much cut by clay horsebacks. *W* = 28-in slate band near center requires heavy blasting. *Y* = Soft. *X* = 5 in bony coal near center. *Z* = Blue band below middle. *AA* = 12 in of draw slate above seam breaks with the coal if holes are too close. *BB* = Massive, no cleavage, sticks to top unless back holes are close to roof. *CC* = 2-in binder of bony near roof. (*a*) One at a time, middle hole first. (*b*) Row above slate fired and coal loaded, then others fired. Center holes fired first. (*c*) 6 times as much coal broken per lb powder when coal is undercut. (*d*) Occasionally coal is snubbed by a shot or picked. (*e*) Drilled with jack-hammer. (*f*) Top bench holes fired first. Center hole on each bench fired before rib. (*g*) Varied as thickness of bony coal changes. (*h*) Two center holes fired first. (*i*) 1, center hole in slate; 2, 3, 2-hole row just above slate; 4, 5, rib holes in top row; 6, center hole in row just below slate; 7, 8, rib holes in this row; 9, center hole in bottom row; 10, 11, rib holes in this row. (*j*) 3 middle holes in lower row fired before rib holes; 2 holes in upper row fired last. (*k*) 1, 2, center holes in top row; 3, 4, holes next outside; 5, 6, rib holes top row; 7, center hole below; 8, 9, rib holes in bottom row. (*l*) 1, left center hole above bony; 2, extreme left; 3, right center; 4, extreme right. (*m*) 1, 2, 3, central holes, right to left; 4, 5, outside holes. (*n*) About 6 oz per $1\frac{1}{4}$ by 8-in cartridge. (*o*) Method secures 56% lump coal over 1-in screen. (*p*) Found best for mechan loading. (*q*) 1, 2, snubbing holes just above sulphur band; 3, 4, 2 center holes in upper row; 5, 6, 2 rib holes in upper row. (*r*) 1, two rib holes in upper row; 3, center hole; 4, 5, two cut holes below binder. (*s*) Holes in 2 vert rows near rib, above band. Lower pair fired first. (*t*) 62–65% lump coal produced; aver 7 ton per lb explosive in rooms; 4 ton in entries. (*u*) 1, snubbing holes just above blue band; 2, upper row. (*v*) Holes are below center, collars of 2 cut holes 10 ft apart; toes, 4 ft. Fired in sequence, cuts first. (*w*) 9 in soft coal at top picked out. Holes placed in a row below lower slate band, inside pair fired first. (*x*) 1, 2, center holes; 3, 4, holes on either side; 5, 6, rib holes. (*y*) Coal also sheared by pick. 40% dynamite in horsebacks and for " brushing " roof. (*z*) 1 row below and 2 above slate band; 3 center holes fired first, then other 6 at one time. (*aa*) 1 row below, other above bony. 1, center holes below bony; 2, rib holes below; 3, center holes above; 4, rib holes above. (*bb*) 11 ft between center and rib holes; 255 tons per 50 lb explosive. (*cc*) Pick snubbed also, 2 rows above blue band. Holes fired singly, beginning with center hole in lower row, then rib holes, then center hole in upper row. (*dd*) Pick snubbed, $2\frac{1}{2}$-in holes. (*ee*) 1, 2 center holes; 2, 2 rib holes. (*ff*) Fired simultaneously. (*gg*) Lower row fired with instantaneous elec cap, center back hole with 1st delay, upper rib holes with 3rd delay. (*hh*) Top row above bony, 2nd row just below bony with a row of snubbing holes below. Snubbing holes fired first in order; then second row, beginning at center; this drops coal below binder. Binder is picked off and then top coal broken, beginning with center hole. 35% of coal is on a 3-in screen and 35% is minus $1\frac{3}{4}$-in slack.

shows driving a chute entirely in coal on a pitch of 40°–50°. Slightly more than 1 cut of 5 ft per shift is made; aver powder consumption per 30-ft chute, 50 lb. In driving a heading in Buck Mountain seam (Fig 776), the miner in one breast starts a blind heading through the pillar, a heading from the next breast being driven to meet it. Hole No 1 is charged with 4 sticks of dynamite, and the broken coal removed; then hole No 2 is drilled, charged with 3 sticks, and fired; the resulting cut should be fairly square A second cut is made by holes 3 and 4; then hole 5 is drilled and fired. If second cut breaks through to the blind heading, a second hole will be unnecessary, as the rib can be squared up with a pick The blind heading is similarly driven, except that usually there are only 2 cuts. In Buck Mountain seam, breasts are driven as in Fig 777. All holes are drilled in bottom bench in the so-called " mining seam," viz, the portion most easily drilled and giving the best results on blasting, 2 cut and 2 rib holes making an aver round. Cut holes are charged with 5 sticks, rib holes with 3 sticks, of 20% dynamite. If necessary to break the " middle stone," a 3-ft plug hole is charged with 1.5 sticks of 20% dynamite. Aver advance, one 5-ft cut per shift. **Illinois methods** in bituminous coal (Table 94). In flat seams, the face is undercut before blasting. This reduces power consumption, minimizes danger from blow-outs and increases yield of lump coal. Fig 778, 779, 780, showing holes in faces undercut by hand or machine, are fairly typical of American practice. Table 93 summarizes data published by T. Marvin in 1926 (613).

110. FLUSHING

Flushing ("slushing" or "silting") corresponds to sand-filling in metal mines (Art 92). It was probably used first in 1884 in Penna for extinguishing a mine fire. It has been extensively developed in the U S and abroad, not only to check and isolate fires, but also to regulate subsidence (Art 114), and to dispose of culm banks; its use lessens stream pollution near anthracite breakers. Following notes are largely from Bull No 60, U S Bur of Mines, by C. Enzian in 1913; see also Bib (372, 373).

Materials for flushing. Culm (Sec 34) is excellent; easily drained and when well packed resists heavy press. Compact culm will often stand in a vert face without timber, and can be driven through without spiling. Having low abrasive qualities, culm is readily conveyed by water in pipes and launders. Its use for flushing is decreasing with the widening sale for finer sizes of coal. Ashes, sometimes available at steam-operated mines, wear pipes more than culm, but resemble the latter in other respects. A drawback to their use in anthracite mines is that they mix with coal mined next to flushed areas and can not be separated from the finer sizes in the breaker. Breaker refuse (rock, slate, and bone) has good supporting qualities. It requires crushing to less than 1.5 in and is harder to transport in water than ashes or culm, but rarely chokes the pipes. Sand and gravel are effic, but very abrasive; they have thus far proved too costly in the U S. Granulated slag is used abroad in mines near blast furnaces. It is an ideal filling material, having natural cementing qualities and being strongly resistant to pressure. ¶

Modes of handling filling material on the surface, between the surface and the mine, and underground, resemble those described in Art 92.

Few data are available on the lateral distance to which filling may be transported in pipes under a given head. Silesian practice allows 300 ft horis for each 100 ft of available head; the distance is affected by size of pipe and thickness of pulp. Water in pulps varies from 40% to 90% of total vol, depending on grade and size of pipe (or launder), effective head and kind of filling. Troughs (launders) (Fig 660) are used where possible; they are often lined with cement, terracotta, or sheet iron. Pipes are required to carry pulp under press. Wood-stave pipe resists acid and abrasion, and, due to its lightness and convenient length of sections, is easily installed; but it is unsuited to high press, and dries out and collapses when not regularly in use; it wears unevenly and springs out of line; its life is short. Steel or W-I pipe is readily attacked by acid water, and is more quickly abraded than wood; it is heavier and harder to place than wood-stave pipe and generally costs more. Abroad, wood-lined steel pipe has been used. C-I pipe is heavy and hard to handle underground, but resists abrasion and acid water; its life is about 3 times that of W I and 5 times that of steel. Bell and spigot joints permit deflections. Location of mine with respect to a foundry determines whether this pipe is cheaper than others. **Terracotta pipe** resists acid and stands wear until the glaze wears off, after which abrasion is rapid. It is unsuited to high press and because of its brittleness must be handled carefully and protected from roof falls. Its cost is comparatively low, but its life is short. **Glass-lined pipe** has been satisfactory in Europe, in an effort to reduce wear at bends and elbows; its high cost practically prohibits its use in the U S. **Porcelain-lined pipe** is highly effic for small-size filling material, as it has exceptional wearing qualities, resists acid and has low frictional resistance; it is widely used in Europe, but is too costly in U S. In Penna, wood-stave pipes are probably most used for low heads, C-I or steel pipes for higher heads; much flushing is done through unlined bore holes and troughs; the latter are preferable to pipes.

Fig 782. Bulkheads for Dips of 10° to 25°

Bulkheads (barricades, Art 92). Their design (Fig 781–784) varies with dip of seam. They are placed a short distance *B* (Fig 781), the haunch distance, above the lower end of the working to be flushed. Table 95 gives empirical formulas.

Fig 781 shows construction for flat workings; leakage at the bottom is prevented by manure or dirt packing. Props are lagged with 1 layer of 1.5-in plank, or 2 layers of 1-in.

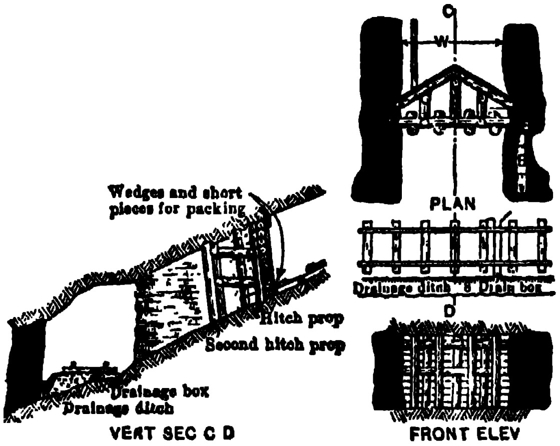

Fig 783. Bulkhead for Dips of 25° or More

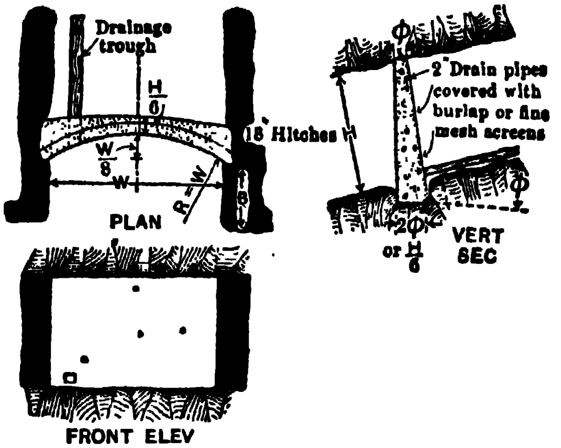

Fig 784. Masonry Bulkhead

Bulkheads are made stronger on steeper pitches, and their drainage is carefully provided for, to avoid subjecting them to the full hydrostatic head of overlying water and culm. They are drained by troughs and screens (Fig 781, 782); or by filters of hay, straw, burlap, and dry-walling. A trough returns the water for reuse if necessary more quickly than the other devices. Fig 784 shows an arched concrete bulkhead; good for heavy press and where timber is costly.

Table 95. Size and Spacing of Props in Barricades

	D = diam of prop, in	S = spacing of props c to c, ft	B = haunch distance, ft
Flat workings, 0° to 10°	D = L	S = W + H	W + 2
Chute workings, 10° to 25°	D = 3 L + 2	S = 2 W + 3 H	W + 2
Pitch workings, over 25°	D = 7 L + 4	S = 4 W + 7 H	2 W + 3

W = width of opening, ft. H = height of opening, ft. L = length of prop, ft. Number of props required for a barricade = (W + S) + 1.

Data in Table 96 are from plants with capac of at least 400 cu yd daily.

Table 96. Costs of Flushing in the U S, ¢ per cu yd (C. Enzian, in 1913)

Material	Surface transport			Intermediate transport		Underground tr'sport		Distribution			Drainage		Total

Material from a distance in returning empty coal cars	Cost of material, loading, freight, unloading, preparing and surface transport			1–1 1/2	4/10–8/10									

111. TIMBERING. USE OF STEEL SUPPORTS

Timbering in coal mines is similar to that in metal mines with differences in detail and terminology. Props, and 3-piece sets (Art 20) for gangways, etc, are of round timber.

Common sizes of legs (posts) are 10 to 14-in diam, of collars (caps) 8 to 10-in; in Penna, legs have a batter of 2.5–3 in per ft; in bituminous mines they are often vert. Lagging is 3-in round or 6-in split, in 6-ft lengths. Sets are usually 5 ft apart; in heavy ground they are doubled, at 2.5-ft centers. In moderately thick pitching seams, gangways may be timbered with a single row of lagged props along the high side, corresponding to stull timbering in metal mines (Art 38, see also Fig 235). When length of such props exceeds about 12 ft, they are replaced by 3-piece sets on flatter dips, or by " post and bar " (half or 2-piece sets, Art 20) on steep pitches. Rooms and breasts are timbered with props set with a slight underlie (Art 38); their spacing depends on character of roof. Headboards are sometimes used; generally props are wedged against the roof. In flat rooms or moderately pitching breasts, where the roof tends to flake off, caps may be placed between props, at least over the track or chute (355).

Steel supports are increasingly used in both coal and metal mines, especially for wide openings and those of semi-permanent character, as haulageways, pumprooms and shaft stations. STEEL *vs* TIMBER. Steel lasts much longer, especially in moist, foul air. It is procurable in sizes that will carry heavier loads than any available timbers. Less excavation is required and cost of erection is usually less than for timber of equivalent strength.

Disadvantages of steel are its relatively high first cost (unless second-hand material is available), and that it can not be so readily cut and fitted underground, unless gas-oxygen torches are used. It may be required by heavy press regardless of other factors; its installation is often justified by saving in maintenance.

Proper size of steel for given service cannot be definitely computed, because it is impossible to measure the weight to be supported. Steel members for replacing timber are slightly heavier than required for equivalent strength. In a new region, their size is based on experience with wood or steel under similar conditions elsewhere.

Types. Props may be of standard H-sections, of old rails, or other available material. Wooden or steel base blocks and head boards are generally necessary, to prevent props from being forced into floor or roof. Fig 785, 786 show examples of gangway sets made by the Carnegie Steel Co in numerous forms and sections of leg and collar. Legs are commonly of H-section (Fig 786) or of 2 channels (Fig 785); collars of I-beams; joints may be rigid or adjustable. Entry and gangway roofs are often supported by I-beams, H-sections or rails, resting on wooden legs, concrete pillars or walls, or in hitches in the coal ribs. Arches and cambered girders are widely used in British and Continental mines. Lagging may be of wood, or, for fireproof construction, of old rails, sheet steel or corrugated iron. Brick or concrete arches are sometimes turned between collars of adjacent sets. Concrete slabs, with light wire-mesh reinforcement, may be built over the collars in pumprooms. For examples of steel supports in shaft stations and pumprooms, see Sec 12 and 13 respectively. For further data, see Carnegie Steel Co catalogs and Bib (374, 375).

GROUND MOVEMENT AND SUBSIDENCE

The following Articles were written originally by Alan M. Bateman, Prof of Economic Geology, Yale Univ. Revised in 1926 by H. G. Moulton, Consulting Mining Engineer. Revised and enlarged in 1938 by Stephen Royce, Consulting Mining Engineer and Geologist, and Geologist for Pickands Mather & Co.

112. THEORIES AND PRINCIPLES

Status of information. While ground movement and subsidence have long been studied and many theories advanced, data are scanty and often conflicting.

In the U S, committees of the Am Inst of Min Engs are investigating the subject with reference to coal, non-ferrous metal and open-cut mining. Best current sources of information are: COAL MINING. Comm Rep, A I M E, 1926 (469), containing tabulations and data and Bib from 1913 to 1924. OPEN-CUT MINING (470, 471). GENERAL. Bull 91, Eng Exp Sta, Univ of Ill, by Young and Stoek, 1916 (465), contains an extended Bib. (See also Bib 472, 473, 621, 673, 674).

Economic features. Heretofore, the chief interest in subsidence has concerned surface damage, since ground under buildings must generally be supported to prevent injury from settlement. In general, subsidence must be prevented where towns are located over workings; where settlement would affect the grades of R Rs, sewers and piping; where water courses overlie mine workings and subsidence fractures might admit much water; and where, in case of large mines, surface effects would be too great to permit subsidence, except in areas containing no permanent improvements. Subsidence can sometimes be controlled to produce such uniform surface settlement that buildings are not seriously damaged; as in case of certain regular coal seams where the coal was completely extracted.

Possible subsidence affects choice of location of mine shafts and surface plant. Mills should be placed where they can be supported, or at points safe from settlement; otherwise foundations and machinery may be injured.

The problems of subsidence as affecting mining operations themselves are now usually more important than surface effects. In some mining methods, press caused by subsidence of overlying strata aids in breaking the mineral; in metal mines, control of subsidence reduces mining costs and dilution of ore. Coal-mining practice tends toward complete extraction of coal, accompanied or followed by uniform subsidence; this minimizes danger of loss from squeezes. Subsidence is sometimes desirable for filling voids, as when extracting sulphur from deep deposits by hot water.

General principles. Withdrawal of support caused by removal of minerals subjects the overlying rocks to 2 kinds of distortion: (*a*) local caving of stopes; (*b*) a general, widespread movement. The second type is, however, only an extension of the first. The extent of displacement over a large area depends on strength of overlying strata and method of removing its support.

For example, at Hidden Creek mine, Granby Consol Co, Anyox, B C, the orebody was a lens of Cu and Fe sulphides; footwall, slate; hanging wall, greenstone. One stope had an unsupported roof with a span of 300 ft; top of the arch was approx 400 ft below surface. The ground stood over this large area because the roof rock was strong, and formed a strong natural arch over the stope; if the arch were not properly shaped, the roof would cave, and, in weaker rock, caving would extend over a large area. The extent to which local caving in stopes may develop into general caving, with failure of the surface, therefore depends upon the strength, depth and character of overlying rock, the area of support removed and mode of removing it.

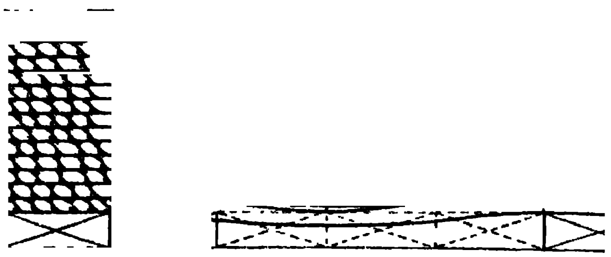

Fig 787. Fayol's Experimental Subsidence of Horiz Strata

General surface failure over a large area is of 2 kinds: (*a*) Usual type in coal mining consists of settlement of bedded rocks over worked-out seams, where beds are comparatively flat and thin; (*b*) in extracting ore from bodies underlying massive rocks, the action may be merely local spalling over stopes, but may extend to complete collapse of the surface. Subsidence of bedded rocks over coal mines appears to involve beam action to some extent; the strata bend and break, due to tensile stresses. Subsidence of massive rocks over metal mines involves failure from fracture by compression; as over stopes of the Miami copper mine (Art 86); surface cracks first appeared, followed by subsidence along vert breaks.

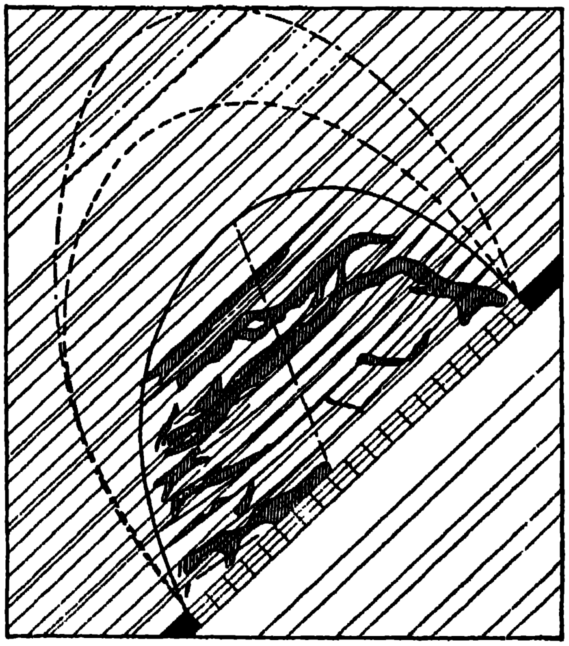

Fig 788. Fayol's Experimental Subsidence of Inclined Strata

Early theories. From studies during latter half of last century in France, Belgium and Germany, many mathematical theories of subsidence were developed. Best known is that of H. Fayol in 1885 (467), based upon experiments with artificial beds of earth, sand, clay and plaster, in small boxes. The conclusion was that fracture of the ground would spread out in form of a dome, the increased vol of broken material filling the area affected, finally checking movement at some depth bearing a definite relation to thickness of mineral removed. In homogeneous, or in flat lying stratified rocks, these domes tend toward a semi-ellipsoidal form, with major axis vert, and the base of the half ellipsoid coinciding with the limits of mining (Fig 787). As mining is extended, laterally or in depth, new ellipsoidal domes develop, and the older, interior domes continue to show increased movement along their surfaces as long as subsidence continues within and below them. These successive domes produce the phenomenon shown in workings over a mined orebody, where

the ground is displaced downward in successively greater scarp movements as the center of mining is approached. In case of inclined strata, the axis of doming tends to be warped toward the normal to the bedding, and lies between that direction and the vert (Fig 788); (205). These reactions to subsidence are affected by fault planes or other planes of weakness in the terrane (Fig 789, 790). For a historical study, see Bib (465). Recent experiments in sand by W. J. Mead, of Mass Inst of Tech, have confirmed the mechanical principles of this type of movement, early developed by Fayol and elaborated by Goupillière.

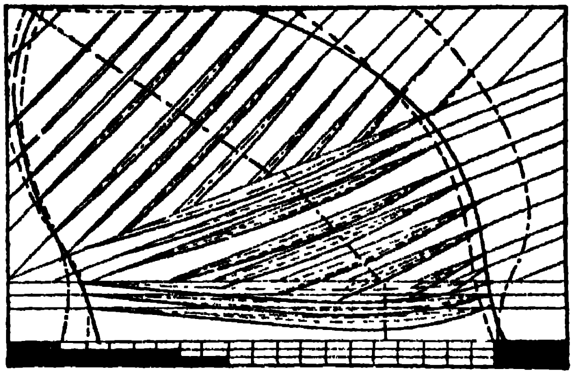

Fig 789. Fayol's Experiments with Uncomformable Beds

Recent theories. Following discussion is abstracted from a paper by George S. Rice (472). GROUND MOVEMENT, without some of which there can be no subsidence. Small movements of hanging wall or roof are evident in every mine where falls occur or timbering is needed, and in deep mines by a flow of the rock that gradually closes openings. Greater movements occur in orebodies mined by top-slicing or similar method, and in coal mines worked by longwall and pillar withdrawal. The successive changes between these first movements underground and surface subsidence are veiled with uncertainty, even in nearly horiz bodies of homogeneous material. The variables of dip of strata, and their strength, possible faults, mining method, character and depth of overburden, and character of the underlying strata, add complexities.

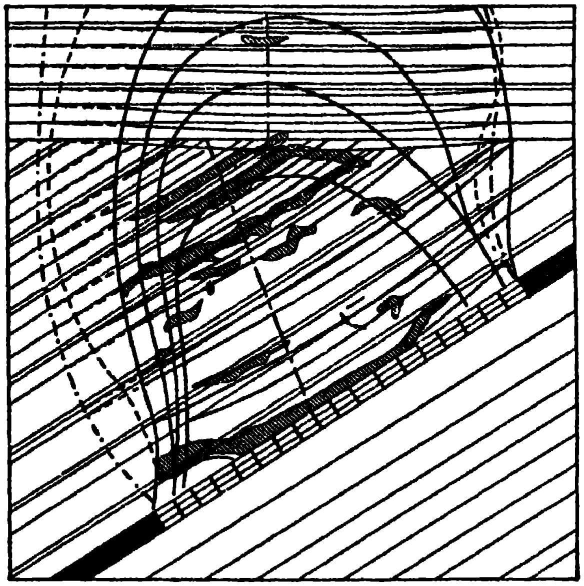

Fig 790. Fayol's Experimental Subsidence of Horiz over Inclined Beds. (Fig 787–790 from Goupillière, Vol 2)

(See also recent papers, in *Trans* A I M E and *E & M Jour*, by P. B. Bucky, Assoc Prof of Mining, Columbia School of Mines, detailing his experiments on strength of rock strata and pillars, and allowable span of roof over mine workings.—R. P.)

Effects of ground movement that seriously concern mining, from both safety and economic standpoints, are: (*a*) Simple falls of rock or ore. (*b*) "Bumps" (Sec 23). In this case, gradual settlement of the immediate roof probably causes rigid strata above, comparable to beams under heavy load, to break successively when subsidence leaves a sufficiently wide unsupported space (622). Such breaks cause a hammer-like blow on the lower rocks, transmitted as a shock wave to the mine roof; this, being elastic, does not collapse, but loose material is thrown down, timber smashed, and wind blasts produced. Firedamp outbursts may occur simultaneously. (*c*) Squeezes in coal mines (Sec 23) may cause subsidence, but it is slight, as the pillars remain in place. (*d*) Flow of rock, even of the granitic type, in mines 3 000–5 000 ft deep, as in the Lake Superior district, may slowly close shafts or other workings. (*e*) Extensive falls of hanging wall in metal mines, and rock readjustments in deep mines, set up violent air blasts. Such falls sometimes occur in thick coal beds, with high open chambers, as in India. (*f*) Irregular subsidence and rupture of upper beds, in room-and-pillar mining. If the beds are close together, mining the upper ones may be impracticable, due to difficulty and cost. In longwall, or where workings are sand-filled, permanent damage is small. (*g*) In ore veins that are thick, dip steeply, and have relatively weak walls, if sublevel-caving be used, the wall rock may slump in with the ore and lower its value. (In Lake Superior iron mines and elsewhere, such dilution is controlled by flooring sub-levels with plank; Art 71.—Author.)

Mechanics of ground movement. A commission, appointed in 1825, to investigate surface cracks in vicinity of the coal mines at Liège, Belgium, concluded there was no danger from subsidence over workings deeper than 300 ft. In 1838, Gounot proposed his theory of the law of the

normal, *i e*, planes normal to dip of the bed limit the fracturing from an excavation. A similar theory was advanced about 1838 by Trollez, of France. Later, Rucloux and Durmond, of Belgium, Callon, Culomb, and Goupillière, of France, Schulz, von Sparre, von Dechen and Hausse, of Germany, and Jicinsky and Rziha, of Austria, each developed theories. Schulz criticised the law of the normal, considering that the plane of fracture varied with the material and in shale was vertical.

Although Fayol is generally credited with the dome theory, Rziha apparently first proposed it, on theoretical grounds only, in 1881–82; he also believed that stratification of the beds had little effect on angle of break, and described a "falling space," approx a spheroid, the rocks within which dropped when the force of gravity exceeded cohesion. Surrounding the falling space, Rziha thought there was a "friability" or "tearing space"; also that, in very deep mining, the increase in vol of the broken rock may prevent surface disturbance, and proposed the formula: $h = M \div a$, in which h = harmless depth; a = coeff of increase of vol; M = vert height of excavation.

Fayol made extensive laboratory tests, as well as mine observations, and in 1885 summarized the contradictory opinions advanced to that time, as follows: 1. Extension of movement upwards: (*a*) movement is transmitted to surface, regardless of depth of workings; (*b*) the surface is not affected when workings exceed a certain depth. 2. Amplitude of movements: (*a*) subsidence extends to surface without sensible diminution; (*b*) movements become more feeble as they extend upwards. 3. Relative positions of surface subsidence and mine workings: (*a*) subsidence always takes place vert above the workings; (*b*) subsidence is limited to an area bounded by lines drawn from perimeter of the workings and perpendicular to the beds; (*c*) subsidence can not be referred to the excavation by either vert lines or lines normal to the beds, but only by lines at 45° to the horiz, by angle of repose of the material, or by some similar angle. 4. Influence of gobbing: (*a*) Use of packing protects the surface effectually; (*b*) packing merely reduces the effect of subsidence.

Fayol's conclusions were that ground movements are limited by a dome having for its base the excavation and that their amplitude diminishes as they extend farther from center of the area, this also being true of the vert effects; also that, if workings are very deep, there will be no surface subsidence, because of increase in bulk of broken rock (Table 97); this is not substantiated by more recent data.

Table 97. Fayol's Tests on Volumes of Different Materials, when Crushed to Granular Size (20 mm) and Compressed; Original Vol being Unity (465)

(*a*) Corresponds to vert rock press at depth of 1 638 ft (*b*) Corresponds to vert rock press at depth of 3 276 ft	Increase in vol	Vol when compressed	
		By press of 1 422 lb per sq in (*a*)	By press of 2 844 lb per sq in (*b*)
Clay	2 16	1.00	0.90
Shale	2.29	1.28	1.16
Sandstone	2 14	1 36	1.25
Coal	2.02	1 30	1.25

U S Bur of Mines' tests on naturally broken anthracite mine rock, when compressed in a steel cylinder at 833 lb per sq in, showed a shrinkage in vol of 26.2%. This press was taken to be equivalent to rock press at 860 ft below surface.

Since Fayol's work, other enginers have advanced theories and empiric formulas regarding angle of break, angle of repose, probable vert subsidence, and its extent relative to the mining excavation. Rice found the assumptions for coefficients in the formulas are such as to destroy the practical value of the formulas, except for identical conditions. The possible combinations of factors are infinite. Factors include the various strengths of rock and earth strata; their relative dryness; their dip; shape of excavation and whether packed or not; and, most important, the method of mining.

The following diametrically opposed views are still held: (*A*) Surface subsidence always extends beyond the area of excavation, a view supported by British authorities, and by many instances in the U S. (*B*) Subsidence does not extend beyond the area of excavation. The mine subsidence committee of the Mining and Geol Inst of India recently reported, after making accurate observations at 24 collieries, that " Where no packing is done and pillars are taken out completely, the area of subsidence is less than the area of excavation; and in seams dipping less than 1 in 5, where no packing is done and pillars are completely removed, there is no draw." That is, the break does not extend beyond the vert plane extending from edge of the excavation; a view substantiated by data from mines in Penna and West Va (469). See also recent papers on model tests.

Rice's experience at the Ladd and Cardiff mines (longwall field of northern Ill) shows that there is always a draw in advancing longwall. In Great Britain, where this system is in general use, cracks opened in brick buildings ahead of the face, but they mostly closed when subsidence was complete a few years later. Survey monuments and time studies at other mines in the Spring Valley, Ill, longwall district, have established the fact of draw. But, experience in mines using room-and-pillar system and drawing pillars within panels, where surface subsidence was well within vert planes bounding the area of pillar withdrawal, confirms the views of the India subsidence committee. L. E. Young reports similar findings in Ill in 1916 (623).

In investigating ground movement, the arching stresses and strength of rock strata acting as beams have been much discussed, but their relative importance is difficult to determine. Where the rock stratum immediately over the excavation, acting as a beam or flat slab, has broken (and as each successive layer breaks), the beam stresses are transferred to an arch spanning the excavation and resting on the solid strata on each side (Fig 791). The doming effect is probably a fact, but when the dome reaches the surface its shape may have been modified greatly by the dip and strength of the rocks. Recent instances have repeatedly shown that shale, for example, breaks approx vertically, regardless of dip of its bedding planes. Break as shown (Fig 792) is usually nearly vert.

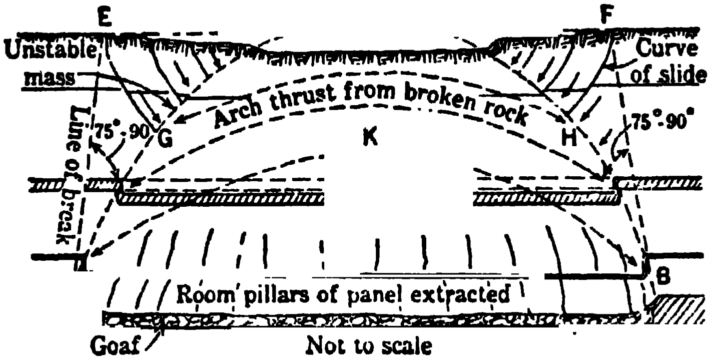

Fig 791. Suggested Mechanics of Room-and-pillar Caving (623)

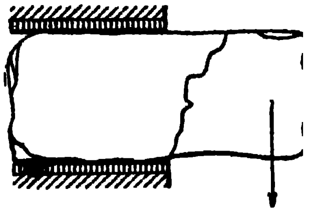

Fig 792. Rock Layer acting as a Fixed Beam, showing how doming effect may start in horiz strata at edge of excavated ground (465)

When an excavation is in a bedded deposit, or thick coal seam, not back-filled nor tightly packed, the overlying rock breaks when its span becomes too great for its strength as a beam. The overlying stratum acts as a beam fixed at one end projecting from the solid; hence, on breaking near either support, the fracture usually inclines inward toward the excavation (Fig 792). Layers above break similarly, forming a flat dome increasing in height with the successive falls. The edges of such caved strata show a saucer-like shape of the initial breaks, if the ground is at all uniform (Fig 793). As the successive breaks occur, the space between the broken rock and the roof lessens; finally, if the depth of excavation is not too great, relative to its height and width, the dome breaks through to the surface. Meantime, the fragments falling from top and sides of the dome make a roughly conical pile, down which the fragments tend to roll and wedge against the dome walls. When the pile reaches a height greater than the width of excavation, Rice believes there will be an arch thrust through the mass of partly compacted broken rock, which tends to prevent further spalling of the sides of the dome or planes of break (Fig 794). Civil engineers have considered this in tunneling and trenching in earth and sand.

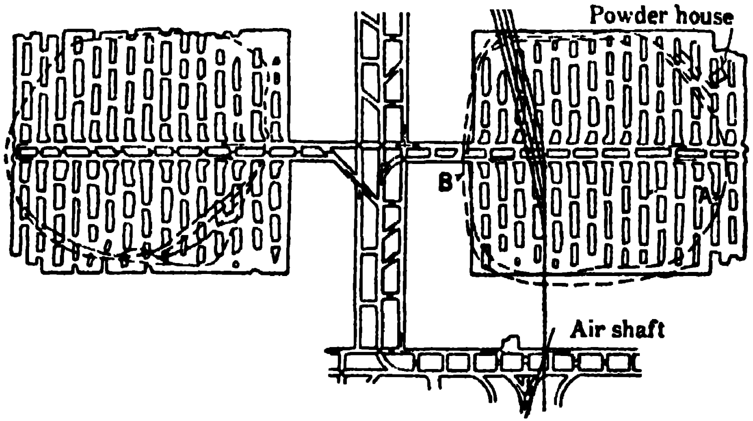

Fig 793. Effects of Subsidence in Panels of a Penna Coal Mine; dotted lines show cracks, 8–10 in wide at A, and 2 smaller ones at B (623)

J. C. Meem's experiments (473) with dry sand in a cylinder are confirmed by the behavior of dry granular material in high bins; the wt on the bin bottom is independent of the height of the column of material above a moderate height compared to the bin diam. The wt of material above this height is carried by the bin walls (Sec 12).

Filling a stope with ore or waste prevents the walls from caving, due to the arching effect of the loose rock. Also, after the first load comes on the stulls under a shrinkage stope, added filling does not increase the load on the timbers (unless the horiz width and length of the stope are great.—Author). In tunneling under caved ground, although forepoling and heavy timber may be needed, the timber does not bear the full load of loose material above it, but only the part under the natural arch formed in the broken material. As arching of the compacted rock fragments supports the sides of the dome, there is no draw effect when the room-and-pillar or limited-panel method of mining is employed, unless the excavation has too great a diam. If an excavation in a bedded deposit continues on one or both sides, as in longwall, the stability of the arch buttresses is continually being impaired, and the zone of fracturing extends beyond the vert; this movement is probably assisted by the shifting arch stresses and produces the effects of draw always observed over longwall workings. Draw usually proceeds at an angle of 65°–75° with the horiz, but the actual plane of break curves outward from the excavation and is affected by the character of the ground (Fig 794, 795). In homogeneous rock, the plane of break may be the resultant of the vert wt component and an arch thrust from the broken rock, which would add to the load on the rock in place, giving the downward movement a disrupting effect. In a very thick orebody, lying at some depth and mined by caving, after the first general break to surface similar arching of the broken capping would probably prevent the side walls from falling until the descending capping, by further caving, had exposed them to a considerable height (Fig 796); then normal rock slides would occur, as shown in the Miami-Inspiration cave.

Fig 794. Theory of Stresses in Subsidence where using Longwall

The preceding discussion deals with only a few problems of this intricate subject, but touches on the most disputed ones.

Summary of Rice's views. 1. Mining by room-and-pillar, with the pillars left standing, may not cause subsidence unless the pillars are too small or the bed is near the surface. Conversely, the dome of breaking will not reach the surface unless the deposit is very thick, compared to its depth, as the broken rocks will wedge and their increase of volume will fill the dome. (Regarding this statement, allowance must be made for compressibility of the broken rocks, which is apt to be high where the depth is considerable.—Author.)

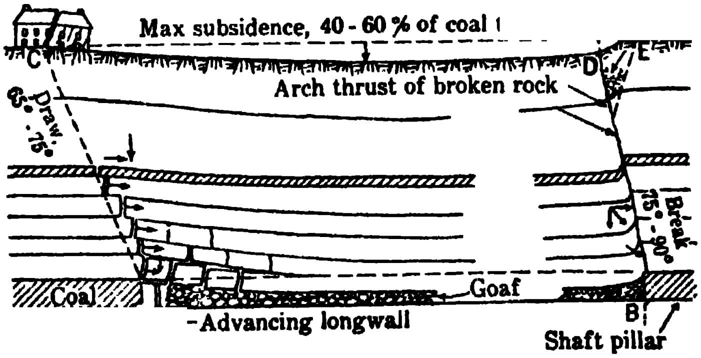

Fig 795. Suggested Mechanics of Longwall Subsidence

2. When pillars are partly or wholly extracted in a panel of moderate size, surface subsidence is ultimately inevitable. When a deposit is thick, compared to its depth, and the lateral width of deposit or panel is of moderate size and the area excavated surrounded by a barren pillar or solid mineral, surface subsidence rarely extends beyond the area of deposit or panel; that is, there will be no draw, because the arching thrusts of the broken rock buttress the walls (Fig 791). Vert subsidence will then approx the height of excavation, less amount of broken material left in place; provided the rock strata, after the first falls, tend to come down *en masse* and thus not greatly increase in volume

3. **Longwall, or equivalent method, inevitably causes surface subsidence, independent of depth of deposit, accompanied by a draw; that is, subsidence extends beyond the workings, and over the solid mineral to a line subtending an angle of 65°–75° from the horizon of the excavation. The angle will be modified by dip of the strata and by faults. In longwall, subsidence ranges from $^1/_2$ to $^2/_3$ of the thickness of the bed, varying with amount of packing. As longwall is usually practiced only when the roof is shaly, the packs are so compressed that old ground when reopened is often as tight and hard as the original. Where hydraulic sand-filling is used, subsidence is negligible.**

Fig 796. Suggested Mechanics of Subsidence in Block-caving of a Large Orebody

Rice's "plane of stability" differs from the angle of repose of loose material, because it refers to rock or dry earth in place. It is a warped plane extending from edge of the excavation to the surface, where it meets the theoretical line of draw; hence, the line of draw is a chord of the warped plane, below which the ground is not affected. Position of the warped plane, with respect to a straight plane, depends on the relations of the arch thrust of the broken ground, sliding movement beyond the vert, and resistance of the rocks to rupture under the combined stresses (Fig 794).

113. MISCELLANY, SUBSIDENCE

Effect of variations in rock structure. Subsidence is affected by homogeneity and strength of the overlying rock and by faults or other planes of weakness. Homogeneous material usually develops its normal lines of fracture and subsidence only at depths great enough to cause press exceeding the shearing strength of the rock. Hence, weak rocks fail in shear and show lines of fracture outside the area directly above the excavation at comparatively shallow depths; whereas strong rocks tend to break in vert planes, or form domes within the vert planes at shallower depths, and will not develop subsidence areas beyond the area of excavation until greater depths are reached.

No figures are available, from which an exact relation between strength of strata and depth causing complete failure can be determined, but empirical data may be obtained from observing particular cases; for examples, see Bib under "Status of Information" (beginning of Art 112). Fractures are often localized at a contact between a harder and a softer rock stratum. Presence of igneous intrusives in a sandstone or limestone formation modifies the lines of subsidence, unless the press resulting from depth of the excavation exceeds the shearing strength of these rocks. Similarly, planes of weakness (as faults) localize breakage of strata and affect subsidence.

W. R. Crane (673, 674) demonstrates the important effects of bedding, fault planes, and joint fracture systems, in controlling subsidence movement. He finds that the major yield takes place along a mean, or resultant, of the various fracture systems in all directions toward the mine openings, weighting them in order of prominence of occurrence as well as in proportion to their steepness of dip. The flattest inclined planes of weakness are given great weight in determining the ultimate limit of draw, but the actual displacement on these limiting planes is apt to be small in amplitude and long-delayed, unless such flat fractures greatly predominate in number over the steeper ones. Crane's work above cited was chiefly on the Lake Superior iron and copper ranges. A large predominance of flat fractures in controlling subsidence at Rio Tinto mines, Spain, is described by R. E. Palmer (675).

The effects of "natural shrinkage stoping" by local fragmentation of the overlying rocks in subsidence may lessen or prevent surface subsidence, where the rocks immediately over the workings are weak and fractured, where the rocks above these are physically strong and unfractured, where the total stresses are less than the shearing strength of the stronger overlying rocks, and where the volume of subsidence is small relative to the cross-section as a whole. Where the overlying rocks are not much affected by fractures and natural planes of weakness, but are too weak to resist the shearing stresses, ellipsoidal domes of subsidence are apt to develop above the zone of fragmentation. As the fragmental material is compressed under the weight of these domes, new domes develop of greater width and height until the surface is reached, being drawn in an area which is apt to be less than the mined area. Such a case, stopping just short of subsiding the surface, occurred at the Brier Hill shaft of West Vulcan iron mine, Norway, Mich (676).

Wherever subsidence domes intersect important fractures, the yield transfers to these fractures and tends to fan out along them. In such event, surface subsidence may be greater in area than the mined area underground, or may equal it; whereas in pure dome subsidence the subsided surface area is usually less than the mined area (Fig 791, 796). Where the mined orebodies are along major fracture systems, the ellipsoidal dome subsidence either does not occur, or is confined to the earliest stages of movement. In such case, yield takes place along the local fracture system, spreads to any intersecting fractures, and, in any overlying homogeneous unfractured rocks, is controlled by the angle of yield in such rocks, or else spreads into them in form of a new system of domes. A case of this kind is described by C. E. Mills, at the United Verde mine, Ariz (677).

Where strong vert fractures, dikes, or other zones of weakness enclose an orebody, subsidence domes may be confined within such fractures and work up to surface without spread, or lateral draw; for example, the Athens iron mine, Negaunee, Mich, as described by C. W. Allen (678) and by W. R. Crane (673). In this case, sub-level caving, retreating from the deeper end of the orebody, was used to control the progress of caving, lessen the weight on the workings, and to delay breaking of the surface and consequent tapping of water-bearing overburden.

Dome subsidence results in a minimum of loss of volume, as subsidence works up to surface; fragmentation produces a max loss of volume in subsidence. Compressibility of the fragmented material sometimes lessens its helpful effect. In shallow workings, the cantilever or beam action of very strong overlying strata, as limestone or quartzite, may arrest the upward progress of caving in workings of moderate volume. But such action is rarely long-lived at a depth over 500 ft, unless the span of subsidence is very small. Keying and arching may terminate " natural stope " caving at great depths if the dip is steep, or the width small compared to length. Natural stopes resulting from reduction of volume in concentrating iron orebodies naturally from the jasper in place have been found on the Gogebic Range, Mich, unfilled after very long periods.

Mud runs and air blasts occur when subsidence taps water-bearing overburden so as to bring it into contact with openings in the mine. Such dangers are encountered on the Lake Superior iron ranges, and sometimes result from tapping a mud- or water-filled natural cavity, a common condition in any limestone territory. Bulkheads are the only safeguard against these conditions, unless the water can be drained from the suspected source of the mud, as at the Kimberley diamond mines (Art 88).

The waterhammer effect, produced when masses of fast-moving quicksand strike a rigid obstacle, is enormous. If solid rock is available in a drift, a bulkhead 12 ft thick, of reinforced concrete and hitched 6 ft into the rock at top, bottom and sides, with steel rails in the concrete, will stop almost any run. It should be poured from a small sub-drift 10 ft above the back of the main drift. If the drift to be blocked is no longer used, some 30 ft of timber cribbing should be put in on the dangerous side before the bulkhead is poured; otherwise, steel plate and oak laminated doors, 2–3 ft thick, can be recessed in the bulkhead in a V-shape with the point toward the cave, hung on ball-bearing hinges like safe doors. The bulkhead is then provided with 4 or more extra-heavy, 12-in relief pipes with valves, which are left open, to be closed slowly when the mud run occurs. Such a bulkhead withstood over 2 500 lb per sq in at the Judson mine, Alpha, Mich, in 1919, and saved the main level, the mine, and the men underground. The site for the bulkhead must be prepared with a minimum of shattering, and checked over carefully before pouring. An 18-in seam of slaty paint rock was forced out under such a bulkhead in the Amasa Porter iron mine disaster, Mich, in Feb, 1918. Major disasters have also resulted from such mud runs at the Keel Ridge, Mansfield, Milford, and Barnes-Hecker iron mines in the Lake Superior region. Properly designed bulkheads have averted them at other mines, notably the Chapin and Judson.

Air blasts result from sudden collapse of large mined openings, which forces air under press through communicating workings. Bulkheads, or the blasting in of large volumes of ground to block access of air blasts, are the only preventives.

Accumulation of water in the gob above top-slicing or sub-level caving sometimes causes local mud runs. Drainage, blasting in of the hanging wall, and vigilance whenever a usual water flow lessens or suddenly ceases, are the chief precautions. Where subdrift caving starts beneath water-bearing surface, a back of ore must usually be sacrificed and much lagging and planking be used as the slices are taken out, to guard against mud runs. Bulkheads of timber with trap doors at strategic points are safeguards. They should be double, V-shaped, and well hitched to the rock or solid ore, and doors fitted to close on cutting a rope, with an axe hung to a chain and staple for this purpose only. In reclaiming workings after a quicksand run, bulkheads are the chief protection. Sometimes 3 or more will fail before a mud rush is stopped by a final bulkhead.

Spread, propagation, and detection of subsidence. Whether subsidence is of the local fragmentation, or the dome type (as already described); or follows fracture systems in the rocks; or is communicated to surface material above; or is a combination of any of these movements, its periphery is always marked by a spreading halo of tension cracks, affecting the rocks or soil, and any drifts, shafts, structures, pavements, pipes, railroads, or other improvements in the affected zone. The appearance of tension cracks is the advance notice, as their transformation into shearing movement is the first stage, of subsidence at any given locality. Surface survey monuments should early be set in threatened areas and periodically checked to measure their movement, both horiz and vert. Such observations, correlated with mining progress, and with geological conditions, make possible the forecasting of further damage in time to prepare for it.

Time-lag element in subsidence is a difficult phase of the problem. There is always a lag between mining and the start of subsidence, and nearly always between cessation of mining and the end of subsidence. Thirty to 40 million tons in a series of iron orebodies in a steeply-dipping formation at Ironwood, Mich, were mined by a caving system over 25 or 30 years before subsidence amounted to more than local caves at the outcrop. Regional subsidence has since been widespread. Shafts and crosscuts underground suffered 4 or 5 years before the trouble reached surface. Depths of mining ranged from surface to over 2 000 ft. Changes in rate or location of mining are sluggishly registered at surface 1 or 2 years after they occur. Movement is mostly on fracture systems.

A comparable amount of iron ore in folded hard iron formation, having great shearing strength, has been removed in certain areas of the Marquette Range of Mich over the past 75 years with no surface effect, at depths to 1 500 ft or more. On the Menominee Range, a cave from mining about 1 500 000 tons took 9 years to reach surface, appearing along a steeply dipping fault whose outcrop nearly parallels the formation. Mining was suspended during 1 month. Surface monuments showed that subsidence ceased within a day of the stoppage of mining, and recommenced within a day of resumption. Orebody top was about 500 ft below surface, current mining about 1 000 ft; formation dips 60° south; fault, 80° north.

At an Ariz copper mine, depth of orebody 1 000 to 1 700 ft, net voids 800 000 cu yd, subsidence took 5 years to reach surface along a fault zone of 50° dip; 10 years to reach surface by dome subsidence under incompetent malpais flows. Lag after mining is several years.

Rules. Subsidence transmits fastest along fault fractures; the steeper the fracture the quicker the transmittal. Doming is more deliberate. Yield on multiple intersecting fracture systems is slowest and most widespread. Large deep orebodies subside the surface later than shallow orebodies of less size. Natural block-caving of a small area in steep-dipping soft slate worked up 1 000 ft without spread of area or decrease of volume in 1 year at a Menominee Range mine. Keying and arching may indefinitely delay subsidence in moderate-sized orebodies in hard rock. When such situations yield, the action is apt to be sudden, with little warning.

Topography in subsidence. When surface movement has begun, its behavior may be controlled by topography more than by mining. The Turtle Mountain slide and disaster, which wiped out part of the town of Frank, Alberta, in 1903 (476), was caused by the mining of a relatively thin seam of coal, dipping steeply into the base of the mountain. A landslide on a mountain side was caused by a relatively slight disturbance. In regional subsidence, a steep mountain side takes precedence over low-lying territory in a manner suggestive of hydraulic head, with most of the subsidence working up the mountain side.

Subsidence in open-pit mining (Art 96, 97) is confined to lateral draw. Large-scale open-pit mining began in the great shallow orebodies of the Mesabi iron range, Minn, where ore stands successfully on a $^1/_2$: 1 slope, and rock on slopes of $^1/_4$: 1 to $^1/_2$: 1. This in a bedded formation with dip of 5° and under. On the Gogebic Range, Mich, the same beds are open-pitted in 2 mines, the dip averaging 60°–70°. Original practice was modeled on Mesabi lines, and serious slides resulted, as ore will not stand successfully at steeper than a 1 : 1 slope, diorite at 50°, and footwall slate and quartzite are being cut back to a 30° slope. Experience shows that stripping dumps should not be close to the walls of such pits, or failure of the walls will be promoted by excess weight. On the Cuyuna Range, Minn, ore banks standing at 53° failed, in part due to upsetting press from a mica schist footwall, which swelled on exposure to weather. The slope after stability was restored is 40°–45°. In exceptional cases ore will stand on a slope of $^3/_4$: 1, but 1 : 1 is about the best that can be expected. These beds dip from 60° to nearly vert. Thus, flat-lying strata are more stable under open-pit conditions than steeply inclined beds. Surface material stands at angles of 1 : 1 for clay, hardpan, and boulders, $1\,^1/_2$: 1 for sand and gravel, to 1.7 or even 2 : 1 for fine sand. All of these slopes flatten greatly if the pits contain water.

Effect of subsidence on surface structures. Injury is not caused by amount of subsidence but by its manner. Greatest damage results from irregular subsidence, or from a change in relation of subsided areas to adjacent areas.

For example, a church at Stassfurt, Germany, built of stone masonry about 400 yr ago, has sunk 21 ft (due to potash mining) without collapsing. Similar phenomena have been observed in the Penna anthracite district. But, a building standing at a junction between subsided and undisturbed ground will be damaged. The draw resulting from subsidence often causes tension cracks, having horiz without vert displacement, as in the foundation of a shaft house of Miami Copper Co (625). J. J. Rutledge in 1923 (624) cites damages to buildings from draw resulting from squeezes and pillar failure, in advance of completely robbed areas in Oklahoma coal mines. Other causes of foundation settlement may result in damage greater than those from subsidence in mining operations. Another kind of subsidence damage is due to a change in relation between subsided surface and adjacent surface, thereby affecting grade lines and drainage Change in drainage may cause overlying land to become water-logged, depreciating its agricultural value. This matter is purely economic, relating to damage as compared to cost of preventing subsidence, including loss of mineral left in pillars.

An extreme type of violent surface dislocation, of earthquake intensity, from sudden subsidence of underground workings, often accompanied by air blasts underground, is well known in the Lake Superior copper country (see *Proc* Lake Superior Min Inst, Vol XII, p 58, with photographs). The disturbance originates usually from abandoned, inaccessible workings; details of the underground movements are therefore unknown. This explosive type of subsidence results from collapse of large areas of old workings in hard rock on pillars that ultimately fail.

114. CONTROL OF SUBSIDENCE

Subsidence may be checked by increase in vol of the subsiding area. If the excavation be filled wholly or in part by natural or artificial supports, subsidence may be controlled or prevented. If the control is incomplete, protective steps may be taken underground and on surface.

In narrow stopes, subsidence is localized chiefly in a caving upwards, continuing until the back arches itself and supports the overlying strata. Support is necessary only to sustain the ground between the excavation and the top of the arch. Timbering usually suffices, its chief purpose being TO PREVENT THE STARTING OF CAVING. In large excavations of metalliferous deposits, having considerable vert thickness, and in coal and salt, subsidence is often more extensive and timbering ineffectual. In coal mines, the necessity of artificial support depends on method of mining, value of coal in pillars compared to cost of filling, and value of surface, or amount of possible damage if surface is not owned by the mine.

W. R. Crane (673) suggests minimizing surface effects by following means: (1) carry working face or long dimension of the workings parallel to the principal line of draw; (2) leave blocks of unmined ground to be removed later, if possible; (3) fill with waste rock in blocks between pillars; (4) fill surface caves at outcrop of ore with waste rock to support walls; (5) blast out hanging and footwall rock to fill the cave, if practicable.

Shaft-pillars. Young and Stoek (465) summarize rules from different authorities for calculating shaft-pillars in flat coal seams, as follows: MERIVALE. $S = 22\sqrt{D \div 50}$, where S = length of side of pillar, yd; D = depth of shaft, fathoms. ANDRE. Area of pillar for a 450-ft shaft is 35 sq yd; area increases 5 sq yd per 75 ft increase in depth. DRON. Draw a line enclosing surface buildings. Leave shaft-pillars so that the extension of solid coal beyond this line = $^1/_3$ depth of shaft. WARDLE. Pillars not less than 120 ft sq, increasing with depth of shaft. If the minimum be 120 ft sq for depth of 360 ft, add 30 ft for every added 120 ft of depth. HUGHES. Allow 1 ft breadth per ft of depth; hence, a 600-ft shaft should have a pillar of 300 ft radius. PAMELY. Up to 300 ft, make pillar 120 ft; for greater depths, add 1 ft for every 4 ft depth. FOSTER, R. J. Radius of pillar is $3\sqrt{Dt}$, where D = depth shaft, t = thickness of seam. MINING ENGINEERING (London). For shallow shafts, allow a minimum of 60 ft radius; for deeper shafts, $R = 60 + (D \div 10)\sqrt{t \div 3}$, where R = radius of pillar, D = depth, t = thickness of seam, all in ft. ROBERTSON, E. H. $R = (D \div 6) + 2\sqrt{Dt}$, where R = radius of pillar, D = depth of shaft, t = thickness of seam, all in ft. CENTRAL COAL BASIN rule, Ill. Allow 100 sq ft of pillar for each ft of depth; if bottom is soft, increase by half; if coal is thicker than 5 to 6 ft, pillar should be larger.

The diversity of opinion regarding shaft-pillars is shown graphically in Fig 797. Fig 798 shows effect of a shaft-pillar (467); depth of seam 453 ft, thickness 60 ft, and on 2 sides of the pillar 25 ft of the thickness has been removed. Surface was affected to points *C*, *D*, and horiz masonry at *C″*, *D′* became curved. To protect surface structures, Scotch engineers leave pillars $^1/_3$ to $^1/_5$ larger than floor plan of the structure. In flat seams at Connellsville, Pa, for depths of 150–300 ft, a margin of 25–30 ft of coal is left around a building. If the tract is large, 50–60% of the coal underlying is removed, remainder being left in pillars.

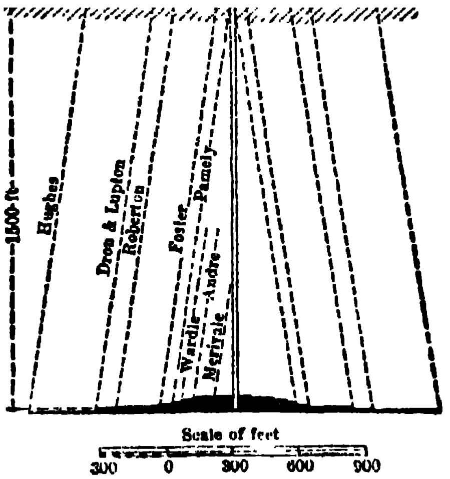

Fig 797. Sizes of Shaft Pillars, according to Different Formulas (Knox)

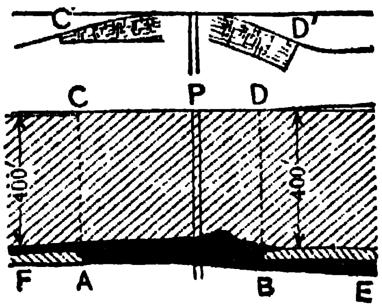

Fig 798. Effect of Shaft Pillar on Surface Subsidence (Fayol)

For dipping beds, relative positions of surface structure and pillar are shown in Fig 799 (474). Richardson (466) suggests "construction of a cross-sec showing the surface object and underlying orebodies; from each end of the object draw lines cutting the reefs toward the rise side and making an angle with a horiz plane equal to angle of fracture. The portion enclosed within these lines is the pillar required. **Angle of fracture is taken as half** way between the vert and normal to the planes of stratification.

The above data apply mainly to subsidence of relatively thin beds or seams, as in coal mining. In mining large, irregular-shaped orebodies at depth, experience shows that shaft pillars are rarely long-lived at a steeper angle than a 65° cone about the collar of the shaft. Conditions of weakness, fracture systems and faults, previously discussed, may greatly flatten this angle of safety.

Effectiveness of filling. Vert movement is reduced in extent but not prevented. Ordinary filling is compressible (see tests below), and never fills excavations completely. When roof settles, the resistance of filling, weak at first, increases rapidly, and soon stops movement.

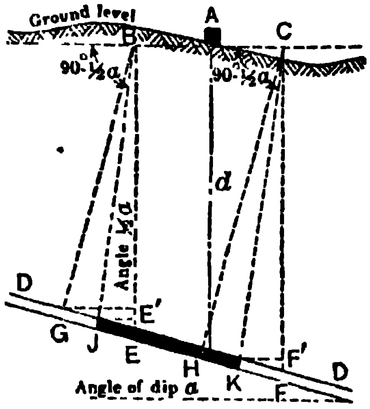

Fig 799. Position of Pillar with Respect to Surface Object (O'Donahue)

Belgian engineers believe the most careful packing gives no guarantee against damage to surface buildings; it only lessens subsidence (467). In the Westphalian mines, filling greatly reduces vert subsidence, but has little effect upon its lateral extent (465). A French engineer says: "In working by a system which permits the roof to fall, movement of strata gradually diminishes and stops at a certain level; with filled longwall, it is almost independent of depth; leaving sufficient pillars can alone insure safety of the surface" (467).

Fayol's observations at Commentry mines (467) are: (*a*) Certain seams, 3.25–6.5 ft thick, difficult to keep open without filling, have hardly required timbering from the time they were filled. (*b*) For soft rock, formerly used, a hard incompressible rock was substituted; haulageways became steady, roof settled much less, and cost of timbering decreased. (*c*) Some filling was done imperfectly; roof slabbed off and required much timber. Filling was then done carefully, leaving no spaces. Soon the press was hardly felt at the face, and all timbers could be saved. Fayol showed that in the same formation, in an excavation 39 in high, subsidence would reach a height of 658 ft if the roof sank without breaking; if roof broke, it would reach 541 ft; by filling, it would be reduced to 262 ft.

Summary of opinions: (*a*) filling greatly diminishes subsidence; (*b*) does not prevent it; (*c*) minimizing open spaces by careful packing is important. Fayol's figures are based on mine gob which undergoes fairly high compression; sands or crushed materials com-

press but little (see tests below), but their use is costly and may be impracticable. In narrow excavations, filling limits and usually prevents subsidence.

Effectiveness of pillars. In general, pillars are the only means of protecting shafts, important workings, or surface objects of value. In Belgian and English coal fields, they prevent surface damage, if about 50% of the coal is left.

Fayol stated respecting room work that, if enough pillars be left, the surface is unaffected; the mesh of the network of pillars and working places should be smaller as workings are shallower. As depth increases, workings can be enlarged in proportion to area of pillars, provided the different zones of subsidence are kept distinct from one another. The structure and character of the rocks may modify above statements, but, in properly spaced and proportioned workings, disturbance may be limited to the vol within the zones, as in Fig 800, where odd numbers represent rooms with their domes of subsidence Z_1, Z_3, etc. If pillar 2 be removed, these affect a larger area. Also, a small pillar may not effectively protect a surface object, because the zones of subsidence on either side overlap. In Clay Co, Ind, in an area which subsided from workings at depth of 20 to 40 ft, an outline of each pillar could be traced on the surface. Richardson states that on the Rand, when a pillar has been left, subsequent pull or draw on each side often causes more damage than if no pillar existed.

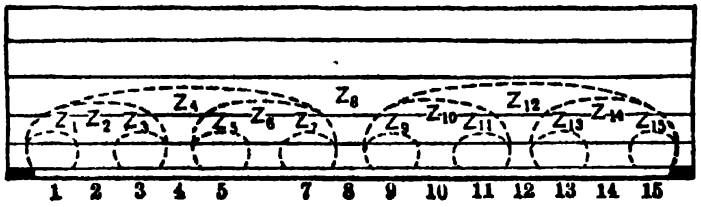

Fig 800. Effect of Extent of Excavation on Amount of Movement (Fayol)

General conclusions: Adequate pillars afford the only effective prevention of subsidence for coal mines, unless hydraulic filling (Art 110) is available. Timbering serves in small stopes of metal mines, when its strength exceeds the force exerted by the portion of the roof below the dome of equilibrium. It is held that in coal seams timbering prevents the overlying beds from breaking and expanding before general subsidence occurs; hence it may increase rather than diminish the surface effects. Properly spaced pillars of sufficient size will protect workings and surface objects.

Table 98. Safe Unit Stresses for Stone (Douglas)

	Crushing, lb per sq in	Shear, lb per sq in	Tension, lb per sq in
Granite......	1 020	200	150
Limestone....	800	150	125
Sandstone..	700	150	75

Supporting strength of pillars has not been determined. Tests show the crushing strength of selected pieces of rocks and coals, but pillars are usually composed of layers varying in hardness and friability; laboratory tests do not apply to the pillar as a whole. In Lake Superior copper mines, rock pillars at 3 000-ft depth, amounting to 10% and more of the lode matter (trap rock) have failed by fracture or flowage of the wall rocks (679).

In making computations, empirical formulas are necessary, aided by an approx estimate of strengths of the rocks based on tests. An aver of numerous tests of the Rand quartzite gives a mean ultimate crushing strength of 7 521 lb per sq in (466). Since tested cubes are weaker than the same area in a wide bed, Richardson thinks 10 000 lb is a probable figure; or, at great depths, even 15 000 lb. Taking sp gr of quartzite as 2.83, the above figures give 8 183 and 12 275 ft, respectively, as the depths at which quartzite will fail under its own weight (Table 99); for inclined strata, multiply the figures in the table by the cosine of the dip. Ultimate strength of trap rock forming pillars in Lake Superior copper mines is 16 666 lb per sq in (465). Tests of building stone (475) have little value in subsidence; rocks of the coal measures are unsuitable for building. Moisture lowers crushing strength of sandstone about 40% (Table 100). Tests of crushing strength of Illinois coal gave an aver max of 1 486 lb per sq in; coal from the Pittsburgh seam, 3 155 lb (465). An aver of 45 tests by Daniels and Moore (478), upon different sized prisms of Penn anthracite,

with press applied parallel, normal and inclined to the bedding, shows a crushing strength of 1 926 lb per sq in (see also Table 101); 12 samples of bituminous coal gave 1 007 lb per sq in. On a clay floor, the bearing power of the pillar does not exceed that of the clay (Table 103).

Table 100. Crushing Tests, North Carolina Sandstones (475)

Absorption, %	Conditions	Crushing strength, lb per sq in
4.2	Dry	10 736
4.2	Wet	6 399
3.71	Dry	11 741
3.71	Wet	6 174

Supporting strength of filling is greater with fine materials than with coarse. Though sands have a high percentage of voids, they are almost incompressible to the crushing point of the grains. Voids of broken rock are smaller in percentage, but larger in size; as pieces are in contact in few places, the angles and edges crush sooner and allow considerable compression. This crushing takes place under a press less than the crushing strength of a single piece. If voids of broken rock be filled with sand, its compressibility is lessened. Mixtures of large pieces of sandstone and shale, used for filling in coal mines, have about 40% voids. Fayol states that in workings 300–900 ft deep, such filling is compressed 30%, leaving a vol about 12% larger than the original material in place (467). The commission investigating the Frank slide, Alberta, concluded that under aver conditions settlement would be 5% of thickness of bed, if ordinary sand were used; an inappreciable amount, with granulated slag; 10–15% with loam, sandy clay, and ashes; 40–60% with dry packing (476). See Table 102.

Water should be kept out of partly subsided areas; it may loosen sands or clays and cause surface movement, resulting in further underground subsidence. Workings extending under watery strata or creeks may cause downward movement of water, which will loosen the rock and start subsidence. Streams flowing over excavated ground should be

diverted, to prevent inrush of water and sand. Water in mine workings should be confined to drains, to prevent undermining or disintegration of pillars; if allowed to run through filled areas, it carries away the finer materials and reduces the vol of fill. In salt mines, the water menace is more serious. DISINTEGRATION OF MINE PILLARS due to oxidation, decomposition, slacking, or solution, can be prevented by coating them with concrete (gunite) or plaster.

115. THE LAW AS TO SUBSIDENCE

Barring special enactment, or a reservation in the title, the surface owner in U S and in the British Empire is entitled under the common law to the subjacent and lateral support of his surface. Lateral support applies to the natural land surface only, not when burdened with buildings; grant of surface for building purposes implies a grant of lateral support; its removal through flow of quicksand into adjacent excavations, with resulting damage to buildings on adjoining lands, was adjudged in favor of the building owner in Cabat *vs* Kingman (166 Mass, 403). This American decision is surprising when compared with English precedent, where in the case of Popplewell *vs* Hodkinson (L. R. 4 Ct. Exch. 247), it was decided that water drained from subsurface by an adjacent excavation and causing subsidence damage to adjoining surface did not give the damaged surface owner cause for redress. Again in contradiction is the case in England, subsequent to the Mass case, where a quicksand flow into an excavation was found cause for redress of an owner of adjoining subsided buildings (Jordesan *vs* Sutton, etc, Co. L. R. 1899, 2 Ch. Div. 217).

Trend seems to be that removal of lateral support is ground for damages in all cases of damage; in the case of buildings the decisions are not so uniform, except where negligence in mining can be shown. Reservations or special agreements may modify rights to lateral support. Subjacent support is a positive right of the surface owner in all cases where it has not been specifically waived.

Severance of mineral ownership from the surface ownership does not waive the right to support. (Victor, etc, Co *vs* Morning, etc, Co, 50 Mo. App, 525). It is held that the mineral owner must so mine his mineral as not to disturb the surface This is true also where the mineral estate has been divided into two parts, one below another. The Marquette Cement Co, at LaSalle, Ill, succeeded in enjoining the longwall coal mining operations of the Oglesby Coal Co, 300 ft below the former's limestone quarry, in court proceedings in 1917 and 1918. See Charles H. Shamel: " Mining, Mineral, and Geological Law." For recent British enactment and practice, as well as the Provincial, Dominion and Colonial laws of the British Empire, see Briggs: "Mining Subsidence."

116. CONCLUSIONS AS TO SUBSIDENCE

Subsidence is the almost universal result of large-scale mining operations. Foresight in the location of shafts, equipment, and townsites, outside the zone of probable subsidence of the orebody AND ANY LIKELY EXTENSION THEREOF would save the industry much expense and the loss of untold tonnages extending under cities, the replacement of which cannot be borne by the mining profit.

The natural laws governing subsidence are, in principle, clear. The haphazard appearance of subsidence action is illusory, and is due to the interaction of these principles with varying local conditions. Certain broad generalizations are possible, but are safe only where not contra-indicated by local conditions. Deep-level, regional, large-scale, long-lived subsidence in rock has a tendency to develop an ultimate angle of draw of about 63°. Subsidence at Bisbee, Ariz; Ely, Minn; the footwall on the Gogebic Range, Mich; the Eastern Menominee Range, Mich; to name a few deep-level cases in widely divergent geol settings, all have angles of draw close to this figure. Extreme depth, closing local fracture systems by simple pressure, tends to confine subsidence to the doming type, which in turn tends to maintain draw within about a $^1/_2$: 1 slope.

The exact depth at which rock flowage exists in the undisturbed crust of the earth is unknown. Mining depths have already encountered rock flowage in pillars and other points where the unit stress is multiplied over that normal to undisturbed ground at the same depth. The sheared, schistose, sheeted, and jointed rocks of the Pre-Cambrian, often yield by a pseudo rock flowage at depths as shallow as 1 000 ft. Actual yielding takes place along the shear and joint planes with which these old rocks are scarred. Such yield is usually a slow, creeping process, rather than the violent and sudden collapse of younger and less scarred rocks. Experience emphasizes the wisdom of allowing ample margins of error for the safety of expensive shafts, equipment and buildings, town-sites, and other improvements, to guard against the appearance of unexpected local factors.

PLACER MINING METHODS

Revised, 1940, under Direction of O. B. PERRY, E.M.

Introductory. Classification: (*a*) Surface methods which are applications of open-cut work (Art 95–101), and of dredging (Art 128, 129). These are the most important and varied, since most placers occur at or near the surface. For a detailed classification of methods and equipment, see Bib (181). (*b*) Underground methods for deep or buried placers (Art 117) are known as Drift Mining or Drifting (Art 130).

Placer mining includes the work of excavating and transporting placer gravels, and of recovering their contained gold or other valuable mineral, which is usually done by concentrating or "washing" the gravel in running water. All the common methods of excavating and handling earth and rock (Sec 3, 5) are utilized where suitable. The term placer mining, as sometimes used, excludes hydraulicking (Art 123), dredging, and drift mining; general term "alluvial mining" then includes all methods of mining placers (286).

Exploration or prospecting of placers, to determine their value and yardage prior to exploitation, is done by drill holes or shafts (Sec 25).

117. PLACER DEPOSITS

Definition. Placers are deposits of sand, gravel, or other alluvium, containing particles of valuable minerals in workable amounts. Native gold is the most important placer mineral; a large part of the world's output of platinum and cassiterite (stream tin) is derived from gravels; other minerals for which alluvial deposits are regularly worked include monazite, columbite, ilmenite, zircon, diamond, sapphire, ruby, and other gems; native Ag, Bi and Cu, amalgam, palladium, cinnabar, occur occasionally in gravels; some phosphate deposits (Art 98) may be classed as placers. The terms "gravel deposit," "gold-bearing gravel," and "alluvial deposit" are used loosely instead of "placer" or "placer deposit." The following paragraphs deal chiefly with gold placers; their bearing on other placers is obvious.

Geology. "Three conditions operate to form placers: (*a*) Occurrence of gold in bedrock to which erosion has had access; (*b*) separation of gold from bedrock by weathering or abrasion; (*c*) transport, sorting, and deposition of auriferous material derived from erosion. Erosion, while operative in most cases, is not absolutely essential, as residual placers may be formed by the weathering in place of auriferous bedrock" (377). The primary SOURCE OF PLACER GOLD is almost always in auriferous veins, stringers or other orebodies. These deposits were not necessarily rich; they may have been entirely eroded, or their remnants may not be workable.

Gravel deposits are often concentrations of enormous volumes of rock, in which gold may have existed in stringers too small to mine. Thus, in the Klondike, no large orebodies have been found in connection with the placers; the prevailing country rock is schist, containing numerous unworkable quartz stringers sometimes showing gold. To produce the present placers, it is estimated that 136 cu miles of rock, averaging less than 2¢ in gold per ton, have been eroded and concentrated. Some gold may be deposited from solution in residual placers; this agency is unimportant in the deposition of gold or formation of nuggets in stream gravels (307, 378).

Weathering and erosion. Deep secular decay of gold-bearing rocks preceded the formation of most important placers; it can occur only in base-leveled regions of topographic maturity. Under such conditions, rocks break down into clay and fine particles, which are removed by wind and slow-moving water. This effects surface concentration of heavy and resistant minerals, and sometimes forms commercially important residual deposits, as the eolian placers of Australia. A subsequent uplift which rejuvenates the streams will cause rapid removal of the residual mantle and further concentration of its heavy minerals along water courses. Placers formed by the concentrating action of running water are called SORTED PLACERS. Rapid erosion of fresh rocks by swift streams rarely produces extensive placers. A geological history involving several cycles of base leveling and uplift favors the formation of rich placers, as deposits of one period may be reconcen-

trated in streams of a later cycle. Many rich placers in Alaska, California and Victoria were thus formed; they are called RESORTED PLACERS (377, 379, 307).

Distribution of gold in sorted and resorted placers is irregular; normally, but not invariably, heavy gold is concentrated on bedrock or within a few ft of it; coarse gold is sometimes scattered through the lower part of a deposit, but, except in minute quantities, gold is never distributed uniformly through a great thickness of gravel. In small creeks, pay gravel may occupy the whole width of the stream bottom; in larger streams, there may be some gold at all points on bedrock, but most of it is usually concentrated along a narrower streak, known as the "paystreak," "pay-lead," "channel," "run of gold" (England), or "gutter" (Australia). Paystreaks often follow devious courses, bearing no apparent relation to that of the present stream; Fig 801 shows a case in point. Paystreaks may split or cut off suddenly; they may or may not occupy the deepest part of a stream channel; they may form at any elevation in a gravel deposit, on top of a stratum of clay or other impervious material, which is called a "false bedrock." Some placers have several paystreaks, thus formed and overlying each other (307).

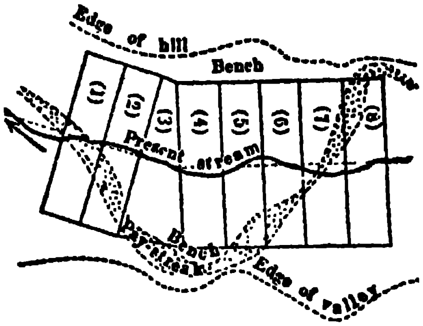

Fig 801. Meandering Paystreak

Various hypotheses have been advanced to explain the formation and idiosyncrasies of paystreaks. J. B. Tyrrell holds that Klondike paystreaks occupy the bottoms of the original V-shaped gulches formed in the early period of stream action. Clay is the chief product of secular decay and is quickly removed by active erosion; hence, gold concentrated in such weathered material would be deposited in the bottom layer of the sediments laid down in a new stream. As the stream widened and meandered the paystreak would be covered. A later uplift might produce a new gulch at a lower elevation; depending on its location, the old paystreak might descend into it or remain in its original position (see Bench placers below). H. L. Smyth points out the fact that the whole contents of a stream bed must be in motion to allow concentration of heavy minerals; such motion occurs in young streams where gravels are shallow and floods occur. Lindgren ascribes paystreaks to the following causes: (*a*) partly to a natural "jig-like" movement in moderately deep, water-soaked gravels, during long conditions of fair balance between loading and erosive power of the overlying stream; (*b*) partly to a slow forward and downward movement of large bodies of stream gravels, which would allow heavy minerals to work downward; (*c*) largely to the fact that heavier gold particles entering a stream bed from an adjoining hillside are not carried out onto gravel flats of streams of gentle grade (the only ones that have extensive flood plains), but settle on the marginal bedrock of the gravel flat. As the flood plain widens, it covers the accessions of gold along its margin and the final result is a paystreak resting on bedrock and lying under barren or lean alluvium (380, 379, 377, 307). There is no essential disagreement between these statements; all the agencies noted probably act at different times.

Glacial gravels may contain gold; glaciers dissipate the gold which they pick up instead of concentrating it. Hence glacial gravels have little economic value unless they have been concentrated by post-glacial streams or have derived their gold from an unusually rich primary source.

Gradient of auriferous water courses varies between wide limits. Lindgren (307) states that the most favorable conditions for concentration of gold exist in streams of moderate grade, say 30 ft per mile. If sediment is deposited in an overloaded stream, concentration of coarse gold ceases; conditions for formation of rich placers are also less favorable where erosion is very rapid, unless the gold supply is unusually abundant. California streams in the Sierra Nevada have grades of 50 to 100 ft per mile; many in Alaska have grades of 100 to 150 ft per mile. Depressed or elevated ancient river beds may have been tilted and the original grades much modified.

Summary. A knowledge of local geology, regional geological history, and physiographic development is a distinct aid in placer mining; it furnishes an hypothesis on which to base prospecting, exploration, and mining. Further data on the geology of placers are given below and in Art 118; see also Bib (307, 377, 378, 379, 380) and U S Geol Surv *Bull* 337, 410, 498, 533, 534, 592, 739.

Placers may be classified according to their origin into residual, sorted and resorted placers, as above. From the mining standpoint the following grouping, based largely on form, is more useful: (*a*) RESIDUAL PLACERS, which, when formed directly over outcrops or on gentle slopes below them, are sometimes called "eluvial" placers. Residual placers are relatively unimportant; their valuable particles are not rounded by abrasion; concentration in them is superficial, the richest part being at or close to the surface (379). (*b*) HILLSIDE PLACERS occur on valley slopes; are not in well defined channels, but are somewhat sorted by water; a transitional type between residual and gulch gravels. (*c*) GULCH OR CREEK PLACERS are gravel deposits in, adjacent to, and at the level of small streams (Fig 802); they are usually shallow. Gulch placer sometimes denotes gravel in gulches which are dry or carry intermittent streams. (*d*) BENCH PLACERS (terrace gravels) are fragments of old stream gravels partly removed by subsequent stream action which has cut deeper into bedrock. They may occur on the flanks of present valleys (Fig 802), or as remnants of a previous drainage system, the course of which has no direct relation to existing streams. The White Channel, in the Klondike, is of the latter type. (*e*) RIVER-BAR PLACERS occur in bars and gravel flats adjacent to large streams of gentle gradient; their surface often lies a few ft above normal water level. Fine gold is deposited by existing streams in bars at points where the velocity of the water is checked (Sec 2, Art 21). (*f*) GRAVEL-PLAIN PLACERS are formed in flood plains and deltas; the term is not strictly defined. The wide valley at Oroville, Cal, formed by meandering of the Feather River, is a gravel plain; also some of the tundra placers of the coastal plain at Nome, Alaska (383). (*g*) BEACH PLACERS (marine placers) are formed by the concentrating action of waves on a sloping beach.

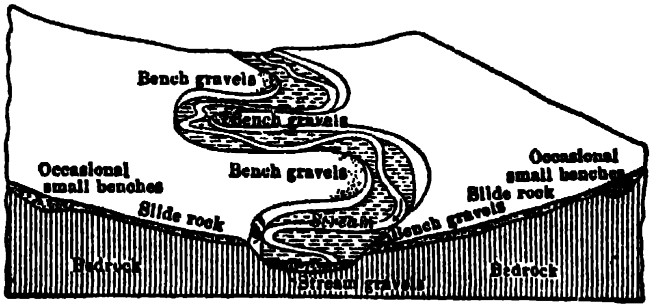

Fig 802. Placer Deposits (U S Geol Surv)

Gold in beach placers may come from a sea bluff of auriferous gravel, broken down and concentrated by the surf; some beaches are probably enriched by gold brought to the sea by nearby streams. Nome beach, a famous example, is 50 to 75 yd wide, slopes 4° to 5° and abuts an escarpment of gravel, muck and tundra 10 to 20 ft high (Fig 803); workable placers occupied 20 miles of beach. Fine gold is concentrated near the bottom of lenticular masses of garnet and magnetite sand, which are 5 to 9 ft thick and normally rest on a clay false bedrock. The lenses are rarely more than 100 ft long, and are not uniformly enriched over the width of the beach. The richest pay was usually in lenses 5 to 6 ft wide by 2 to 6 in thick (377, 381). Beach placers, consisting of surface concentrations of very finely divided gold in magnetite and garnet sands, occur on Kodiak and Popoff Islands, Alaska, on the coast of Oregon and elsewhere. They are constantly shifting; in places, beaches are reworked annually or after storms. Beach deposits must usually be mined by simple hand methods (Art 119). Many disastrous attempts to work them on a larger scale failed to recognize that while individual thin layers may be rich, the aver value of any considerable depth of sand is very low. Wave action sorts beach material into equal-falling grains (Sec 28); where the gold is very fine and associated with fine magnetite and garnet sand, it is difficult or impossible to recover it by ordinary placer mining appliances (382).

Bedrock

Fig 803. Beach Placers, Nome, Alaska (U S Geol Surv)

Buried placers ("deep placers" or "deep leads," Australia) exist in many districts; any of the above deposits may be a buried placer, for example:

A general subsidence, or overloading of streams, may deeply bury the accumulated placers under barren alluvium. In the Fairbanks district, Alaska, deep gravels, laid down as creek gravels in ancient water-courses which occupied the present valleys, are now buried under 20 to 300 ft of alluvium. Bedrock of the old streams was a little steeper than that of the present valley bottoms. Most of these channels are centrally located with reference to the bedrock slope of the present valleys; present streams occupy asymmetric depressions, one wall of which they follow closely. The gravels are covered with "muck" (Alaskan term for black humus, fine sand, clay and silt), derived partly from the valley slopes and deposited in part by sluggish streams. Near the headwaters of the creeks, the deep gravels merge with those of the present streams (383).

The Tertiary stream placers of the Sierra Nevada, Cal, were covered by deposits of rhyolitic and andesitic tuffs and breccias in places 1 500 ft thick. The region was then elevated and a new stream system eroded the present canyons, some of which are 2 000 or 3 000 ft deep. Old gravels now rest as more or less connected remnants, on the summits between the modern canyons (307). Similar conditions, with basalt flows, occur in Victoria. Near Nome, 7 buried beach placers have been found in the coastal plain, indicating periods of subsidence or elevation which shifted the position of the coast line. The richest is the Third Beach, lying 20 to 124 ft deep and 3 miles inland from the present beach, which it roughly parallels; it has been traced 5 miles, and contains placers like those of the present beach (384).

Dry placers is a term applied to auriferous alluvials of various kinds, occurring in arid regions. They seldom lend themselves to large-scale work, but contribute a fairly consistent small output of gold from southwestern U S and Western Australia (Art 119). For description and for "dry-washers," see Bib (409, 452, 506).

118. CHARACTERISTICS OF PLACER GRAVELS

Size of gravel varies from fine sand to boulders of several tons. Numerous large boulders may prohibit methods like dredging (Art 128, 129); they increase cost of hydraulicking (Art 123) or other methods, as they must be broken by blasting or handled with derricks. Size of gravel affects the amount that can be washed or concentrated with a given volume of water, and hence the rate of return on invested capital. In general, the duty of water (Art 123) is highest for small gravel; duty may be reduced by very fine gravel which packs in sluices (Art 124). Best operating results are obtained with a gravel consisting of mixed sizes; pebbles assist in disintegrating clay, and sand increases carrying capac for stones. The term small gravel has various meanings in placer mining; thus, gravel containing stones to 6 or 8 in diam is small for dredging and large for shoveling-in (Art 121).

Shape of gravel may be round and water-worn, sub-angular, or angular. The duty of water in washing gravel is less with angular stones; also with those predominatingly flat.

Character of fine or cementing material. Some gravels consist entirely of rounded stones with a little sand; others, of stones embedded in a clay matrix. At times the fine material is so solidified by chemical action as to cement the stones together, forming CEMENTED GRAVELS. Loose gravel and sand are easily excavated and washed, but it may be difficult to hold the water in dredge ponds in such material. Values in deposits containing much sand are apt to be "spotty"; extensive sand layers are usually barren. Stiff clay increases cost of excavation; in dredging, it reduces output, increases repairs, and prevents free discharge of buckets. Some clays break up readily in water, others ("sluice robbers") form balls that roll through sluices and pick up gold or amalgam. Cemented gravel increases costs like stiff clay, but to a greater degree; it prohibits dredging if much is present; it can often be broken by blasting prior to washing. A few California drift mines (Art 130) crush cemented gravel in stamp mills.

Depth of gravel affects applicability of different methods of mining; see individual methods, Art 121–130.

Character of bedrock. Gold is retained on soft creviced surfaces, where it would not lodge on hard smooth surfaces. In schists and slates (especially if they strike parallel to a stream course), clay, clayey sandstones and tuffs, gold may work down several feet; it also settles into minute crevices in hard rock; it has been found in solution cavities in limestone to a depth of 50 ft (307). In a new locality, the character of bedrock may be inferred from surrounding geology; evidence from shafts or boreholes is more reliable than that from exposures in stream beds, in which decomposed rock would be eroded. Large boulders of adjacent country rock in the gravel usually indicate hard bedrock. Bedrocks of schist, granite, and some sandstone and porphyry, are usually decomposed to a depth sufficient to allow dredging. In one South American hydraulic mine, a granite bedrock is rotted to a depth of 5 or 10 ft; though barren, this material must be washed to recover the gold lying on it. In limestone and slate formations, bedrock is almost always hard and blocky, often with deep crevices. Creviced bedrock increases costs, as it must be taken up to recover the contained gold. In hydraulicking, hard bedrock increases cost of bedrock ditches. Bedrock of regular contour is desirable for all placer methods (385).

Character of gold. Placer gold ranges in size from large nuggets to minute specks called "colors." The size of colors is indicated by the number making 1¢ worth of gold; some gold in the Snake River, Idaho, runs 2 000 colors to 1¢. Gold usually occurs in flattened and rounded grains; angular pieces and crystallized gold, occasionally found, indicate nearness to the primary deposit. Fine gold is sometimes in thin scales, difficult to save; scaly gold and more rarely other forms may be coated with a film of SiO_2, MnO_2, or limonite, which hinders amalgamation. Fragments of quartz often adhere to gold, or form part of nuggets. Gold is commonly associated with particles of magnetite and ilmenite ("black sand"), garnet (ruby sand), zircon and other heavy rock minerals (307). If present in large amounts black sand may pack in riffles of sluices (Art 125) and interfere with gold saving.

Lead in form of shot occurs in placer districts where much hunting has been done; it is caught by gold-saving devices and is separated at the time of clean-up; it generally pays to melt such metal and sell it as base bullion.

Placer gold varies in fineness (purity) from 500 to 999 (parts Au per 1 000); it is always alloyed with silver; sometimes copper is present; it is usually purer than that in veins of the same district; its purity increases with the distance transported and with the decreasing size of grains.

Distribution of values may be the determining factor in choosing the mining method. Thus, all the gold in a deposit 100 ft deep may be concentrated on bedrock in a 4 or 5-ft paystreak. A high-cost method like drifting (Art 130) may give more profit than cheaper open-cut work involving the handling of 95 ft of barren material.

Frozen gravels of Alaska, Yukon, and Siberia must often be thawed by artificial means before they can be worked (Art 128, 130, 131). Even if they could be mined like solid rock, thawing would usually still be necessary before sluicing.

Buried timber occurs in many places in the tropics, and in placers where one or more paystreaks have been previously drifted; it is a serious hindrance to and may prohibit dredging. It may be washed out of the bank in hydraulic mines and, if large, cut into pieces for hoisting by derricks. Standing timber increases cost of open-cut work by the cost of clearing, which, per cu yd, varies inversely with the depth of gravel (385).

Swell of gravel upon excavation is usually 20 to 30%, up to 50% for compact clayey gravel. Swell may vary in different parts of same deposit: its determination is important in all sampling work, to avoid errors in estimating values. Several excavations should be made and the resulting gravel measured loose in a wooden box holding 1 or 2 cu ft; the percentage of swell is computed from the volume of excavation.

Values in gravel are expressed in cents or dollars per cu yd, or per sq ft or sq yd of bedrock. Drift mines often report values per ton. Value per sq ft is the most convenient basis where most of the gold is in thin paystreaks. If 2 or more paystreaks overlie each other, total value per sq ft is obtained by adding values per sq ft of the separate paystreaks; this is simpler than estimates per cu yd. Value per sq ft × 27 ÷ depth in ft = value per cu yd.

119. PAN, ROCKER, LONG TOM, "DRY" WASHERS

The pan and rocker are used by prospectors in searching for placers, by miners for washing gravel on a small scale, and by engineers for recovering gold from samples obtained in placer examinations.

Pan (gold-pan) is a circular dish with sloping sides; top diam, 10, 12.25, 16, or 16.25 in; depth, 2 to $2^3/_8$ in; side slopes, 35° to 40°. Fig 804 shows dimensions of the typical American pan, which weighs 1.5 to 2 lb; the Australian pan is larger.

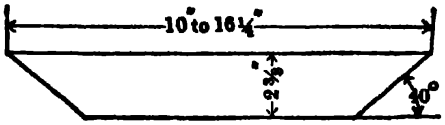

Fig 804. Gold Pan

Pan should be light, but stiff enough to stand rough usage; inner surfaces must be smooth, bright, and free from grease and rust. If properly cared for, pans of polished steel meet these requirements, and are cheap. Agateware does not rust, but easily chips. Aluminum pans are light, do not rust, but lack stiffness. Pans of copper, or with copper bottom and steel rim, are sometimes used for fine gold which will amalgamate; the bottom is silver-plated and coated with mercury.

Operation of panning. The pan of gravel is placed in water, the gravel thoroughly wetted and stirred by hand to break up lumps of clay, and the larger stones are picked out. The pan, still under water, is then given a shaking or gyratory motion, which brings the light material to the surface and allows heavy particles to settle; at intervals the pan is tilted and the surface material washed off. These processes alternate until nothing but gold and a little heavy sand is left, which is dried and the gold separated by blowing, or by a magnet (for black sand), or mercury is added to collect the gold as amalgam. In experienced hands there is little or no loss of gold (Sec 31).

Field of use. Panning is slow, back-breaking work; as the only tools required are a pick, shovel and pan, it is a favorite poor-man's method and is a common temporary expedient in a new district. The pan is indispensable for testing gravel when prospecting and for cleaning-up rocker and other concentrates in large-scale sampling and mining operations (Sec 25, Art 7).

Duty of labor in panning. An experienced man can pan carefully about 100 pans of aver gravel in 10 hr; cemented gravel or sticky clay reduces this figure; duty increases with the percentage of coarse gravel, which need not be panned. A good panner rarely handles more than 1 cu yd aver gravel per 10 hr.

Number of pans per cu yd of gravel varies with the swell (Art 118) and character of the gravel, and the amount put into the pan.

On preliminary examinations the value of gravel is computed from number of pans washed and weight of gold recovered; a small error in the number of pans per cu yd may make a serious error in the estimate of value. Content of the ordinary pan of 16-in diam (Fig 804), computed as frustum of a cone, is 321 cu in. If swell of the gravel is 20%, 1 pan level full holds 321 ÷ 1.20 = 267 cu in of gravel in place; hence there are approx 6.5 pans (1 728 ÷ 267) in 1 cu ft, or 176 pans in 1 cu yd of gravel in place. If each pan is heaped 1.5 in at the center, there will be only 133 pans per cu yd. The number of pans taken as equivalent to 1 cu yd in different districts is usually between 130 and 150. At Fairbanks, Alaska, most miners compute values on the basis of 189 pans per cu yd; where this is done, 1 heaping load on a No 2 round-point shovel is considered a panful (386). Estimates based on panning are valueless unless made by a skilled panner, who is also competent to judge the effect of local conditions.

Batea is a flat conical pan, of wood or iron; its diam varies locally from 16 to 30 in. It is used in Mexico and South America (and in southwest U S for dry concentration of gravel); variations of it are employed by natives of India, Sumatra, Nigeria, etc (605).

Rocker (cradle). Fig 4, Sec 25, shows one design. Gravel is placed on the screen; water is poured over it from a dipper, and at the same time the machine is given a rocking motion. The water and undersize of the screen pass over the apron to the bottom of the rocker, and are discharged over the tail-piece. When the stones remaining on the screen are washed clean, they are removed and the process is repeated. Most of the gold is retained on the apron; some is caught on the bottom, which may have cross-riffles. Clean-ups are made at intervals, depending on richness and character of gravel.

For saving fine gold, the material on the floor of the rocker must be kept loose and free, and spread evenly; clayey gravel, or that containing much fine black sand, often packs behind riffles and tail-piece and requires frequent clean-ups. Before cleaning-up, the material back of the tail-piece is removed, dumped into the screen and re-rocked; the apron is then lifted out and its contents washed into a pan for final concentration; Chinamen are sometimes expert enough to use the apron itself as a vanning plaque. In sampling work, the rocker is thoroughly cleaned-up after each sample has been run through; the tailing must often be re-rocked to save fine gold. On large-scale sampling in clayey gravel, it pays to break up the clay in a puddling box ahead of the rocker. Wooden or galvanized iron pails are convenient for carrying samples to rockers.

Table 104. Dimensions of Rockers in Different Regions

Example No	Length of bottom, ft	Width of bottom, in	Height of tail-piece, in (*a*)	Screen			Slope of bottom (*b*)
				Size, in	Diam of holes, in	Pitch of holes, in	
1	5	14	1.5	18 by 18.25	0.25	1.0	1 : 12
2	5	18	1.5	24 by 21	0.25	0.5	1 : 12
3	6	19(*c*) to 15(*d*)	....	....	0.37–0.5	....	1 : 12
4	4	18	0.75	16 by 16	0.5	0.5	1 : 21
5	4	16(*c*) to 15(*d*)	1.75	20 by 21	0.5	2.0	1 : 11
6	4	15.5	0.75	23.5 by 15.5	0.37	1.0	....
7	4	14	....	13 by 13	....	....	1 : 8
8	4	20	0.75–1	12 by 24	0.25	0.5	1 : 12
9	12	14	1	36 by 12	0 25–0.63	....	....

(*a*) Height at center. Tail-piece is called "lower end-piece" in Fig 4, Sec 25. (*b*) Any desired slope is obtained by blocking up the frame on which the rocker rests (*c*) At upper end of rocker. (*d*) At tail-piece.

Example 1. Rocker shown by Fig 4, Sec 25; recommended by Knox and Haley (385) for sampling, with the comment that most rockers are too high and short and therefore poor gold savers. Ex. 2. A Cal rocker, found by author to be heavy and clumsy; tail-piece unnecessarily high. Ex. 3. A large rocker used by miners (388). Ex. 4. From W. H. Storms (387). Ex. 5. A very satisfactory rocker, used by the author in sampling work. Ex. 6. From D. Waterman, *Min & Sci Pr*, Feb 20, 1909. Ex. 7. Design by S. O. Andros (389). A galvanized iron chute is used instead of an apron; gold saving is entirely by cross-riffles on the bottom. Ex. 8. A Cal rocker; screen set to cover only the upper part of apron, which is 18 in long; this forces all undersize of the screen to pass over the apron; reduction in screen area is compensated by the unusual width. Ex. 9. A Cal rocker, driven by a 1.5-hp distillate engine through an eccentric with a 1-in. throw. Capac, 5 cu yd or more per 8 hr (617).

Rockers should have tight joints, with corners strengthened by galvanized iron or zinc angles, placed outside; 2 or 3 light tie-bolts (Fig 4, Sec 25) aid in preventing shrinkage or swelling. Rockers are sometimes built to knock-down for easy transport (387). Bottom board should be in 1 piece, free from knots and cracks, and of lumber which will not "rough up" when scraped in cleaning-up. If good lumber is not obtainable, the floor may be covered with canvas fastened by quarter-round strips tacked in corners. Canvas makes an excellent surface for saving fine gold. Rocker bottoms may be covered with blanket, which is taken up at intervals and washed in a tub; blankets are good fine-gold savers, but are undesirable in sampling work because of the delay in cleaning-up. Aprons are of canvas, or rubber sheeting with canvas backing; their covering is not stretched tight; a sag is left at the bottom. High rockers are sometimes built with 2 or 3 aprons inclined in opposite directions and superposed, so that the tailing from one falls onto the upper end of the next; 1 apron is sufficient and more convenient for ordinary work. Some Chinese rockers are apronless; to save the fine gold they require expert operators. Screens are of galvanized or black sheet iron with round holes; 18-gage iron is heavy enough for small gravel; 10-gage better for coarse; Table 104 gives usual sizes and spacing of holes, which are slightly countersunk on under side to prevent clogging. Fig 805 shows excellent screen construction. Screen is picked up and dumped by the rocking handle *H* and small block *B*, both being fastened to the screen box. Very heavy rockers are undesirable; they are hard to transport, and, like those having a large roll, are difficult to rock properly. 1-in lumber, dressed to full 0.75 in, is usually heavy enough. Long rockers, if not too heavy, are more efficient than shorter ones for saving fine gold.

Grade of rocker should be adjusted to character of gravel. Too flat a grade causes packing and loss of fine colors; less grade is required for light alluvium than for that carrying much heavy black sand.

Water required. S. O. Andros found that a rocker required 4 to 6 barrels of water per day, in washing samples of dry gravel; the larger amount for loose sand (389). Water can be reused by digging settling pools connected by a shallow ditch, if the gravel does not contain too much clay.

Duty of labor. A rocker may be operated by 1 man, but 2 are better; they spell each other in rocking and handling gravel and tailing. Purington gives the duty of 2 men rocking steadily as 3 to 5 cu yd of gravel (place measure) per 10 hr (390). Duty on sampling work varies widely with size of samples and arrangements for feeding.

Field of use. For mining, the rocker is a prospector's tool, or is used prior to larger-scale operations; it will work small rich deposits in regions of scant water supply. It is invaluable for washing samples in prospecting and examination.

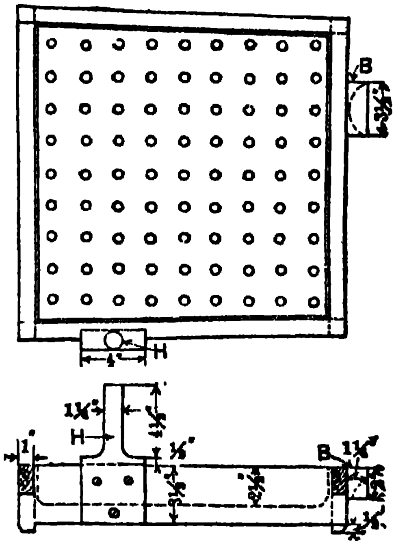

Fig 805. Screen for Rocker

Long Tom is an open box *L*, Fig 806, having at its lower end screen *S*, punched usually with 0.5-in holes. Dimensions vary; Fig 806 represents early California practice (391).

Running water is carried to the head end by a small flume *F*. Gravel is shoveled into the Tom or into the flume *F*; it is shoveled over in the Tom and large stones forked out; the fines are worked through the screen, and with the water fall into a wide "riffle-box" (sluice, Art 124), set on a flatter grade than the Tom. The gold is caught behind the riffles, with or without aid of mercury. Capacity depends largely on the amount of gravel which can be shoveled into it; Wilson says that 2 men (1 shoveling to the Tom and 1 working on it) can wash 6 cu yd of ordinary gravel, or 3 to 4 cu yd of cemented gravel, in 10 hr (388). At times the Tom is operated by 4 men; 2 shoveling-in, 1 forking out stones, and 1 shoveling fine tailing away from the end of riffle box. Toms are now rarely used in the U S; where running water and grade are available, a simple sluice (Art 124) is as effective and requires less labor. A modified Tom 3-4 ft wide by 8-10 ft long, washed by surf, was used in beach mining at Nome (188). For crude washing devices of other countries, see Bib (392).

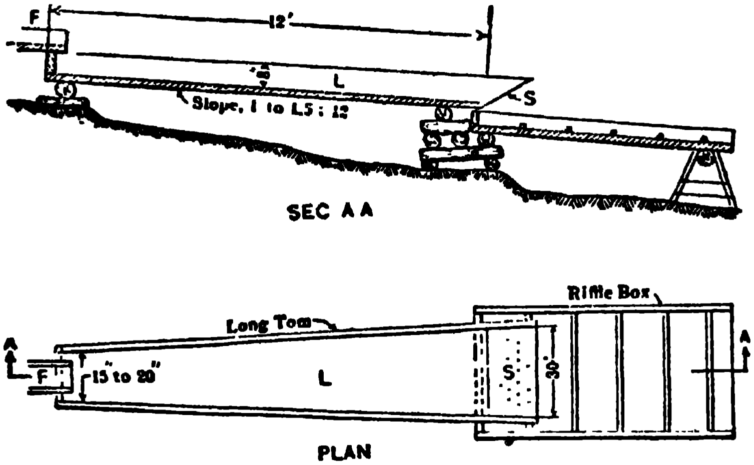

Fig 806. Long Tom (after Bowie)

"Dry-washing" of placer gravel has contributed some gold from small-scale operations in districts where water is scarce, notably Western Australia, Queensland, and the desert areas of Sonora and southwestern U S. Gravels in these districts are largely (not exclusively) of residual origin or have been transported relatively short distances by torrential streams. Hence, the gold is comparatively coarse, and distributed erratically in both

depth and area, though bedrock enrichments are not unknown. Requirements for dry-washing are that the gravel shall be thoroughly dry and disintegrated; cemented gravel has been worked, but only at added expense for disintegration, either mechanically or by slow and laborious hand methods. Clay is unworkable by dry-washing, and causes loss of gold when present. Mechanical separators, used in conjunction with power excavators, are rarely practical, chiefly because the gravel is dug faster than it can be dried; even in an arid region, subsoil may be damp.

A widely used device is the MEXICAN DRY WASHER (444). It is a shallow box, about 18 by 36 in, with a fabric bottom (such as 8-oz canvas) supported on wire screen, and having 5–8 cross-riffles resting on the fabric. Box is mounted at slope of 15°–25° and forms the stationary top of a bellows, whereby a pulsating current of air is forced upward through the fabric. Pulsating current has proved more effective than a steady flow, as from a fan. A screen with $^3/_8$–$^1/_2$-in holes is mounted at top, with a chute delivering undersize to upper end of separator, while oversize falls outside. With this hand device, one man can treat 0.5–1 cu yd per day. A similar machine, with box 11 in wide by 40 in long, having its bellows operated through pulley and crankshaft from a 0.75-hp gasolene engine, was operated near Randsburg, Cal, in 1932 (16) at capac of 0.8 cu yd per hr. For similar portable hand-operated apparatus, as used in W Australia, see Bib (452). For other varieties of separators, both hand- and mechanically operated, see Bib (444, 445, 446).

120. DEFINITIONS AND CLASSIFICATION OF METHODS

Sluicing is a general term applied to many forms of placer mining. A SLUICE is an inclined channel or trough, through which gravel is carried by a stream of water. Stones and light sands pass through and run to waste at the lower end; gold and other heavy minerals settle to the bottom and are caught in riffles. A RIFFLE is a groove or interstice, or a cleat or block so placed as to produce the same effect, in the bottom of a sluice. Art 124, 125 give data on sluices and riffles. Wooden sluices (Fig 825) are sometimes called BOX-SLUICES; inclined ditches, in gravel or bedrock, are GROUND-SLUICES. Riffles in ground-sluices are formed by the natural irregularities of their bottoms.

Table 105 outlines the commoner combinations of excavating and transporting agencies used in open cuts for digging gravel and getting it into sluices. (For underground methods, see Art 130.) Of the methods outlined, dredging and hydraulicking are normally low-cost operations, suitable for mining of low-grade gravels and requiring large capital outlay. The others (excepting

Table 105. Classification of Surface Placer Mining Methods

Method	Outline of Procedure	See Art
Ground-sluicing	Excavation by running water aided by picking; gravel runs into sluices by gravity	121
Shoveling-in	Gravel loosened by pick, and shoveled into sluice	121
Pick and shovel, with transport	Gravel loaded into wheelbarrows, cars on tracks, buckets, or stone-boats Transport by hand, animal, or power to sluices, or to an incline elevating gravel to sluice; gravel sometimes pumped to sluice	121
Plow and scraper Power scraper	Scraper may be hoisted up an incline to an elevated sluice	122
Dragline	Dragline excavator delivers gravel to a sluice, or more elaborate washing plant mounted on skids, wheels or rollers, to keep it within reach of excavator	122
Hydraulicking	Water discharged under press from nozzles breaks gravel from bank and transports it to ground sluice; added water may be used to aid transport	123
Dredging	Mechanical excavator (usually chain-bucket type) delivers to screen, sluices, jigs, etc, all mounted on a boat	127 128
Dragline dredging	Mechanical excavator, usually a dragline, stands on shore of pond and delivers gravel to washer mounted on a boat	129

NOTE. Work with elevators is not included (see Art 126). For various forms of "River Mining," such as wing-damming, fluming, etc, see 9th Ann Rep, Cal State Mineralogist, 1889, p 203. For a more detailed classification, see Bib (181).

121. GROUND-SLUICING, SHOVELING-IN, HORSE-SCRAPING INTO SLUICES

Ground-sluicing. Fig 807 shows typical ground-sluicing in shallow creek gravels, where bedrock grade is steep enough to allow it. Sluice *M* is set at the lower end of the ground to be worked and a shallow trench *T* is dug, preferably on one side of the deposit. *T* is deepened to bedrock by turning a stream of water into it, and if necessary picking up the bottom, the material being washed through the sluice. On reaching bedrock the trench is widened by picking and caving its banks into the stream. Small plank or earth dams *D*, erected where necessary, throw the stream against the bank to aid in undercutting it and so minimizing labor; their skilful use forces a stream to do considerable work without supervision during a night shift. Coarse gold remains on bedrock, finer gold is caught by the sluice riffles. As the bank recedes, exposed bedrock is cleaned with shovels, hoes, hand scrapers, brushes, and wires for digging into crevices; profits may depend upon thoroughness of cleaning, since gold tends to remain on bedrock (in some cases, no other means of recovery is provided). The concentrates may be cleaned up in the same or in a special sluice (Art 125). Large stones are forked out and piled on cleaned bedrock, as at *B*.

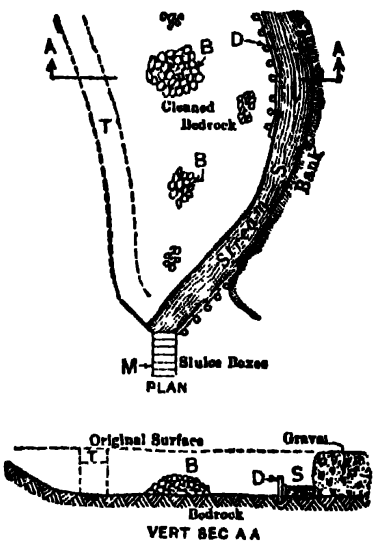

Fig 807. Ground-sluicing (diagrammatic)

Ground-sluicing has many variations. In Alaska, it is often used for cheaply stripping creek gravels covered by muck (Art 118). Tundra and brush are grubbed and burned; subsequent sluicing may be done as in Fig 807, or the water may be led through several channels into which intervening ridges eventually cave; spring floods are thus used to advantage. Also, small streams of water may be caused to trickle down the face of the bank, cutting vertical channels; the ground between caves or is blasted or pried off. Thus, in 1911, Granville Mining Co, Dominion Creek, Yukon, stripped frozen muck 18 ft thick, the bank receding 4–7 in per day; est'd cost, with high wages, 10¢ per cu yd of muck (393). Such work generally stops on reaching gravel. Ground-sluicing uses water as an excavating agent where pressure water for hydraulicking is not available.

Requirements for ground-sluicing: (*a*) Shallow gravel, rarely more than 6 to 8 ft deep. (*b*) Sufficient grade for the available water to carry the loosened soil. Data covering different conditions are lacking. Granville Co (see above) sluiced muck on grades of 17 to 25 ft per mile; grades for gravel are much steeper. (*c*) Plentiful water. Here again data are lacking. Longridge (394) states that it takes about 6 times as much water to move material in a ground-sluice as to do the same work in a box-sluice. Scanty water supply may sometimes be supplemented by pumping back from settling pools at end of sluice. (*d*) Dumproom for tailings at lower end of sluice may be provided by natural grade of bedrock or surface; drag-scrapers may move tailings from end of sluice.

Duty of water and labor. Mead estimates that 2 men can move 20–30 cu yd max of gravel per day by ground-sluicing (395). A native laborer in Swaziland handles up to 10 cu yd of light tin gravel per shift, where a good stream of water is available (396, 397). In Colombia, in gravel 5–15 ft deep, a stream of 135 miner's in (Art 123) moved only 50 cu yd per day (385). Purington gives following data on stripping muck (50–75% ice) in Alaska. On Anvil Cr, Nome, 400 miner's in of water; bank, 20 ft high; grade, 4.5 in to 12 ft; duty of water, 10 cu yd per in per 24 hr. Elsewhere on Anvil Cr, a 4.5-ft bank of muck was stripped with 100 in of water; grade, 3 in to 12 ft; duty of water, 3 cu yd per in per 24 hr. On Crooked Cr, near Council, 55 in of water; bank, 4 ft high; grade, 4.5 in to 12 ft; duty of water, 3.45 cu yd per in per 24 hr (390).

Table 106 gives data collected by E. D. Gardner and C. H. Johnson (16) at ground-sluicing operations in western U S in summer of 1932; at some, a small part of available water was applied through nozzles; greater effectiveness of booming (described below), as compared with continuous sluicing, is indicated. Besides labor cost, expense for supplies was estimated at 2–4¢ per cu yd.

Booming ("hushing") is applicable where the water supply is inadequate for steady work. Water is impounded above the diggings; and by releasing it at intervals it washes gravel through the ground-sluices. Booming is also used for stripping. Dams for booming usually have gates opening automatically when the reservoir is full. A vert or hinged gate is common, controlled by a lever carrying an open box at outer end. The reservoir when full overflows into the box; the added wt lifts the gate, and the box then empties itself. Gates must be so arranged that the dam will not be injured by the rushing water. Booming strips light overburden cheaply. In 1904, on American Cr, Alaska, an area 900 ft long by 25 ft wide was stripped of muck and gravel 5 ft thick in 3 weeks; costs, including dam and gate, did not exceed 7¢ per cu yd (394). See also (390, 391). According to Wimmler (188) in 1927, ground-sluicing and booming in Alaska cost 15–35¢ per cu yd; cost of equipment, $350–$1 500 (excl ditches), of which $250–$500 represented cost of dam with automatic gate. See also Table 106.

Shoveling-in (*i e*, into sluices) has its simplest form in shallow creek gravels, where bedrock grade is steeper than is required for sluices (Fig 808). Sluice *S* is on bedrock, with the lower end raised and flattened to give headroom for dump *D*. Added dumproom is obtained as needed by extending lower end of sluice.

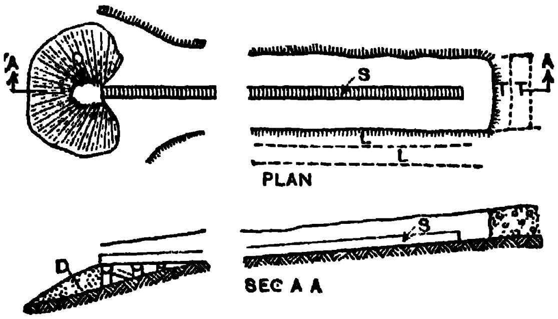

Fig 808. Simple Shoveling-in

Gravel is excavated in transverse cuts *T*, or more often in longitudinal cuts *L*. Only the finer material goes through the sluice; large stones are piled on cleaned bedrock. Transverse cuts deliver all gravel at the head of the sluice, but require use of barrows for lateral transport in all but narrow pits; with longitudinal cuts the sluice must be shifted when the bank has receded about 12 ft from it, otherwise, shoveling cost becomes excessive. In wide deposits, shifting may sometimes be avoided by feeding the main sluice from narrower and steeper radiating or lateral sluices.

Water is conducted to head of sluice in flumes, pipes, or canvas hose. On Seward Peninsula, Alaska, "flume hose" is commonly 12 to 14 in diam, of 12 or 14-oz duck, sewed with 3 seams. It is light and flexible, but begins to rot after about 4-mo service (398). If a stream flows in the creek bed, water is dammed above the diggings.

Ideal conditions as in Fig 808 are rare. The required grade must often be created artificially, by excavating under the sluice, or by mounting it on trestles (Fig 823). The elevated sluice is erected cheaply and quickly; it is often the only means of obtaining dumproom; bedrock trenches facilitate shoveling, but are too costly if deep or in hard rock. In ALASKA, wherever feasible, muck and top gravels are first removed by ground-sluicing; the underlying pay, rarely more than 5 or 6 ft thick, is then worked by shoveling-in. Barren gravel often overlies the pay; where grades do not allow this to be ground-sluiced it is removed with barrows or scrapers; only the pay gravel is sluiced.

Sluices, riffles, grades, water, clean-ups (see Art 124, 125).

Drainage of pits. Ideal condition is a self-draining pit (Fig 808). Where grades are flat, dams are generally necessary, both above and below the area worked; they are built cheaply, of logs, earth, or brush (see Sec 43, Art 16).

Seepage is preferably removed by bedrock drains, on grades as flat as 1.5 in per 100 ft; they are started on the surface at the proper distance downstream to reach bedrock at the lower end of the pit and then continue on bedrock grade. Purington (390) gives following data on Alaskan practice, which is fairly typical. Drains are usually 2 ft sq, lagged with horiz poles held at 4-ft intervals by posts and caps. After the first cut in the pit is taken, the drain is covered with logs and moss laid on the caps. For small operations, 10 by 12-in box-drains of 1-in plank are adequate. A perforated standpipe should be placed over the drain at the lower end of the pit; drains may require flushing to keep them open. In the Fairbanks District an open unlagged drain, 3 ft deep by 3.5 ft wide, took 2 men 6 weeks to excavate. Lagged drains in hard ground may be costly. Seepage may be pumped out. The cheap homemade China pump, operated by an overshot waterwheel, can be used only when there is more water than is required for sluicing. Pumping costs more than drains.

Table 107. Duty of Labor Shoveling into Sluices in Alaska. Purington (390)

Location	Depth of gravel, ft	Height of lift, ft	Cu yd per man per 10 hr
Klondike (*a*)	2	9	3.5
Birch Cr (*b*)	4.41	(*c*)	5.0
American Cr	......	....	2.75 (*d*)
Fairbanks (*e*)	3.0	....	7.5
Nome (*f*)	5 to 7	....	5.76
Solomon River (*g*)	3.0	....	3.75
Council Dist (*h*)	3.5	....	6.63

(*a*) 2 men, platform used. (*b*) Aver of 12 operations. (*c*) Height of lift not over 6 ft. (*d*) Large boulders interfered with work. At one point, a 5-ft bank was shoveled at rate of 4 cu yd per man-shift. (*e*) Aver of 3 operations; lifts less than 5 ft; some bedrock taken up. (*f*) Aver figures; Pioneer Co, on Anvil Creek, 3-ft bank, obtained a duty of 9 cu yd. (*g*) High lift and irregular bedrock. (*h*) Aver figures, including one case where, on a limestone bedrock, with a double lift, duty was 3.5 cu yd; another where, with 8-hr shifts, 3-ft bank and 5-ft lift, duty was 12 cu yd.

Duty of labor in shoveling-in varies with height of bank and character of gravel and bedrock (Table 107). Shovelers can throw to heights of 6 to 8 ft (9 ft limit); for greater heights platforms must be built and the gravel re-shoveled from them. During boom years in central Alaska, 7–8 cu yd per shift was considered aver man's work. The time required for careful cleaning of a creviced bedrock materially reduces the shoveler's aver output. Table 108, from Gardner and Johnson (16), gives data on 6 shoveling-in operations in western U S active in summer of 1932.

Limitations and costs. Shoveling-in is adapted to shallow gravels. It is simple, does not involve large expenditure for plant and can be carried on in remote districts where cost of installing mechanical excavators would be prohibitive. In ALASKA, where labor and supply costs are high, the cost of plant, including dams, drain ditches, water ditch, and a string of 10 sluice boxes (Art 124), is from $500 to $2 000 (390). The method has the great advantage of allowing careful cleaning of bedrock. Operating costs vary widely with wages and duty of labor; only rich gravels can be worked at a profit. Wimmler (188) in 1927 quoted following cases from Alaska where overburden was removed by booming or ground-sluicing, and pay gravel worked by shoveling-in; all costs are per cu yd: (1) Hot Springs dist; cut 50 by 500 ft; frozen muck and some gravel boomed to depth of 25 ft for 7¢; shoveling-in of 2.5 ft of gravel and bedrock, $2.30; combined cost, 30¢. (2) Little Minook Cr, Rampart dist; cut 12 by 600 ft; 18 ft of muck and gravel boomed for 18¢; shoveling-in 2 ft of gravel and bedrock, containing 50% boulders, $2.20; combined cost, 38¢; this was a fourth cut and cost less than first. (3) Little Minook Cr; a first cut 12 by 1 000 ft boomed 7.5 ft deep for 22¢; shoveling-in 2 ft of gravel with 60% boulders, $2.80; combined cost, 77¢. (4) Greenstone Cr, Ruby dist; pit 60 by 200 ft; sod stripped by hand; muck and gravel ground-sluiced to 6-ft depth for 38¢; shoveling-in 2 ft of gravel, $1.65; combined cost, 70¢ (5) Greenstone Cr; bench deposit with favorable grade; ground-sluiced 10 ft of muck and gravel for 26¢; shoveling-in 1 ft of gravel for $2.56; combined cost, 47¢, incl deprec. Elsewhere, combined costs are 25¢–$1 per cu yd.

Cars and barrows for loading sluices. Fig 809 shows radiating tracks for small mine cars (Sec 11). To use this method the head of sluice must be at or near the level of bedrock, which must have a fairly regular contour. Barrows may be used similarly and on rougher bedrock by laying plank runways.

Inclined barrow runways, for loading an elevated sluice, are usually at right-angles to the sluice, for working by longitudinal cuts (*L*, Fig 808). For cost of barrow and car work, see Sec 3, 5. An objection to them is that they dump large amounts at one time; this makes the flow in the sluice uneven, causes clogs and is not conducive to good gold saving. If the sluice can be loaded at a single point (Fig 809), a dump or "mud-box" (Fig 828) decreases these troubles and allows forking out of large stones.

Scraping into sluices, with drag or wheel scrapers, is possible in small gravel on soft rock; Sec 3 gives details and cost of scraping. Purington gives following data for Alaska (390): A 2-horse wheel scraper, working in small gravel on soft schist bedrock, handles 30–40 cu yd per 10 hr at about one-third the cost of shoveling-in; 1 plow loosens for 4 scrapers. Scrapers dump through a hatchway in a platform over head of sluice (Sec 3). Examples from western U S (18) in 1932. (1) Horseshoe Bend on Green River, below Vernal, Utah. Loose gravel 4 ft deep, no boulders over 8-in and no clay; gold very fine, black sand abundant. Man and 2 boys, with team of burros and 3.8-cu ft slip scraper handled 6.5 cu yd per day, loosening by hand and scraping 25 ft to hopper and screen at top of sluice 20 ft long; water pumped by 1.5-hp gasolene motor from nearby river. Est working cost, $1 per cu yd. (2) Tailings from Blue Channel drift mine Folsom, Cal; originally partially cemented, but disintegrated by several years' weathering; some clay but no coarse boulders; gold somewhat rusty. Tractor with 7-cu ft scraper dragged material 300 ft to screen and hopper; bucket elevator raised it 26 ft to head of 12-in sluice 110 ft long. Water pumped from old shaft, 20-ft lift. Black-sand concentrates amalgamated in small concrete mixer; final recovery in a short sluice. Two men handled 20 cu yd per shift; total gasolene for tractor, elevator, pump, and amalgamator, 25 gal per shift; est total cost (labor @ 40¢ per hr), 62¢ per cu yd.

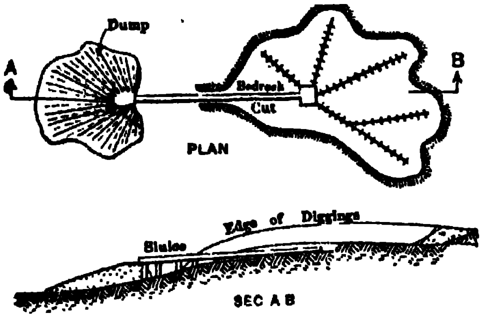

Fig 809. Loading Sluice with Cars (after Young)

122. DERRICKS, CABLEWAYS, INCLINES, MECHANICAL EXCAVATORS

Except for certain applications of dragline excavator, these devices are now seldom used. They have been successful mechanically, but, as operating costs are high compared to dredging (Art 128), gravel must be richer to yield a profit. Many installations have failed financially, through failure to recognize this fact and ignorance of limitations of different types of equipment.

Derricks may be used in shallow open cuts in the following ways: (*a*) gravel is shoveled into barrows, wheeled to a fixed point and dumped into the derrick skip or bucket; (*b*) gravel is shoveled into stone skips, or buckets mounted on small trucks running on rails and pushed by hand to within reach of the derrick boom; (*c*) gravel is shoveled into buckets which are slid along skids by the derrick tackle. Plan (*a*) requires greatest amount of lateral handling; miners spend much time in wheeling and dumping instead of picking and shoveling. Plan (*c*) is the most efficient in this respect. Derricking is adaptable to shallow beds, where the gravel must be elevated to sluices and where excavation and cleaning of bedrock are necessarily done by hand.

Cableways (Sec 26) with self-dumping carriers (Art 130) are sometimes substituted for derricks. Operating cost is higher than for the derrick when used as above, because cableways involve tramming and dumping at a point under the cable. The automatic dumping carrier is of little advantage, since a man on the dump box is always necessary. For a large installation in Montana, see (409).

Alaska. Data from N. L. Wimmler (188) in 1927. Method of shoveling gravel into barrows, wheeling to bucket, hoisting latter up an inclined cableway, and dumping it automatically into sluice, was still employed in 1924 at a few small mines in the interior district, where necessary sluice grades and dumproom were not otherwise obtainable. Such pits rarely exceeded 150 ft diam. Shoveler spent 1/4–1/3 of his time wheeling to central point, where bucket, holding 2–5 barrow loads, rested in a pit with its top level with runways. Shoveling duty of 7–9 cu yd per day was good work. Steam hoists were 5–15 hp. Examples: (*a*) On Ophir Cr, Innoko dist; overburden (18 ft of frozen muck and 4 ft barren gravel) was ground-sluiced for 16¢ per cu yd; 5 ft of gravel and bedrock was mined as above for $1.75 per cu yd; combined cost for 27-ft depth, 42¢ per cu yd. (*b*) On Chatham Cr, Fairbanks dist; 10 ft of overburden was ground-sluiced for 16¢, and 4 ft of gravel and bedrock mined as above for $1.25 per yd; combined cost for 14-ft depth, 48¢ per cu yd.

Inclines were sometimes used in Alaska for hoisting from a pit to head of an elevated sluice. From foot of incline, a system of radiating tracks was laid on floor of fairly level pit, over which cars loaded at edges of pit were trammed by hand; hoists were operated by steam. Fig 811 shows a similar method of hoisting in cars loaded by scraper.

Power scrapers (Sec 3, Art 6; see also Art 91, and Sec 27) are adapted for mining and elevating gravel from shallow placers; unsuited to hard or blocky bedrock; a soft, even bedrock may sometimes be cleaned with scrapers, but final hand cleaning is usually necessary. Power scrapers are also advantageous for removing tailings from ends of sluices. Large heavy scrapers are generally used; small drag or wheel scrapers are too light and too difficult to hold while loading when drawn by power. EXAMPLES follow.

Auburn, Calif. Gardner and Johnson (18) describe use in 1932 of a power scraper at Mammoth Bar. As in Fig 810, a 1 $^3/_8$-in track cable was stretched from top of a 64-ft mast (a spruce tree 24-in diam at bottom and guyed with $^7/_8$-in ropes) to a bridle rope stretched across the river 700 ft downstream. The loaded 1-cu yd Page bucket was hauled at 300 ft per min by hoist with 95-hp gasolene engine and 1.25-in rope, returning empty by gravity at 1 200 ft per min. A grizzly at top of hopper was about 20 ft above ground. Most digging was under water; upon completing removal of the expected 100 000 cu yd, it was intended to pump out the pit and recover any missed gravel, while also cleaning bedrock by hand.

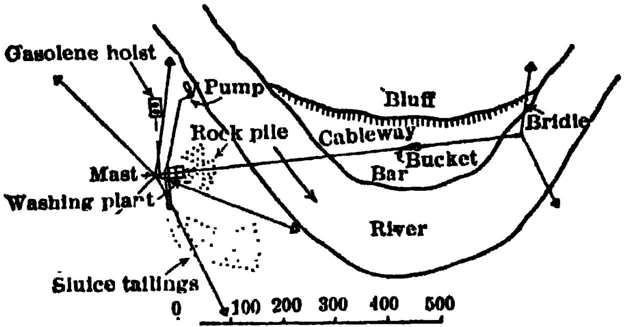

Fig 810. Placer Mining with Power Scraper, Auburn, Calif

Sierra Leone Goldfields, Ltd (448) was operating in 1932 in a narrow valley of the Pampana River, West Africa, at a point 12 miles from nearest motor road. Topsoil nearly barren; richness of gravel increased with depth, but main pay was in upper 2 ft of bedrock under gravel which required blasting; total depth excavated, 10–25 ft. Gold varied from small nuggets to almost dust. Sauerman slack-line cableway with 1-cu yd bucket (scraper), centered on one side of channel, excavated semicircular area with 600-ft radius, discharging into hopper about 50 ft above ground level; operation repeated after moving equipment 1 200 ft upstream. Sluice, of steel pans 12 ft long, 4 ft wide, 2 ft high, bolted together, was 200 ft long; riffles of steel rail rested on coarse wire screen. Natives raked the gravel down sluice; water flumed from intake 2 miles upstream. Heavy sands were collected every 10–15 days, rewashed on 12-in sluice, 15 ft long, and finally panned. Crew, about 50 natives.

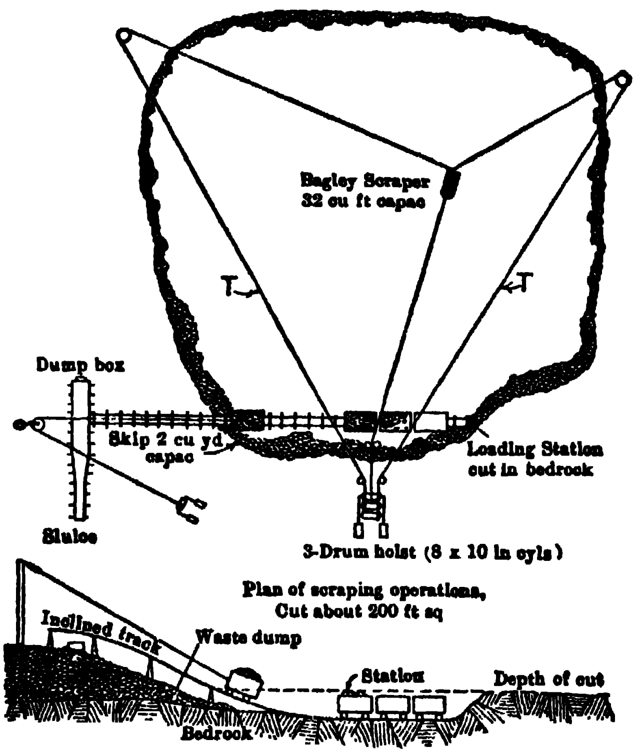

Fig 811. Bagley Scraper with Incline and Auxiliary Hoist

Alaska. Steam-driven scrapers were widely used in the interior districts, but by 1924, according to Wimmler (188), few remained in operation, due to diminishing aver value of deposits for which they were suitable. Conditions favorable for scrapers: (*a*) large areas of shallow gravel; (*b*) freedom from large boulders; (*c*) soft and relatively smooth bedrock, not too deeply fissured; (*d*) unfrozen gravel; (*e*) pit free from water, by natural drainage, bedrock ditches, or pumping; (*f*) requisite sluice grade and dumproom not otherwise obtainable. Scrapers were usually Bagley (bottomless) or slip.

Bagley scraper, at larger mines, dragged gravel to a central point, discharging into a 2.5–4-cu yd car at depressed loading station; car then hauled up incline and dumped automatically into head of sluice. Scrapers 3.5–5 ft wide, 1.25–2.5 cu yd capac, and weighing 3 100–4 125 lb, proved more suitable than larger ones. They were operated by 3-drum hoists driven by 2-cyl, 8 by 10-in to 10 by 12-in steam engines; ample power was essential for economical work. Under good conditions, scraper made 30–50 trips per hr; usual range 15–40 cu yd per hr into sluice. Fig 811 shows typical arrangement of larger mines in Fairbanks dist. Total depth worked, 15–35 ft, of which, pay gravel was 6–8 ft, and bedrock, 2–4 ft. Area of pits, 80 000–120 000 sq ft. Crew on each of 2 10-hr shifts, 6–8 men. Power cost with 80–150-hp wood-fired boilers, 4.8¢ per hp-hr; with 180-hp coal-fired boiler, 2.4¢ per hp-hr. Cost of scraping and sluicing only, 45–90¢ per cu yd; total cost (incl stripping) to 15–35 ft depth, 40–60¢ per yd. Equipment investment, $15 000–$25 000.

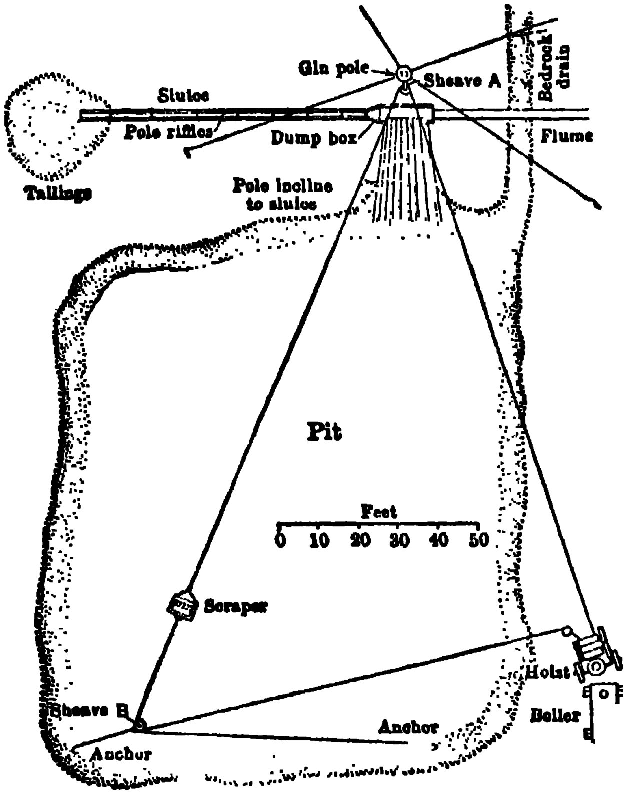

Fig 812. Slip Scraper dragged up Incline

Slip scraper is restricted to shallow deposits; other conditions as above. Usual capac, 0.75 and 1 cu yd, but load arriving at sluice is often only 0.5–0.75 of capac. In typical work (Fig 812) scraper requires 2 men at loading point, but discharges into sluice automatically at top of inclined runway. On completing a cut the width of scraper (4–4.5 ft) and about 1 ft deep, tail sheave *B* is shifted along the anchor cable, which is fastened to a row of deadmen across far end of pit; max length of pit, about 300 ft; width usually about half the length. With 150–300-ft haul, scraper can make 10–30 trips per hr; usual range, 50–125 cu yd delivered to sluice per 10-hr shift. At a 65 000-sq ft pit in Innoko dist, 4 ft of overburden was ground-sluiced for 14¢ per cu yd, and 4 ft of gravel and bedrock were put into sluice by 13 men with a 0.75-yd scraper in 95 days, for $1.55 per cu yd; combined cost to 8 ft depth, 87¢ per cu yd. Boiler, 40-hp, burned a cord of wood per shift; no pumping required. Plant, excluding ditch, cost $6 500. At another pit in same dist, 150 by 230 ft, after removing 10 ft of muck for 7¢ per yd, crew of 6 men, with 0.75-yd scraper, moved 6 ft of gravel and bedrock in 74 10-hr shifts, at $1.35 per cu yd; combined cost, 54¢ per yd No pumping required; 50-hp boiler drove 3-drum hoist; equipment cost $7 000. In Hot Springs dist, at a pit 140 by 290 ft, 4 ft of muck and top gravel were ground-sluiced for 15¢ per yd; 7 ft (10 500 cu yd) of gravel and bedrock were mined and sluiced by 7 men and 1-yd scraper in 110 10-hr shifts, at $1.32 per cu yd; combined cost, 89¢ per cu yd. About 100 miner's in of water were pumped. Two 40-hp boilers burned 4 cords of wood per shift.

Power shovel has rarely been a commercial success in gold placer mining, though it suggests itself for use when hydraulicking is prohibited by lack of water and grade (165, 385, 390, 401, 402). Failure due to one or more of following causes: (*a*) attempts to dig frozen gravel; (*b*) hard bedrock which can not be dug by shovel and must be cleaned by hand at large expense; (*c*) lack of mobility, as compared with hydraulicking; a serious drawback which leads to costly delays; (*d*) failure to provide transport and washing facilities in proportion to its digging capac; it is therefore idle much of the time; (*e*) gravel is delivered from dipper or cars intermittently and in large amounts; the sluice or other gold-saving device is first over- and then underloaded, resulting in a loss of gold. Storage bins and automatic feeders ahead of the sluice obviate this difficulty, but entail added headroom and greater first and operating costs; (*f*) trouble with disposal of tailings from sluices or washing plants. Some of these difficulties have been due to improper management, but item (*c*), probably the most important, is inherent in the power shovel.

Shovel mining of placer tin in Nigeria. Data from W. E. Sinclair (449) in 1933. Cassiterite is commonly concentrated in a 3 to 4-ft bed of "wash," a hard, cemented gravel with streaks of tough clay lying on bedrock of decomposed granite, and covered with up to 100 ft of tenacious clay, hard and tough when dry, sticky and treacherous when wet. These and other conditions (bedrock usually lower than natural drainage level, scarcity

of water during 6 mos and lack of storage facilities, generally level topography) favor use of power shovels, with gravel pumps for lifting the tin-bearing material out of pits.

One successful operation employed a 300-ton, full-revolving steam shovel, with 6-yd dipper and 95-ft jib for stripping a through cut 60 ft wide at bottom, followed by a caterpillar-mounted steam shovel with $^7/_8$-yd dipper; the latter took up only half the width of "wash" exposed, leaving other half as a bench for the return trip of stripping shovel. Thereafter, lateral stripping was dumped on the area previously occupied by "wash"; 17 cu yd of overburden had to be moved to expose 1 cu yd of wash. The small shovel loaded into 1-cu yd, side-dump cars, hauled by gasolene loco to end of cut, and dumped into a sluice leading to gravel-pump sump. An 8-in centrif gravel-pump, driven by 90-hp steam engine, raised the mixture 65 ft to sluice boxes at top of bank (Art 126). Stripping at 2 500 cu yd per day (not full capac) cost in pence per cu yd: fuel (coal @ £3 per ton, del'd), 2.49; white wages, 1.19; native, 0 75; oil and stores, 1.15; repairs and spares, 0.44; overhead, 0.38; total, 6.4d. Mining of "wash," pence per cu yd: breaking, loading and hauling (800 ft), 6.80; labor at gravel pump, 1.32; labor at sluice boxes, 1.90; white supervision, 5.14; coal, 5.72; oil, stores, and repairs, 2.36; management and misc, 1.99; total, 25.23d.

Inca Placers, Lumberton, Fort Steele Div, B C. H. Sargent (399) in 1938 described operations by Consol Min & Smelting Co, Palmer Bar Cr. The deposit of unsorted gravel, 400 ft wide and $^1/_2$ mile long, parallel with stream and 5–30 ft above its level, is unusual in that gold (fairly coarse) is confined to upper 3–6 ft; of several drill holes to bedrock, the deepest showed 200 ft of underlying barren gravel. Boulders large and numerous, but barren overburden is absent. Water from a dam 0.5 mile upstream is flumed along upper edge of deposit.

Methods used: (*a*) Hand shoveling into sluices running downhill from the flume towards the creek; limited to small areas, and generally unprofitable, due to boulders. (*b*) Digging by Diesel-power shovel, discharging on belt-conveyer 70 ft long (gasolene-driven) which elevates gravel to upper end of a substantial line of sluice boxes; conveyer is mounted to permit shifting along the sluice. (*c*) Use of 2 auto-trucks to carry gravel from power shovel to foot of conveyer. Trucks are loaded from a movable pocket covered by grizzly with 6-in spacing; oversized boulders stacked by same shovel, but largest are not moved from the pit.

Dragline excavator (Art 97 and Sec 3) has recently attained considerable prominence in placer mining, both in deposits of dry gravel and in those of which part or nearly all is excavated from under water. The dragline has many of the drawbacks of the power shovel and can not dig as hard material, handle boulders so readily, nor work successfully on an irregular rock surface. But it is more mobile and has these distinct advantages: (*a*) it has a wider digging radius, hence less frequent moves are necessary; (*b*) it stands on the surface and dumps at a considerable elevation above its track; thus grade for sluices may be obtained without a separate elevating device, under conditions impossible for a power shovel standing on bedrock; (*c*) the operations of loading, tramming and elevating cars, common to many power-shovel operations, are rarely necessary; the long boom of the excavator enables it to do its own transporting and elevating. Dragline excavators can also mine small yardages of loose gravel which would not warrant installation of a dredge. Following examples illustrate applications of the dragline for excavating, transporting, and elevating gravel to movable sluices or washers. For use of dragline with floating washing plants (Dragline Dredging) see Art 129.

Atlantic City, Wyo. Data from C. L. Ross and E. D. Gardner (118) in 1935, on dragline excavator and track-mounted washer operating in 1933–1934 along Rock Cr. Elev, 7 600 ft. Channel 100–250 ft (aver, 200 ft) wide. Well rounded and easy digging gravel, 9–12 ft (aver 10 ft) deep, containing few boulders; 65% of material washed was below $^3/_4$-in diam. Upper 3 ft was barren soil; bedrock, diorite schist decomposed to depth of 2–5 ft into tough blue clay, sloped 2° (not enough for sluicing). Most of the gold, rounded and relatively small, was in lowest 6 in of gravel; higher gravel carried 5¢ per yd; black sand not abundant. Excavator was a caterpillar-mounted dragline, with 60–ft boom and 1.25-yd bucket when using gasolene; 1.75-yd with 40° fuel oil. Hopper of washer was 27 ft above base of excavator. Washer (total wt 55 tons) moved on a pair of 90-lb rails, in 15-ft sections, spaced 15 ft 7 in apart; each rail rested on ties at top of a 4-ft embankment (above bedrock) placed for the purpose by the excavator. Washer was carried on 7 wheels on each rail, and was dragged ahead, 15 ft at a time (4 times in 24 hr) by the excavator. Washing equipment: (*a*) hopper holding 3 bucket-loads; (*b*) trommel, 4.5 ft diam, in 3 4-ft screening sections (5 ft blank at each end) punched with 0.25-, 1.5-, and 0.75 by 1.5-in holes; (*c*) 5 parallel sluice boxes, 28 in wide, 12 ft long, 19-in drop, with iron-capped riffles 1.75 in high spaced 1.25 in apart; (*d*) tailings sluice, 28 in wide, 72 ft long, with same riffling and grade as the boxes and discharging 8 ft above bottom of cut; (*e*) stacker, a 26-in rubber belt 40 ft long, with rise of 8 ft. Water (1.25 cu ft per sec) was drawn from creek at max distance of 1 200 ft from the washer, through 12-in slip-joint pipe in 15-ft sections, one of

which was removed (or added) at each move of washer. Centrif pump, with 75-hp gasolene engine, gave a 50-ft head. Pump was carried forward, in 1 200-ft steps, by the excavator.

For OPERATING PLAN see Fig 813. Creek was first diverted into a ditch 50–100 ft outside the channel. Stripping to full width of channel was done on 2 trips in opposite directions. A drain ditch was dug 4 ft into the decomposed bedrock along each side of channel, its material being dumped on top of exposed gravel, while overburden was piled outside. Stripping was kept at least 50 ft ahead of gravel digging, normally by stripping during night shift and digging gravel the other 2 shifts; in Spring and Autumn, when freezing prevented washing, stripping might advance far enough to permit washing for a time on 3 shifts, when next resumed. Usual rate of stripping was 1 000–1 200 (aver 1 150) cu yd per 8 hr. Gravel removed in 15-ft cuts across full width of channel, the dragline standing alternately to right and left of washer. About 18–24 in of decomposed bedrock was taken up, with care to mix it with gravel to aid disintegration. During 240-day season of 1934, plant advanced 6 500 ft upstream, washing 420 000 cu yd (aver recovery, 23.75¢) at total cost (incl stripping) of 11.9¢ per yd, comprising: labor and supt, 4.5¢; fuel, 1.8¢; other supplies, 2.7¢; royalty, 1.7¢; deprec, taxes, insurance, etc, 1.1¢. Crew included 6 men each on AM and PM shifts, and 5 men at night; superintendence by owners.

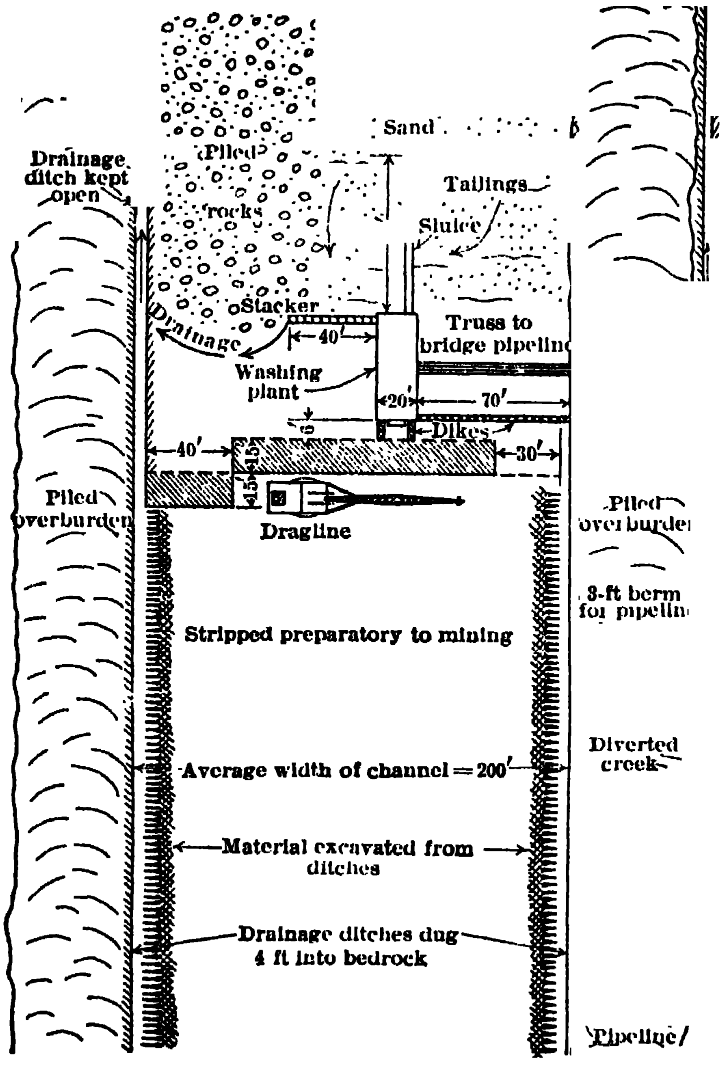

Fig 813. Dragline and Movable Washer, Atlantic City, Wyo (118)

Calaveras County, Cal. Data from S. R. Fox (166) in 1935. Lidgerwood dragline with 60-ft boom and 1.5-yd Page bucket made cut 120 ft wide, dumping into 14 by 14-ft hopper of a movable washer. Excavator had 60-hp boiler, fired with 1.5 cords of wood per 9-hr shift. Washer, mounted on rollers on a plank-track, had 4.5 by 22-ft trommel punched with $^3/_8$-in holes and a few 0.75-in holes at lower end to save occasional nuggets and provide coarser pebbles to counteract packing behind riffles. Total length of tables and sluices, 70 ft, of which 55 ft had Hungarian riffles (Art 125); riffles caught over 95% of total yield and about half of all the flour and flaky gold recovered; remaining 15 ft of sluice was floored with coconut matting under wire screen. Coarse tailings stacked by 24-in belt 40 ft long, disposal being aided at times by portable hydraulic giant. Water supplied by 10-in centrif pump, driven by water wheel under 300-ft head; same wheel drove 20-hp generator supplying 15-hp motor on trommel and stacker. A 30-ft move of dragline took 10 min; of washer (dragged by tackle from dragline), 20 min; total moving time of 3 hr was consumed mainly with water connections, using canvas tubing at elbows, with flexible and slip joints in metal pipe, total moving time probably would be about 1 hr. Total operating costs, 16.7¢ per cu yd.

Hillsboro dist, N M. Data from O H. Metzger (450) in 1938. Area of about 1 200 acres in Dutch Flat was being worked by 2 dragline excavators with 1- and 1.25-yd buckets, and a transportable washer having four 36-in Ainlay bowls. One dragline was used for stripping 2–6 ft of soil, amounting to about half of total excavation; other dragline for gravel, at about 300 cu yd per 8 hr. Grizzly over washer hopper discarded boulders; gravel passed to trommel washer rejecting all over 0.25-in to stacker; undersize to Ainlay bowls, of which only 3 could be run when water was low. Tailings from bowls passed by Wilfley pump to coarse stacker, water being impounded for reuse. New water was pumped 4 miles from wells. Entire washing plant driven by 65-hp engine; fuel for this and all other equipment was gasolene. Washer, mounted on wheels, was moved by caterpillar tractor. Yield reported as 50–75¢ per yd; tailings, about 10¢. Costs: excavating (incl stripping) and washing, 16–20¢; pumping, etc, 4–5¢; total, 20–25¢ per yd, excl capital charges and royalty. One-shift work required 10 men at combined wages of $50.

Willow Cr, Iditarod dist, Alaska. One dragline installation described by N. L. Wimmler (188), operated for several years after 1916, working 4–6 ft of light gravel under 12 ft of frozen muck; bedrock, soft slate decomposed to sticky clay on top. Bucyrus dragline with 60-ft boom and 1.5-yd Page bucket (weighing 3 700 lb), driven by 60-hp boiler, was mounted on skids and rollers. It excavated 1 ft into bedrock, uncovering 100 000–150 000 sq ft per season, or about as much as could be cleared of overburden in that time by ground-sluicing. Aver pit, 110–120 ft wide by 150 ft long, required 5 positions of dragline, radiating about 65 ft from central dump box at head of sluice. Water, 160 miner's in. Labor cost (5 men), $57 per day; wood (1.25 cord), $25 per shift; no pumping required. In 1922 (good water supply) 130 000 sq ft (67 400 cu yd) of overburden was ground-sluiced for 9¢ per cu yd. In 52 10-hr shifts of 7 men, 24 100 cu yd of gravel and bedrock was treated for 28¢ per cu yd. Combined cost, to 19 ft depth, 16¢ per cu yd.

Circle dist, Alaska. J. B. Mertie, Jr (463) gives following data on 2 similar operations in 1936–37. MASTODON CR. Pay gravel in length of 0.75 mile varied 120–160 ft wide, 12–15 ft deep, with 4–5 ft of overlying muck; bedrock was fissured mica schist. Aver diam of gravel, 12 in, with numerous boulders to 4-ft diam. Gold, fairly coarse, was distributed through 5–6 ft depth of gravel (9 ft in some places) and sometimes penetrated 3–4 ft into bedrock, of which 1.5 ft was normally scraped. Caterpillar-mounted dragline with 55-ft boom and 1.25-yd bucket was operated by 120-hp, 6-cyl Diesel engine. A bulldozer was used to push gravel from margins of cut to within reach of dragline. Elevated sluice, completely enclosed and weighing about 30 tons, was mounted on 2 skids. Square dump box had rail grizzly discharging larger boulders over the side. Sluice, 80 ft long, 30 in wide, was of steel boxes lined with wood; grade, 13.5 in per 12 ft. Cross-riffles were of steel rail, heads up, and 0.5 in apart at base. Sluice water was supplied at 4 200 gal per min by 12-in pump, driven by 160-hp Diesel engine, and drawing from a dam downstream from workings. Under good conditions, 15 men could treat 1 000 cu yd per day. DEADWOOD CR. Pay gravel about 250 ft wide, 6 ft deep, covered with 5 ft of muck, and resting on fractured bedrock, of which 2–4 ft was scraped. Gravel was well rounded, mostly smaller than 10 in (aver, 5 in) with few boulders as large as 2 ft. Gold fine (5–6 mg) and flaky, and 85% of it was on or in bedrock. Caterpillar-mounted, Diesel-driven dragline had 55-ft boom and 1.5-yd bucket. A bulldozer was used as on Mastodon Cr. Elevated sluice, on skids, had dump-box 7 ft wide, 34 ft long, with block riffles, and 50 ft of steel boxes 34.5 in wide, with Mn-steel cross-riffles; grade, 1.4 in per ft. A No 1 giant with 4-in nozzle, working on gravel in dump box, was supplied with 4 000 gal per min by 10-in centrif pump driven by 97-hp Diesel engine; water came originally from a ditch, but within sufficient head. Crew of 17 men cleaned 3 000 sq ft of bedrock per day.

Power excavators in general. Modern types are often constructed to operate, after necessary but simple alterations, as either shovel or dragline; full-revolving machines are most flexible; those of walking type have an advantage over caterpillar-mounted on soft ground. For use of draglines delivering to floating washers, see Art 129. For sizes, capac, digging and dumping radii and lifts of shovels and draglines, see Sec 3, 27. For placer mining, dippers or buckets of less than 2-cu yd capac are usually preferred. For respective advantages of dragline and shovel, see paragraphs above. Table 109 gives data on 5 placer operations using power excavators reported by Gardner and Allsman (165) as operating in 1937. S. R. Fox (166) offers following advice relating to draglines: (*a*) Small, light, convertible shovel-draglines, with 35- to 40-ft booms and 1-yd or smaller buckets are not satisfactory for placer mining; their short reach entails too frequent moves, and the light bucket will not dig efficiently at depths below 20 ft. (*b*) A 60-ft boom and the heaviest model of 1.5-yd Page bucket make the smallest effic combination, which should have about same capac as a 2-cu ft chain-bucket dredge. (*c*) For estimating, not more than half the max rated capac should be assumed as attainable; best basis is record of actual performance over 30- or 60-day period. (*d*) Washer should be designed for capac 20% greater than that of excavator.

Table 109. Data on Five Placers Using Power Excavators in 1937 (165)

	I	II	III	IV	V

(*j*) Incl depreciation. (*k*) Based on total yardage, incl stripping.

123. HYDRAULIC MINING OR HYDRAULICKING (See also Art 98, 126)

Term "**hydraulicking**" is applied to excavation of gravel banks by streams of water under press from nozzles. Method was invented in Calif, 1852, by E. E. Mattison; Bib (391) gives history of development. In the U S, most deposits suitable for hydraulicking have been exhausted or, until recently, were unworkable due to legislative restrictions on disposal of tailings; recent governmental program of constructing debris dams has permitted some revival of hydraulicking in Calif (464); (see Dumproom, below).

General plan of work. Water is impounded in reservoirs, or diverted from streams, and conducted in ditches, flumes, and pipes to an elevated point above the placer and thence to the working face through pipes. Pipes terminate in GIANTS or MONITORS (Fig 819), which control direction of jet. Gravel is broken partly by direct impact of jets, partly by undercutting and forcing banks to cave. Water flows away from the face (usually in bedrock ditches), carrying gravel to a sluice leading to a dump; the giants

often "pipe" fallen gravel into the sluice, and "bank water" (see below) is often supplied for same purpose. As the face is washed away, the bedrock cuts and sluices are advanced. Cemented gravel banks may require blasting before they can be disintegrated by water (Bank blasting, below). Gold is captured chiefly in the sluice.

Details of water supply and methods of opening and advancing working faces, arrangement of pipe lines, giants, sluices, etc, vary with local conditions; the accompanying cuts indicate diversity of practice (see also Fig 843). Fig 814 shows ideal conditions of grade and dumproom; Fig 815, layout for a bench placer; Fig 816, a mine on a small stream (404), where bedrock grade (2.35%) was insufficient to provide dumproom, and tailing had to be elevated; the pit itself was used for a dump as work proceeded upstream.

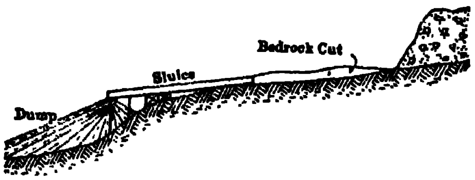

Fig 814. Simple Layout for Hydraulicking (after Young)

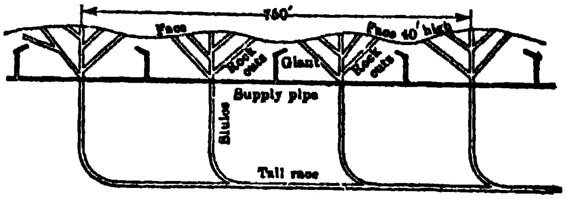

Fig 815 Layout for Hydraulicking Bench Gravel, Klondike (after Purington)

Tunnels are sometimes driven, to carry sluices to lower ground furnishing a gravity dump; also for opening placers, where local conditions prevent open-cut entry on bedrock. Thus, in Fig 817, tunnel *T* is driven on sluice-grade to the lowest point of the bedrock, and connected with surface by 1 or more shafts, *S*. Gravel is hydraulicked into the shaft, the timbers and protecting lining of which are removed as excavation is deepened. On reaching bedrock, the gravel bank is hydraulicked to the sluice in the tunnel. Bowie states that 300-ft shafts in Calif were readily operated in this way; their cross-sec was 3 by 3 ft to 4.5 by 9 ft; tunnels were 7.5 to 8 ft high and 2 to 3 ft wider than the sluice, to give room for construction and cleaning-up (391).

The principal problems of hydraulic mining are connected with water supply, sluice grades, and dumproom; the method appears simple, but has rigid limitations. Some small-scale hydraulicking is successful, but as a rule it is adapted to large outputs; it requires large initial investment, and skilled management and engineering.

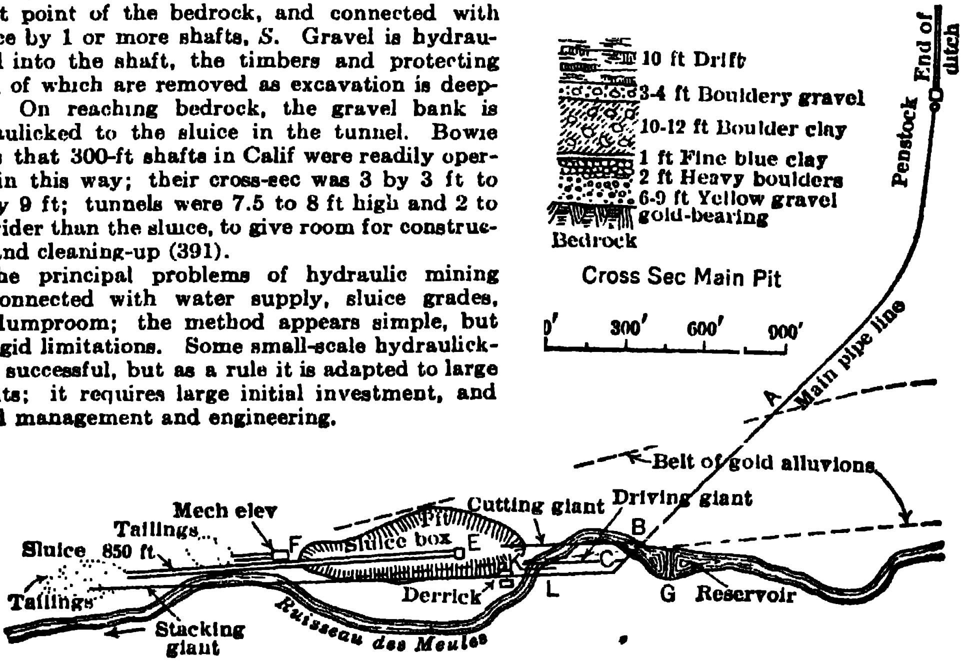

Fig 816. Hydraulic Mine near Beauceville, Quebec

Size and tenor of deposit must be such as will amortize the investment required for its exploitation and pay the profit desired. Minimum gold content that will yield a profit may vary with locality from 4 to 50¢ or more per cu yd, depending on capital invested, rate of working, life of property, working costs and gold recovery.

Character of gravel and bedrock (see Art 118).

Water supply must be ample for required output. Speed of working determines rate of return, and depends largely on amount of water available (see Duty of water, below), which is related to the press; a small amount under high press often breaks as much gravel as a larger amount under a lower press. But the output is often determined by the sluice

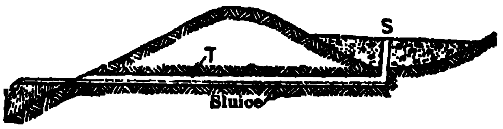

Fig 817. Hydraulic Mine opened by Tunnel (cross-sec)

capac (Art 124), instead of the cutting capac of the giants. Pressure must be sufficient to allow giants to be set at a safe distance from face and still do effective work. Giants usually operate under heads of 200 to 400 ft, occasionally 600 ft; less than 200 ft is apt to give a low duty. Shallow creek placers of Alaska are hydraulicked on a small scale with heads of 35 to 100 ft; danger of sudden caves and slides from high banks requires higher press, so that the giants may throw streams from a considerable distance. With heads over 600 ft, the requirements for heavy pipe, bracing, and anchorage become exacting (385). Numerous attempts made to pump water for hydraulicking have nearly all been commercial failures (390) (compare Art 98).

Grade for sluices best adapted to most cases is 4–5%. Cost and difficulty of operation increase as grade flattens, until a point is reached where hydraulicking is impossible (Art 124). Grades may be increased artificially by use of elevators (Art 126).

Dumproom must be available at end of sluice; it is computed from surveys, allowance being made for the swell of excavated gravel.

A deep canyon, or a torrential stream which will carry away tailing, provides ideal dumps. Bench placers are usually well situated as regards dumproom. Large dumps are built up on sloping ground by gradually extending lower end of the sluice (Fig 814); branch sluices are often installed and the dump widened (fanned-out) as well as lengthened. In either case, slope of the ground must be steeper than the sluice grade. Tailing must sometimes be impounded to prevent damage to low-lying mining or farming land. This condition may prohibit hydraulicking, due to impossibility or cost of installing and maintaining DEBRIS DAMS, especially for large-scale work. Hydraulicking in the Sacramento and San Joaquin drainage areas, Calif, practically ceased in 1893, when the Caminetti Act was passed, creating a Federal commission to regulate hydraulic mining and prevent further silting-up of these rivers. For details of this act, and for types and construction of debris dams, see Bib (405, 464). Amendment of the Caminetti Act, and passage of the Placer Mining District Act by the Calif legislature in 1934, encouraged renewal of hydraulic mining in that State. Present Calif law permits erection of storage dams behind which the mines of the district may discharge their tailings upon payment of designated fee. At the privately owned Bullard's Bar dam, on North Yuba River (capac 80 000 000 cu yd), storage fee was originally 3¢ per cu yd measured at pits; later reduced to 2¢ with rebate for volume of boulders stacked in pit, which reduced storage charge to about 1.5¢ per cu yd.

Timber is necessary for houses, flumes, trestles, sluices, riffles, sluice linings, etc. For a large operation, a sawmill is usually required at the start, located preferably near the head of the supply ditch, either above or below where the water is diverted. Timber is then floated to points where it is needed. Cheap timber materially reduces costs (385).

Working season is often limited by climate or water supply. Alaskan seasons vary from 100 to 120 days. Where climate permits continuous work, water is rarely available the year around, even with reservoirs for impounding flood waters and melting snow. Length of season, proper scale of operation, annual returns, and capital, are closely related.

Summary. Requirements for successful large-scale work are rarely satisfied completely. Adequate amounts of gravel, gold, water and head, and a feasible working season are essentials. Lack of natural sluice grades and dumproom generally prohibits extensive hydraulicking, but may sometimes be met by use of some form of elevating device; the latter adds an operating and capital cost which may or may not be prohibitive.

Miscellaneous data on equipment. WATER SUPPLY is usually the most costly item; see Sec 38 for general data on rainfall, runoff, reservoirs, ditches, flumes, and pipes. Flumes are preferable to ditches in all doubtful ground; both should be provided with turnouts and sand gates. Distributing reservoirs are required near end of ditch to avoid wastage when giants are turned off; their number, size, and importance increase with the length of ditch and number of shut-downs that occur. Almost any reasonable expenditure is justified for preventing breaks in the supply system; constant operation is essential to large output and low costs. A PRESSURE BOX (penstock) is necessary at upper-

Operation of giants. Banks are usually broken by undercutting and caving. Working faces should be kept square and advantage taken of corners. Narrow pits or deep concave faces are avoided, as workmen are constantly menaced by falling material. Water should be turned away from a bank that is about to cave, otherwise the rush of caved material may reach the giants and men. Water cuts fastest where thrown against a bank at an oblique angle. Banks shaped as in Fig 815, with giants placed opposite a nose, allow effective use of water and reduce danger from caves, as the latter fall outward at right-angles to face and not toward the giant. Some Alaskan operators work creek gravels 15–50 ft deep by setting the giant on top of the bank and piping downstream, but the duty of water thus obtained does not indicate a high effic (390). With 1 giant, part of the bank is caved, then with a larger nozzle the fallen gravel is washed to sluices. With 2 or more giants, their time is apportioned between caving and sluicing. BOOSTER GIANTS may be used to drive gravel across flat bedrock to sluices. Ruble elevator (Art 126), when used, requires a separate giant, and another is often used (sometimes only periodically) for spreading tailings piles.

Number of giants depends on size of working face, character of gravel, press and amount of water. Practice tends towards use of a small number of large giants, rather than a larger number of small ones; the former cut faster and save labor. Giants are placed to command as much of the face as possible, to work advantageously in a combined attack on one point, and as near the face as is safe (406). For best results, at least 2 giants and 2 working faces are required, so that hydraulicking may proceed on one face while boulders are being removed from the other (394).

Height of face for economical work is normally limited to a max of 150–200 ft; higher banks are usually worked in benches. Conditions allowing high benches are: high water press, compact gravel that does not "run" when caved, and a wide pit. Where the bottom layer of a high face is tough, the upper gravel may be piped off far enough to allow giants to be moved closer to the face and exert more force.

Bank-water (bank-head or bye-water) applies to streams brought to the pit in ditches, not under press. Bank-water is allowed to run over the face, aiding in disintegrating clayey gravel, thawing frozen ground, moving gravel to sluice, and maintaining a steady flow through it.

Bedrock cuts or ditches are a continual and sometimes serious source of expense in most hydraulic mines; in some early Calif mines, they reached 60 ft depth (391, 407); in case shown in Fig 815, 4 men were constantly employed in extending bedrock cuts (390). When much clay is present, more branching bedrock cuts are required than for fine sandy gravel (406); grade of bedrock also influences spacing of cuts. Drainage of pits is usually provided for by sluices; occasional bedrock drains are required.

Boulders too large to be piped to and through the sluice are removed by derricks or cableways or broken up. As derricks must be located behind the giants, they must have long booms and masts and are cumbersome to move. Cableways do not interfere with giants, but have restricted reach sidewise. Derricks and cableways may be operated by small water wheels; either is usually preferable to blasting where boulders are numerous, especially if sluice grades are flat (406). Sledging, if feasible, is generally the cheapest mode of breaking boulders if done by cheap labor and without delaying piping; "mud-capping" (Sec 5) usually costs more than blockholing. R. H. Ernest, Round Mountain Mining Co, Nev, states that for mud-capping 839 rhyolite boulders, many highly silicified, aver size 4 cu ft, 402 lb of 40% gelatin dynamite were used or 0.481 lb per boulder.

Bank blasting is sometimes necessary in cemented gravels before they can be broken down by giants. Small T-shaped tunnels (Fig 818) are usually driven at the foot of high banks. Drifts *D* are charged with explosive and drift *E* is tamped solid with the excavated material. Only enough explosive is used to shatter the ground; in some cases several cross drifts *D* are driven. A blast will usually shatter nearly twice the area of ground covered by the drifts. In some cases, where only the bottom layer is cemented, the top gravel is hydraulicked, and small shafts are sunk to bedrock, where the explosive is placed in small chambers. Bank blasting has seldom been employed in recent years.

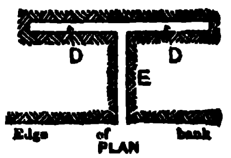

Fig 818. Bank Blasting

Miscellany. CLEANING BEDROCK is sometimes done by giants; hard creviced bedrock must be cleaned by hand at high cost. LIGHTING is necessary at night, since work is

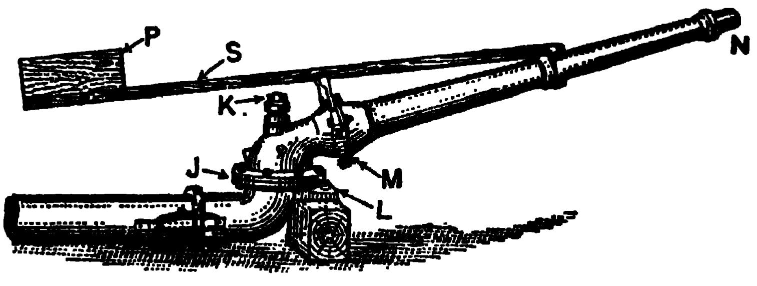

Fig 819. Giant or Monitor

continuous; modern equipment usually includes a small hydroelectric plant. **Labor.** Skilled men required are: nozzle tenders, carpenters, blacksmith; sometimes a machinist and derrick winchman. For SLUICES, RIFFLES, etc, see Art 124, 125.

Table 110. Sizes and Weights of Hydraulic Giants (Joshua Hendy Iron Works, San Francisco, 1939)

Giant No	Inlet diam, in	Butt diam, in	Std Nozzle diam, in	Heaviest Part, lb	Shipping weight, lb
1	7	4	2, 3	120	390

(*a*) From Joshua Hendy Iron Works, San Francisco, Cal, in 1939. Flow based on discharge coefficient of 0.90; see under "Discharge through nozzles"; also Sec 38.

Giants (monitors). Fig 819 shows a modern, double-jointed giant, connected to pipe line by a slip or a flanged joint. It can swing horizontally through a full circle about the joint *J*, and through a wide vertical angle about joint *M*. Weight of the spout is counterbalanced by lever *S* and weighted box *P*; lug *L* is bolted to a heavy timber, securely fastened and braced to bedrock; guide vanes are set inside the spout, to prevent rotary motion of the jet which destroys its solidity.

Details of construction vary. A vertical king-bolt *K*, to take the thrust as the water enters the giant, is common; top of the bolt should have a ball-bearing to reduce friction when the giant is swung. Some makers replace the king-bolt by a special ball-bearing joint at *J*, to avoid obstruction to the flow, but the king-bolt is a good safety precaution, and, with well designed pressure boxes, should give no trouble by catching stringy matter. Tables 110, 111 give data on Hendy giants; other makers build giants of similar size and wt.

Nozzles (*N*, Fig 819) of different makers are not interchangeable; nozzle of any size may be attached to a giant up to the max it will take. They must be carefully designed and highly finished, otherwise the jet is ragged and cannot be thrown as far without spraying. Grit cuts the nozzle, and destroys shape of jet.

Deflectors. Small giants, or those working under light heads, are pointed by hand; deflectors are required on large giants and in general where the head much exceeds 100 ft. Deflectors are of 2 kinds: (*a*) A short flexible coupling *C*, with ball joint and leather gasket, is inserted between nozzle *N* and end of spout *P* (Fig 820). (*b*) A short section of pipe, a little larger than the nozzle, is attached loosely to its end and projects over the jet; it may have a threaded tip, replaceable when worn. Both types turn freely on gimballed joints, and are controlled by a lever *L* (406). The reaction of the jet, when diverted by the deflector, forces the giant in the opposite direction; *L* is easily moved and gives a sensitive control. Type (*b*) is best for heads over 300 ft, but requires a separate deflector for each size of nozzle. A single deflector of type (*a*) will take any nozzle smaller than the max that can be used on the giant.

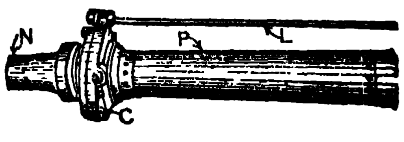

Fig 820. Deflector for Giant

Discharge through nozzles (Sec 38, Art 9). Approx calculations may be made by the formula, $Q = Ca\sqrt{h}$, where Q = discharge, cu ft per min; a = cross-sec area of nozzle, sq in; h = head at nozzle, ft; C = constant depending on coeff of discharge.

For giants with inside vanes (see above) the coeff of discharge is put by Longridge (394) between 0.8 and 0.85; by J. J. Garrard (397) as 0.94. Corresponding values of C are 2.68, 2.84 and 3.14, respectively. Makers' tables usually give full theoretical discharge ($C = 3.34$) with no allowance for friction.

Miner's inch (Sec 38, Art 19), unless otherwise stated, is taken here as equivalent to a flow of 1.5 cu ft per min, corresponding to its legal definition in Calif and Mont (40 miner's in = 1 cu ft per sec). INCH-DAY is the volume (2 160 cu ft) delivered by 1 miner's in flowing 24 hr. Old records of the duty of water in hydraulicking require careful scrutiny; in Calif alone, the inch varied locally from 1.2 to 1.76 cu ft per min (391).

Duty of a miner's inch in hydraulicking is the cu yd of gravel which can be broken down and sent through sluices in 24 hr by 1 miner's in. It varies with height of bank, character of gravel and bedrock, grade of bedrock, amount and pressure of water, manner in which the water is utilized, and with all the factors influencing sluice capacity (Art 124). Published data rarely state completely all the factors involved. See Tables 112–117; also Art 124 and under examples below.

Table 112. Duty of the Miner's Inch at North Bloomfield and La Grange Mines, Calif

Bowie (391)

	Date	Cu yd gravel washed	Miner's in-days	Grade of sluices	Height of bank, ft	Duty per in-day, cu yd

	1874–1876 (*e*)	284 932	207 010		50– 80	1.37
	1875–1878 (*f*)	459 570	302 960		40– 50	1.52
	1880–1881 (*g*)	329 120	203 325		10– 80	1.57
	Total . .	2 433 834	1 713 195	....	......	1.42
	1908 (*h*)	....	.....	8 in per 12 ft	100–200	7–10

Note. Duty of miner's in in early Calif work was estimated by State and U S Army engineers at 1 to 7.5 cu yd, aver about 3 cu yd. J. H. Hammond gave following data: At Hobson's mine, Placer Co, piping a 120-ft bank, using 500 in water at head of 360 ft, with sluices set on grade of 12 in per 12 ft and paved with rock riffles, duty of a miner's in was 24 cu yd in light free gravel and 10 cu yd in coarse cemented gravel. By increasing sluice grade to 18 in per 12 ft and using iron riffles, duty of one inch in light gravel increased to 36 cu yd. These figures are exceptionally high (407). (*a*) Larger part of material moved was top gravel. Sluices, 6 ft wide by 32 in deep. Block riffles used almost entirely; rock riffles in tail sluices. (*b*) Sluices previous to 1881 were 4 ft wide by 30 in deep, paved with blocks. (*c*) French Hill claims. (*d*) Light Claim. (*e*) Chesnau Claim. (*f*) Kelley Claim. (*g*) Vigno Hill. (*h*) Data from P. Bouery, Supt, pub by Joshua Hendy Iron Works, Bull No 111. Sluices, 6.33 ft wide by 47 in deep. Higher duty is due to steeper grades, higher banks, and improved riffles (Art 125), and to use of water under heads of 400 to 600 ft.

Purington comments on Table 113 as follows: The high duty of the miner's inch in the Klondike (Ex 11–18) is due to well rounded gravel containing no large stones, heavy sluice grades, and use of block riffles. Low duties at Nome (Ex 21–27) are due partly to the fact that the gravel is flat and rough, partly to use of hydraulic elevators, which take 50 to 66% of the available water. Duties given are for both giant and elevator water (Art 126). Iron riffles are commonest, but have little effect on duty because the sluices are short. Dimensions and grades refer to bedrock sluices leading to the elevator. The figures are based on operators' statements and comparatively short runs.

Table 114 shows difficulties of starting large-scale hydraulicking, and close relation between costs and output. Frozen ground makes ditch construction hard; new ditches require constant repairs, but these lessen with time.

Table 115, from Wimmler (188), gives data on sluices and duty of water at Alaskan mines active within a few years prior to 1927; stated flow of water includes that from all sources, ground-sluicing water, in addition to cutting water, being required in all cases except at Little, Osborne, and Ophir Creeks, where hydraulic elevators were employed. The somewhat lower duties, as compared with Calif and Mont (Table 116), are explained by: (*a*) lower available grades on bed rock; (*b*) prevalence of flatter pebbles in some districts, and of heavy gravel in others; (*c*) large amount of ground-sluicing (or elevator) water required by above conditions; (*b*) frozen gravel in some localities.

Table 116, after Gardner and Johnson (17), gives duty of water in sluices at mines operating in western U S in 1932. For riffling of same sluices, see Table 120.

Cost and operating data. Hydraulicking costs from 4¢ per cu yd under very favorable conditions in Calif to 25¢ or more in Alaska. Unfavorable conditions, as frozen gravel, or necessity for elevating tailing or for pumping giant water, may increase cost to 60¢ or more. Records of cost usually include only operating expenses, omitting capital charges; the latter may be very high; thus, a number of Calif mines spent $200 000 to $500 000 in preparing for work; the equipment of 1 mine, including 290 miles of ditch and 8 miles of pipe, cost $2 000 000 (409). Following examples (see also Art 126) give costs under various conditions. Table 117 relates to 6 hydraulic mines active in 1932 in western U S.

Salyer mine, Trinity county, Cal. Data from Gardner and Johnson (17) in 1934. Deposit of "blue" gravel about 40 ft thick, tight, containing many boulders, capped by clay, and covered by 60 ft of loose gravels and clays. Water system, with 5 000-in capac, included ditches, flumes, and siphons, but no reservoirs, and cost $300 000. Pit was supplied at 350-ft head through 2 16-in pipes with combined capac of 2 800 miner's in. Two giants, with nozzles of 8 to 5 in, according to available water, gave duty of 4.33 cu yd per in-day.

Sluicing required min of 1 500 miner's in. Sluice was 5 ft wide, 350 ft long, dropping 8 in per 12-ft box; wood-block riffles 18 in square, 12 in high, wore rapidly and were to be replaced by steel rails. About half the water and most of the sand passed to undercurrents, which caught about 10% of the yield. Mercury was used in sluice and undercurrents. Boulders in pit were handled by crane on a tractor. Aver crew at mine, 15 men. In 97-day season of 1932, 718 900 cu yd was moved at direct cost of 2.63¢ per yd, incl deprec of mine equipment, but excl depletion, administration, and deprec of water system and other permanent installations. Additional data in Col IV, Table 117.

I—Redding Cr, Douglas City, Cal. II—Omega Hill, Washington Camp, Cal; data for 1931. III—North Fork, Helena, Cal. IV—Salyer, Cal. V—Browning property, Leland, Oreg. VI—Eldorado Bar, York, Mont. (*a*) Incl giant at Ruble elevator. (*b*) Water pumped 120 ft vert, and booster pump to give head of 100 ft. (*c*) Of which, 1 cutting and driving, 1 at Ruble elevator, 1 (3-in) used periodically for tailings disposal; only 2 giants used at a time. (*d*) Ditch. (*e*) Cu yd gravel per day per miner's inch of water. (*f*) Flume. (*g*) Excl supervision and ditch repairs. (*h*) Excl general administration. (*i*) Power, 15¢.

Omega Hill mine, Washington Camp, Cal. Data from Gardner and Johnson (17) in 1934. Ancient river gravel, 30–60 ft deep (lower 6–8 ft cemented) lying under 10–20 ft of volcanic ash. Water supply through 2 ditches: one 16 miles long, with numerous flume sections 6 ft wide; other 8 miles long; both delivered to reservoir 210 ft above pit. Two 6-in. or three 5-in giants were used. Sluice, 48 in wide, lay in bedrock cut and extended 1 700 ft outside, to gulch where tailings dam could be located. At end of sluice, a grizzly with 1-in spacing separated coarse gravel (used for making dam) from undersize, which was delivered behind the dam by another sluice. Previously prepared culvert in bottom of gulch assisted drainage of clean water from the tailings pond. When one pond was full, another dam was made farther down the gulch. Additional data in Col II, Table 117.

Eldorado Bar, York, Mont. Example of placering with pumped water from Gardner and Johnson (17); data refer to operations in 1931. Centrif pump driven by 250-hp motor lifted 4 000 gal per min (356 miner's in) 120 ft vert to head of the bar; suction pipe, 14-in; delivery pipe (500 ft long), 12-in diam. Booster pump at top, with 50-hp motor, developed press of 40 lb per sq in, and delivered about 60 miner's in through 6-in fire hose to 1.25- or 1.5-in nozzle for cutting, or (through same hose) to 1.5- or 2-in nozzle for sweeping; remainder of water pumped was used for bank water. The gravel worked easily; boulders moved by hand. For details of sluice, see Ex 17, Tables 116, 120; other data in Col VI, Table 117. Crew of 4 men on each of 3 shifts worked 500 cu yd per day. Power cost 0.9¢ per kw-hr, plus $1 per mo per hp of connected load, totaling about $75 per day.

Gold Hill mine, Idaho City, Idaho. Data from O. H. Metzger (428) in 1938. A bench deposit consisting of 4 beds of tight gravel alternating with hard clay, and including a bed of soft sandstone, varies in thickness from 25–50 ft at upper end of workings to 150 ft at lower end; the 2 areas, though contiguous, are worked practically independently, each with its own sluice and group of 3 giants, piping in one while clay and boulders are being removed from the other; little work is done where deposit is less than 35–45 ft thick. Bedrock is clay, sloping 8–15% towards Elk Cr. Water comes from 2 sources: from Moore's Cr (rights to 2 700 in) through 8 miles of ditch and 2 40-in siphons each more than 0.5 mile long, and from Elk Cr (rights to 2 300 in) through 10-mile ditch; flows unite at penstock 5 000 ft from and 225–325 ft above workings. Two 20-in pipes convey to header within 1 000 ft of workings; thence 3 18-in pipes run to valves distributing to 6 giants through 15-in pipes. Normal consumption (of 3 giants at a time), 3 000 miner's in (considerably reduced toward end of season); approx aver duty, 1.5–1.75 cu yd per in-day. Giants have 4- or 5-in nozzles; press, 90–110 lb per sq. in. Sluice boxes are 3 ft 7 in wide, inside of liners; drop per 12-ft box, 8 in for the longer, and 6 in for the shorter sluice. Riffles are 4 by 6-in crosspieces, spaced 2–3 ft, and covered with longit 30-lb rails, heads up. Hg is added at 3–5 oz per day to first 3 boxes. Boulders are cleared from ends of sluices by 1-yd, gasolene-driven dragline, which also builds tailings dam, working 3 shifts on the 2 jobs. Boulders in pit are drilled by jackhammer connected to portable compressor. Three-shift operation (June, 1937) required 34 men; total wages, $154.25. In 1937 season of about 70 days, 200 000 cu yd through sluices yielded 900 fine oz, or 15.75¢ per yd.

Salmon Cr, Baker, Ore. Data from Gardner and Johnson (17) in 1934. Unusual feature was use of 0.5-cu yd, gasolene-powered shovel for handling boulders, water supply being inadequate to move them and to loosen profitable yardage of gravel at same time. When not occupied with boulders, the shovel aided in loosening clay-bound gravel. Cutting was done by No 2 giant with 2.25-in nozzle under 150-ft head, using 90 miner's in; an additional 60 in of water came over the bank, about 25 ft high. Bottom 1 ft of gravel, containing most of the gold, was left on bedrock, and washed separately at end of a month's run. For data on sluices and riffles, see Ex 18, Tables 116, 120. Crew on each of 2 8-hr shifts: 1 piper, 1 shovel operator, 2 sluice tenders; foreman on day shift. Gasolene for shovel, 12.5 gal per shift. Est cost (@ 130 cu yd per shift), 20¢ per yd, plus shovel rental, interest, and amortization of plant.

Alaska. Data from N. L. Wimmler (188) in 1927. General. Most hydraulic mining areas in Alaska (except in southern dist and upper Yukon basin) are characterized by: (*a*) Relatively shallow (max, 25 ft) deposits, of both stream and bench types; latter usually only slightly above streams. (*b*) Pay streaks close to bedrock. (*c*) Cemented gravel rare; frozen gravel and overburden fairly common. (*d*) Aver stream grades, 25–150 ft per mile, or less than the 6 in per 12 ft desirable for economical sluicing. (*e*) Water adequate for economical mining obtainable only at high cost for ditches. (*f*) Water supply erratic, and usually under low head; reservoir sites of large capac are scarce. (*g*) Working season of only 90–120 days; as short as 30 days in some localities deficient in water. These conditions affect mining methods in following ways: (1) Use of much of available water for ground-sluicing or bank water; in some places, water thus used may be 3 times the vol of that for the giants. (2) Necessity for frequent moves may lose 40–60% of time available for hydraulicking; loss still greater if only 1 shift is worked. (3) Intermittent operation, pending accumulation of useful vol of water. (4) Frequent necessity for elevating gravel or tailing. (5) Occasional adoption of "piping over the side" of sluice boxes depressed in a bedrock cut (see Dan Cr, below) unusual elsewhere. (6) Operations are relatively small-scale, employing 2–8 men; often, with 50–500 miner's in of water under 35–200 ft head, season's work will be 2 000–30 000 cu yd; a few larger mines, with 500–2 500 in of water under 100–300 ft head, may move 30 000–100 000 cu yd; max, 1 000 cu yd per day. Examples (operating in 1924) follow.

Falls Cr, Yentna dist. Creek deposit of unfrozen, round gravel, aver 8 ft deep, with 10–15% of boulders up to 3-ft diam. Bedrock is clay, shale, and sandstone, easily cleaned. Total water, incl ground-sluice, 300–700 in. Usual pit, 80 ft wide, 125 ft long. Sluice, 36 in wide, 42–54 ft long, on 8-in per 12 ft grade, with steel-shod, 2 by 4-in riffles, set lengthwise. Two giants, 3-in nozzles and 100-ft head, stood on top of bank and alternated in washing gravel from one side of pit to top of sluice, while other side was being cleared of boulders. Tailings required a stacker giant. Crew of 4 men on each of 2 10-hr shifts, at time of max water, could clean about 1 000 sq ft in 2 shifts, or finish an aver pit in 8–9 days. Setup for new pit took 1 day.

Crow Cr, Girdwood dist. Creek deposit of unfrozen gravel 6–25 (aver 12 ft) deep, with 50% of boulders over 6-in diam, many of them large. Bedrock, tough clay, readily cleaned. Total water, incl stacker giant, 2 600 in, of which 1 000–1 400 in was ground-sluice water. Two parallel and adjoining pits, each 100–150 ft wide and 400–450 ft long, were worked alternately but in step, piping in one while clearing boulders from other. Each pit had its own sluice, 5 ft wide, 8–10 boxes long, at 6 in per 12 ft grade; first 2 boxes had transverse riffles of 40-lb rail; others, longit 25-lb rails. A No 7 giant with 6-in nozzle stood at top of bank on center line of each pit, piping to head of sluice; when reach exceeded effic distance, a smaller booster giant on bedrock at one side of pit assisted sluicing. Upon completing both pits, bank between them was washed in and bedrock cleaned by giants. One stacker giant, No 7 with 5-in nozzle, at 170-ft head, served both sluices. Boulders were drilled and blasted, and put through sluice. With crew of 12–18 men, 66 000 cu yd was mined in 1923 at 43¢ per cu yd.

Dan Cr, Nizina dist. Deposit 6–18 ft deep, of rounded gravel containing up to 75% of boulders over 8-in diam, some reaching 6–10 ft. Bedrock, slate of variable hardness, cut by occasional porphyry dikes causing irregularities. Gold, flat and 40–60% of it coarser than 0.25 in. Deposit worked in a chain of consecutive pits, each 500–700 ft long by 175–300 ft wide, progressing up-stream by steps, although working face of each pit retreated downstream. Assuming a completed pit, as at *e*, Fig 821, first step was to install a line usually of 16–20 (never fewer than 8) boxes, 48 in wide and riffled longitudinally with 20-lb rail, in the old bedrock ditch *c*, and erect a pair of short wing dams *d* at top of upper box. As early in the Spring as water was available, a central ditch *g*, the full length of proposed next adjoining pit, was cut through gravel and 5–6 ft into bedrock, using a giant with 4-in nozzle, smoothing the bottom (about 6 ft wide) with picks, to avoid fracturing. Max grade obtainable was 5–5.5 in per 12 ft, sometimes as flat as 3.5 in. Boxes, 48 in wide, 46.5 in deep (inside), riffled lengthwise with 20-lb rail, were then laid on bottom of entire ditch, connecting with the boxes in old pit at *d*. Ground-sluice water, about twice the vol delivered by a giant, was then turned into the sluice at *j*. After an initial cut to bedrock across the head of the new pit, 2 No 4 giants with 5-in nozzles and 275-ft head were set on bedrock, one on each side of the sluice and well out towards edge of pit, as at *h*. The 2 sides were then worked alternately, washing a slice 35–50 ft wide over the side of the depressed sluice on one side, while boulders were being handled on the other. On completing a slice, the giant was moved downstream a corresponding distance; process was repeated until the blocks *f* had been removed, along with 1–2 ft of bedrock. Tailings were stacked continuously by No 4 giant with 4-in nozzle under 310-ft head. Clean-up, usually not until after finishing a pit, involved removing first the sideboards and later the bottoms of the boxes and washing out gravel lodged between them and the walls and bottom of the cut. In 1923, an exceptionally favorable year, 2 pits were completed, respectively 528 by 165 ft, and 480 by 170 ft; latter, averaging only 6 ft deep, took 9 days for set-up, 17.5 days for hydraulicking, and 10 days for clean-up. For the 2 pits, time required was: 22 days for set-up, 42 days (of 24 hr) hydraulicking, 26 10-hr shifts for clean-up. Total cost, $34 124.

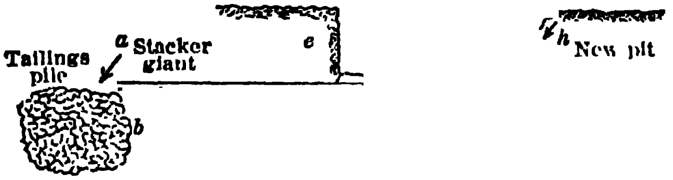

Fig 821. "Piping over Side," Dan Cr, Alaska (188)

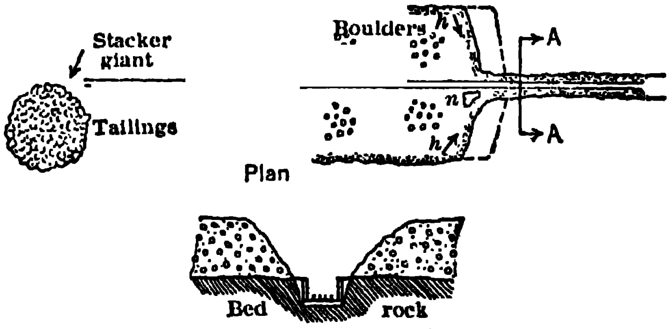

Fig 822. " Piping over Side " on Chititu Cr, Alaska (188)

Chititu Cr, Nizina dist. Stream deposit of coarse gravel 140–150 ft wide, 10–11 ft deep; bedrock, medium-soft slate. Method in 1923–24 resembled that on Dan Cr, except that working face advanced upstream, as in Fig 822. Bottom of bedrock sluice, at grade of 5.5–6 in per 12 ft, was formed of 20-lb rail, laid longitudinally at 4-in centers, and spiked to crossties laid on slate bottom; only the sides of sluice, 3 by 3 ft, were boarded. Opposite sides of pit were worked alternately by giants at *h*; the small triangular block *n* was left till last. to protect men working at boulders on other side. Boulders were piled on

clean bedrock by donkey engine and steel stoneboat. In 1923, one such pit, 460 ft long, 140 ft wide, 11-ft deep, yielded 23 323 cu yd in 44 20-hr days; cost of labor only, 21¢ per yd; in 1924, total operating cost was 51¢ per cu yd.

124. SLUICES

Construction. Sluices are in sections, usually 12 ft long; each section is called a SLUICE BOX. Fig 823 shows typical box for shoveling-in and other SMALL WORK (Art 121). Sides and bottom are 1-in by 12, 14 or 16-in boards, rough or planed on one side; the bottom is 2 in narrower at one end that at the other, so that adjoining boxes will telescope a few inches into each other. Sluices may rest on bedrock, or be set in ditches, or be elevated. They are braced laterally by struts *B*. On the side opposite each shoveler is a board *S*, against which the gravel is thrown, instead of being shoveled carefully into the sluice; this increases the duty of labor and prevents spilling. A collar placed at the junction of each 2 boxes (Fig 824) eliminates braces *C*, Fig 823, which obstruct top of sluice and interfere slightly with cleaning-up. Small sluices may be made with flush joints, like a flume (Sec 38); some operators say this reduces clogs, but the telescoping box is most used because it is easily erected and moved (414). These sluices have a short life, but are cheap and well suited to small work. Worn-out boxes should be burned and the ashes rocked or sluiced to recover gold from cracks and joints.

Fig 824. 14-in Telescoping Sluice Box, Fairbanks, Alaska (after Ellis)

Fig 825 shows LARGE SLUICES for hydraulicking; details vary widely (Table 118); 4 by 4-in sills suffice for sluices up to 4 ft wide; 4 by 6-in sills and 4 by 4 or 4 by 6 posts for wider ones. Sills are 3-4 ft apart; every 3rd or 4th post is supported by angle braces. Posts are dapped into sills, or fastened with cleats, or toe-nailed (Fig 825). Lumber need not be surfaced, but for sides and bottom should be free from knots. To prevent loss of Hg and amalgam, bottom joints are made tight with tongue and groove lumber, splines, or outside battens; close fitting alone is often relied upon. Fig 826 shows a useful device for tightening bottom boards

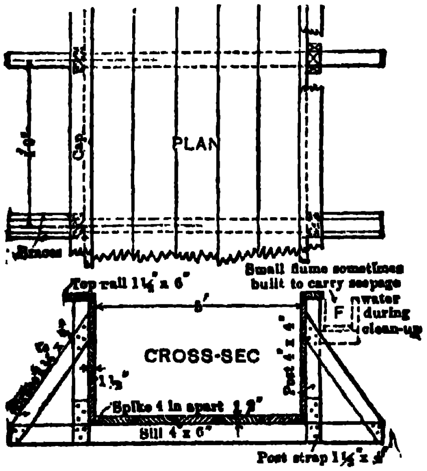

Fig 825. Sluice (riffles and side lining omitted)

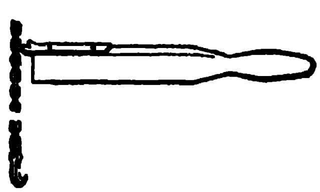

Fig 826. Tightener for Bottom Boards (after Purington)

before spiking (390). Sills must have solid foundation to prevent settlement. As bottom of a new sluice may rise by water collecting under it, ends of sills should be weighted down (391, 406). Following data, referring to Table 118, while old, give elements of cost, which can be adjusted to present costs of labor and supplies.

10	32	24	3″ × 4″	3″ × 4″	1.5	1.5

Ex No 1. Boulder Cr, Atlin, B C (390). Heavy gravel, 400 miner's in of water; duty, 1 cu yd per in-day. Block riffles used at head of sluice, followed by rails. Sawed lumber, $40 per M; difficult to obtain locally boards wider than 8 in. Sluice 1 400 ft long; cost, $6 000. Wages, $3 per 10-hr shift and board.

Ex No 2. "White Channel" bench gravels, Klondike (390). 250 miner's in of water washed 1 000 cu yd per 24 hr. 12 to 14 sluice boxes usually constitute a string. Spruce block riffles, 5 in high and 9 in sq are used; cost 25¢ each and last 1 season.

Ex No 3. McKee Cr, Atlin, B C (390). 2 sluices, 600 and 700 ft long. Top rail, 1.5 by 8 in by 12 ft; post straps, 1.25 by 2 by 14 in; side lining boards, 1.5 by 8 in by 12 ft. Blocks 8 by 8 by 12 in are used for riffles; riffle strips, 1 by 3 by 28 in; braces, 1.5 by 4 in by 1 ft. Each box, with riffles, etc, contains about 540 bd ft of lumber and costs about $25; sluice lumber, $45 per M; riffle blocks, $6 per box-length.

Ex No 4. Silver Bow Basin, Alaska (390). Sluice is in a 9 by 10-ft tunnel, 3 300 ft long; 2 500 miner's in wash 5 000 cu yd gravel per 24 hr. All surfaced lumber. Riffles are 12 by 12 by 12-in spruce blocks, separated by 1 7/8 by 2-in riffle strips. Lining boards, 1-in native lumber; braces, 1 by 8 in. Each box contains about 1 100 bd ft of lumber and 25 lb of nails; total cost per box, $30, of which $10 is for labor. Annual maintenance cost, including renewal of riffle blocks (life 2 yr) and lining boards, $1 000.

Ex No 5. North Bloomfield tunnel sluice, Cal (391). 30d nails used for the bottoms, 20d nails for the sides. Side lining was of worn blocks, 3 in thick and 18 to 20 in deep. Braces, 2 by 4 in by 2 ft. Block riffles, 20.5 in sq and 13 in deep, riffle strips, 1.25 by 3 in by 5 ft 11.5 in long; aver of 19 blocks per 12-ft box. A flume for seepage water (*F*, Fig 825), 13 in wide, 14 in deep, of 1.5-in plank, was built along one side of sluice.

Ex No 6. Bedrock Claim, Cal (391). Boxes, 14 ft long. Top rails, 2 by 7 in by 14 ft. 1 by 0.5-in tongues were set in grooves between bottom planks. Side lining composed of blocks 3 in thick by 20 in sq. Braces, 1.5 by 4 in by 2 ft. 27 blocks, 17 in sq by 13 in deep, used as riffles in 1 box; riffle strips, 1.25 by 3 in by 5 ft Cost per box, $30.86, as follows: 650 bd ft lumber and side lining @ $20 per M, $13; 704 bd ft blocks @ $14 per M, $9.86; 20 lb nails @ 5¢, $1; labor, $2 to $3 per day, $7.

Ex No 7. La Grange mine, Cal; sluice used in 1880 (391). Boxes, 16 ft long, with 4 by 6 in posts at ends. Top rails, 1.5 by 8 in by 16 ft; braces, 1 by 6 in by 3 ft; 36 blocks, 14 by 14 by 8 in, used in each box; riffle strips, 1.75 by 2 in by 4 ft, side lining, 1.5 by 8-in plank, 16 ft long. 420 bd ft of lumber required per 16-ft box, exclusive of riffles. 15 lb of nails used per box. Cost per box, $28.34, as follows: 420 ft lumber @ $30 per M, $12.60; 36 blocks @ 35¢ each, $12.60; 15 lb nails @ 4 1/4¢, $0 64; labor @ $1 to $2.50, $2.50.

Ex No 8 Lorenz mine, Trinity Co, Cal (415). 600 to 700 miner's in wash 500 cu yd in 10 hr. Posts, sills, and braces are bolted together; sills are mounted on skids running full length of box and beveled at each end. Boxes are moved over bedrock to new positions by teams. Block riffles are 11 in or 18 in sq by 10 in deep; riffle strips, 2 by 2 in. Cost per box, about $20.

Ex No 9. Union Hill mine, Trinity Co, Cal (415). Sluice is laid in an 8 by 8-ft tunnel, 1 300 ft long. Frames are of 1.5 by 6-in, 1.5 by 4-in, and 4 by 5-in pieces. Riffle blocks,12 in deep and 11 by 11 in to 18 by 18 in sq. Side liners of 2 by 10 and 2 by 6-in plank last about 3 yr. Riffle sticks 2 by 2 in by 5 ft. 500 bd ft of lumber used per box for frames, bottoms and sides; 525 bd ft for blocks. Cost per box: lumber, $16; blocks, $9, construction, $10.

Ex No 10. River Bend mine, Siskiyou Co, Cal (416). Sluice is at head of an hydraulic elevator. Frames are 4 ft c-c. 12 in sq blocks used for riffles, also rails and transverse angle-iron riffles.

Steel sluices are used chiefly at the head of hydraulic elevators (Art 126). They are tight, have low frictional resistance and are easily bolted together; their cost is prohibitive in most districts (tail sluices for dredges (Art 127) are an exception).

Curves should be avoided if possible; they increase friction and wear, reduce velocity of the water, and if sharp cause splashing. Sluices are curved by making small deflections at successive joints. Brigham (406) says a 5-in "swing" is the max permissible for a 12-ft box; for a sharper turn, use a 4-in swing on a 6-ft box, or 3.5-in on a 4-ft box. Curves should be eased at both ends, and outer edge of boxes elevated $^1/_8$ to $^3/_8$ in per ft of sluice width. Grade of sluice should be steepened at curves; an increase of 15% is desirable on short turns. Bowie (391) gives data on curves, relative to turn-in and turn-out sluices. These work well on steep grades, but require careful design on flat grades at connections with main sluice, otherwise gravel collects above or below the junction. Fig 827 shows a TURN-IN SLUICE, carrying 1 000–1 400 miner's in, adopted after many experiments. Radius of curvature, height of drop, width of opening at the junction, and grades as shown, were all at the limit on which the 2 sluices would run uniformly without depositing gravel. TURN-OUT SLUICES, generally used for "fanning out" a dump, are harder to operate on light grades than turn-in sluices.

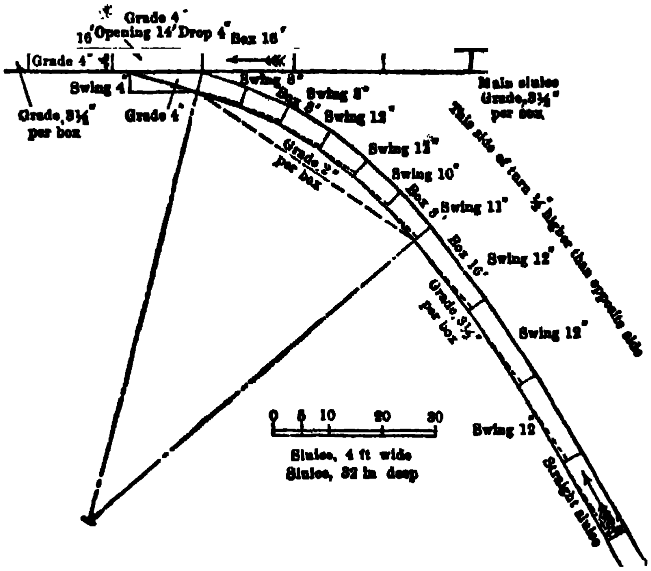

Fig 827. Turn-in Sluice at Head of Tunnel, Delaney Claim, Patricksville, Cal (after Bowie)

A 4-ft turnout was used at La Grange at a point where limited dumproom required sharp curves and grades were only 2.75–4 in per 16-ft box. Originally, the opening at point of divergence was 14 ft wide, with a 1.5-in drop between main and turn-out sluices, and the latter was swung 4 in per 16-ft box; it worked satisfactorily. On increasing the swing to 5 in, the boxes adjacent to the junction choked, and the discharge had to be widened to 24 ft. It was found here that, in a 200-ft swing on a 2% grade, the greatest possible swing per 16-ft box was 8 in for a 4-ft sluice; but the curve could be increased in proportion to the grade. At the turn-in and turn-out a board must be placed diagonally across main sluice, to concentrate discharge and prevent formation of bars.

Duplicate sluices are sometimes installed to avoid delays; one is cleaned-up while the the other is running; both usually empty into one tail sluice. In sluicing tin-bearing gravels, there may be enough concentrate to fill the riffles in a short time and require frequent clean-ups; in such cases, duplicate sluices allow continuous operation.

Bulkheads. Head end of a sluice for hydraulicking is usually flared out by building diverging bulkheads (wing dams) on each side; these aid in collecting gravel and water as they flow back from the face, and assist piping in fallen gravel.

H. L. Mead, in 1913, stated that the sluice mouth at La Grange, Cal, is 6 ft wide and 18 ft high; a heavy bulkhead of this height is built out from both sides. The giants generally work in pairs, first cutting down the bank and then swinging, following the fallen gravel toward the sluice and adding water to it; very heavy material may thus be washed into the sluice. The high bulkhead and high sides of sluice near its head allow gravel to build up and increase the grade; this, with the above method of washing, starts material down the sluice with a high veloc and increases its capac (395).

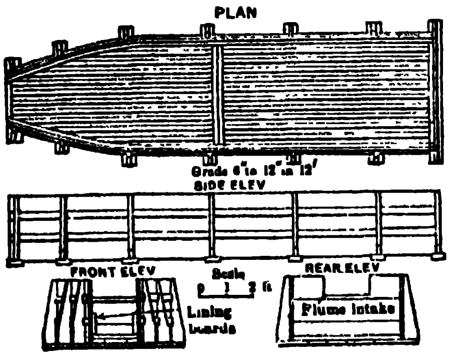

Fig 828. Mud Box or Dump Box (after Purington)

Mud box (Fig 828) has been used on small sluices in Alaska as a puddling or dump box; usually set at the sluice head; in late years it has become less common. In it, sticky clay and mud are broken up and large stones forked out; it may be installed for the latter purpose alone in shoveling-in, if sluice is too narrow to use a sluice fork effectively. Mud boxes have an apron 8 or 10 ft square at one side of the box, on a slope of 35 to 50°; gravel from cableway or derrick buckets, or from skips and power scrapers (Art 122), is dumped on the apron and slides into the box. Mud boxes are set on steeper grades (10 to 12 in per 12 ft) than sluices; they are paved with pole, block, or rail riffles, and collect much of the coarse gold. For sluices 12 to 16 in wide they vary in length from 16 to 24 ft and in width from 30 to 48 in.

Grade of sluices is usually expressed in terms of the fall in inches per box; if length of box is not given, it is understood to be 12 ft. Thus, a 5-in grade means a slope of 5 in per 12 ft. Grades should be uniform; flat sections control the capac of the whole sluice; riffles and linings in steep parts wear faster than others and the flow must be stopped for replacing them. For aver conditions, 6 to 7-in grades are satisfactory. If natural fall is not steep, grades as flat as 2.5 or 3 in per 12-ft box have been used for light gravel and earth. Flat grades reduce the duty of water (Art 123), limit max size of stones that can be sent through the sluice, and hence increase labor cost for handling boulders. Lack of grade may be compensated by increasing the amount of water. Grades over 13–14 in per 12 ft are rare, as higher veloc of flow carries away all but very coarse gold.

At Forest Hill, Cal, some sluices worked on grades of 10 to 24 in per 12 ft. Water was scarce and large stones had to be sluiced (391). See Table 112. Where the fall is unlimited, sluice grades depend largely on the kind of gravel; steep grades are required by coarse, flat, sub-angular, or cemented gravel, and when much clay is present. In general, grades may be flatter, and a larger duty is obtained with a given grade and vol of water, when sluicing a mixture of large and small gravel. In rolling or sliding along, stones stir up fines and keep them in suspension.

Length of sluices should be sufficient to disintegrate the gravel and free the gold. For loose gravel this is accomplished in 100–300 ft. Crude shoveling-in operations in Alaska often use only 3–6 boxes; lengths 36–72 ft (390). No attempt is made to save very fine gold. DROPS (vertical falls) may be installed (where topography allows) to break up cemented gravels and lessen sluice length. General practice is to lengthen a sluice so long as the yield from lower boxes exceeds cost of installing and operating them. Veloc of flow largely determines the minimum size of colors caught by riffles; hence, a greater length than needed to disintegrate the gravel is useless. Short sluices with drops and undercurrents (Art 125) are often more effic gold-savers than long sluices without them. Very long sluices may be needed to transport gravel to dumps; their lower parts are called TAIL-SLUICES. For examples see Tables 116, 117, 118 (notes), and under Cost and operating data, Art 123.

Cross-section of sluices is proportioned to amounts of water and gravel and to veloc of flow, which in turn depends on grade. For minimum first cost and wetted perimeter (hence for minimum frictional resistance and max discharge for a given cross-sec) the sluice width should be about twice the depth of stream, as in flumes (Sec 38, Art 15); it may be impossible to retain this ratio in large sluices. Depth of water should suffice to submerge the largest stones. Width of sluice is adjusted to depth and grade, for the required capac. Fine gravel containing fine gold should have very shallow, wide sluices, on steep grades (see Undercurrents, Art 125). The tendency for riffles to pack increases with depth of stream, which is usually 6–12 in.

W. A. Newman (618) gives accompanying data on aver Calif practice in medium gravel that could be washed at rate of 3 cu yd per miner's in per day; grade, 5–7 in per 12 ft; widths are inside of side boards, before inserting liners. To reduce first cost, and facilitate cleaning out and replacing riffles, the height of sides of a sluice should not exceed 1.3 to 1.5 times the depth of stream. For sluices in deep cuts in firm ground, sides may be lower than for those on or above the surface. If surface sluices clog and overflow, much of the gravel in them above point of overflow must be shoveled out (406).

Miner's inches of water	Width, in
200–300	24
400	30
600	36
1 000	40
1 500–2 000	48
3 000	60

Water required. Data given under Duty of water in hydraulicking, Art 123, are unsatisfactory, as the cutting capac of giant water may be greater or less than its sluicing capac, depending on character of gravel, grade and riffling of sluice, etc. Data in Tables 115, 116, 117 refer to duty of total water entering a hydraulic-mine sluice.

The water used in a small sluice for shoveling-in (Fig 823) is known as a "sluice-head," irrespective of its quantity; it varies from 30 to 60 (occasionally as much as 100) miner's in for sluices 10 to 14 in wide set on grades of 6–8 in per 12-ft box. In British colonies this term means a flow of 1 cu ft of water per sec (394).

Calculations of sluice grades, cross-sec, veloc of flow, etc, can not be made accurately, because the complex relationships between the factors are not wholly known, and few experiments have been made to determine the necessary empirical constants. Most authorities suggest some modification of Chezy's formula, Sec 38, as a basis. For examples see Bib (394, 388, 417).

The author's calculations of *n* in Kutter's formula (Sec 38), for a few sluices where all necessary data are available, show values from 0.027 to 0.04. Calculations should be checked against actual operations under similar conditions; Tables in Art 123, 124 are helpful. Geike gives the accompanying data on veloc of streams required to move materials of different sizes (418). Somewhat smaller velocities suffice for sluices.

Veloc, ft per min	
15	Begins to wear away fine clay
30	Just lifts fine sand
40	Carries sand as coarse as linseed
60	Moves fine gravel
120	Moves pebbles of 1 in diam
180	" " of egg size

Table 119. Capacity of Sluices

Sluice		Grade per 12-ft box, in	Miner's in of water	Bib No
Width, in	Height of side, in			
10 to 12	(*a*)	6	30	(286)
12 to 14	(*b*)	9	67	(286)
72	36	6 to 7	2 000 to 3 500	(391)
48	30	3	800 to 1 500	(391)
48	30	6	2 000	(391)
36	30	2.25	600 to 1 000	(391)
36	(*c*)	....	200 to 600	(406)
48	....	....	400 to 1 200	(406)
60	....	....	1 000 to 2 500	(406)
72	....	....	2 000 to 4 000	(406)
96	....	....	3 000 to 5 000	(406)
120	....	....	4 000 to 7 000	(406)

(*a*) Depth of flow, 6 to 7 in. (*b*) Depth of flow, 10 in. (*c*) Height of side, in this and following examples, is 0.5 to 0.75 width of sluice; depth of flow, 0.33 to 0.5 of clear inside depth of sluice. Duty of water (Art 123) must be known or assumed in designing a sluice for a given amount of gravel.

Van Wagenen (417) states that a veloc of 200 ft per min is necessary to move pebbles the size of an egg, 320 ft for stones of 3 to 4 in diam, 400 ft for boulders of 6 to 8 in diam, 600 ft for boulders 12 to 18 in diam. G. K. Gilbert's experiments on stream and flume traction are also suggestive, Bib (419).

Conversion factors for sluice calculations: Inches of fall per 12-ft box × 0.694 = % grade; inches per 16-ft box × 0.521 = % grade; fall in ft per mile × 0.027 = fall per 12-ft box, in; miner's in of water × 0.025 = cu ft per sec; cu yd of gravel per 24 hr × 0.000312 = cu ft of gravel per sec. If D = duty of 1 miner's in, in cu yd of gravel washed per 24 hr, and the flow of water and gravel is uniform, then $80 \div D$ = ratio between cu ft of water per sec and cu ft of gravel per sec.

125. RIFFLES, UNDERCURRENTS, AND OTHER GOLD-SAVING DEVICES

Riffles have 3 chief functions: (*a*) to retard material moving over them and give it a chance to settle; (*b*) to form pockets to retain gold which settles into them; (*c*) to form eddies which roughly classify the material in the riffle spaces. Their exact operation is not well understood. Strength and shape of eddies (the "boil" of the riffle) is affected by shape and spacing of riffles, their position with respect to direction of flow, and the veloc of current. The boil must be strong enough to prevent riffles from filling with heavy sand (packing), and not too strong to prevent lodgment of gold.

Features of design of riffles, especially for large-scale hydraulicking, are stated by Bouery (420) as follows: (*a*) They should oppose minimum resistance to flow, in order to get high duty from the water. (*b*) They should resist wear, to reduce cost of replacing and maintaining them, and to preserve their gold-saving capacity. Effect of wear on gold-saving should be considered in design and choice of material. (*c*) They should be sufficient in number to save all the gold commercially recoverable. The ultimate economy of a high-cost material, as manganese or nickel steel, compared with cheaper structural steel, may be determined thus: Let A and X represent maker's cost of 2 materials *a* and *b*, and B the cost of transport for either. Assume that the life of the cheaper material (*a*) is 1 year, that of the high-priced material (*b*) is N years. For equal costs at the end of N years, $X + B = N(A + B)$, or $X = N(A + B) - B$. If this equality exists, or if X is greater than $N(A + B) - B$, there is no economy in purchasing high-grade material. If X is less than $N(A + B) - B$, the economy of high-grade material increases approx with N. Good material saves indirectly also, by reducing unit cost of labor and interruptions due to replacing worn riffles (420).

Riffles for small sluices. Fig 829 shows forms commonly used for shoveling-in (Art 121). The pole riffle (*a*) is a favorite in Alaska for coarse gold; (*b*) is the same form made of sawed lumber; (*c*) transverse (or "Hungarian") riffle offers greater frictional resistance, clogs more easily, and costs more than (*a*), but is a better saver of fine gold. In a string of boxes, both types are commonly used. Small riffles are fastened by nails driven into them through sides of sluice; as the nails are not driven home, they are easily pulled when riffles are removed for clean-ups. Wedges may be used instead of nails, but are troublesome.

Riffles for hydraulicking are of many kinds; their importance demands description in detail. In recent practice, the usual types are steel-shod Hungarian and longit riffles.

Cobble or rock riffles (Fig 830) are cheap and resist wear well if of hard rock; their life averages about 5 times that of wood blocks (406). As the surface is rough, they require steeper grades than other riffles. They are well adapted to tail sluices which are cleaned up infrequently, as they are difficult to take up and relay.

Block riffles (Fig 831), where timber is cheap, are often the most economical form for the upper parts of sluices, as they are quickly taken up and replaced. They make a smooth pavement on which stones may roll or slide, and work well. The blocks are 8–12 in deep, set in transverse rows separated by "riffle strips," and are square so that when worn they may be turned to give the smoothest surface; side of the square is an even divisor of sluice width. It is usual to set blocks in adjacent rows to break joints, because longit cracks enlarge quickly and force earlier renewals. At a few mines, better gold recovery is claimed for a pavement in which joints are broken as above, but longit spaces are also left between the blocks of each row (390).

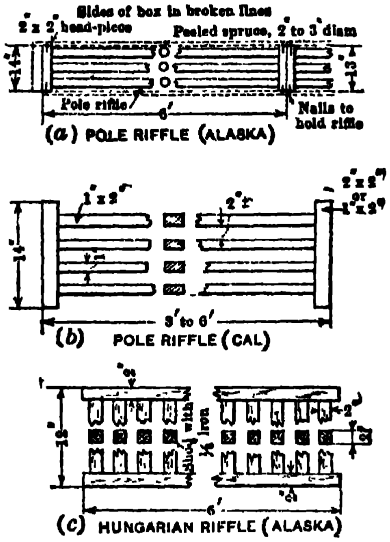

Fig 829. Riffles for Small Sluices

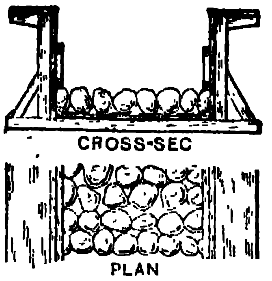

Fig 830.‾ Cobble Riffles

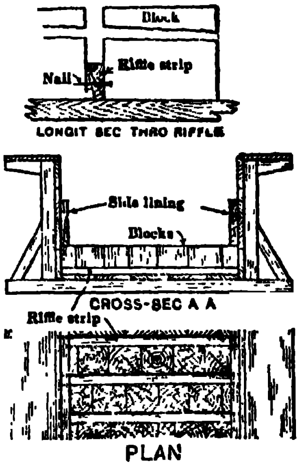

Fig 831. Block Riffles

Blocks are held in place by the side lining and riffle strips. Each strip is nailed to a row of blocks with headless wire nails, which are not driven home but project from 0.5 to 0.75 in. The adjacent blocks are driven against these nails until they rest solidly against the riffle strip. For dimensions, see examples following Table 118.

The objection to block riffles is their rapid wear under heavy service; their life depends on quality of wood, sluice grade, character and quantity of gravel, and amount of water. Long-grained wood, which "brooms up," is best; hard wood is not desirable. On a given grade, the larger the ratio of water to gravel, the less the wear (391). Blocks worn to a thickness of 4 or 5 in are discarded, or used for lining the sides of sluices. Bowie gives accompanying data from early California mines (391).

Locality	Width of sluice, ft	Grade, in per 12 ft	Depth of blocks, in	Life of blocks, in-days of water
North Bloomfield	6	6.5	13	175 000–200 000
Manzanita mine.	5	7.0	13	100 000–150 000
La Grange. . . .	4	3.0	8	100 000–110 000

At Manzanita mine, and also at French Corral mine where similar figures were obtained, poorer timber was used for blocks than at North Bloomfield. P. Bouery, in 1913 (420), states that in 6-ft sluices at La Grange the life of 13-in blocks was 45 days to 3 mo; those in the higher boxes lasted longest. On increasing the duty of water 40%, the life of blocks decreased 60%, so that a clean-up was necessary every 17 days. Consequent delay and expense, and limited supply of pine blocks, led to use of manganese-steel riffles (Fig 836).

Longitudinal rail riffles (Fig 832) are of 20 to 40-lb RR rails, in lengths to 20 ft, usually set upside down and spaced 3 to 5 in or more apart by wooden or C-I spacers. On a given grade, rails will run as much fines and more boulders than blocks (406); they are largely used in the upper boxes of sluices, as they wear fairly well and are easily taken up.

Transverse rail riffles. Bouery's experiments at La Grange, Cal (see under Block riffles), published in 1913 (420), give valuable data on riffles for large hydraulic sluices: La Grange sluice is 6 ft wide, on a grade of 7 to 8 in per 12 ft; depth of water, 12 to 18 in.

Experiment showed that transverse were superior to longit riffles. A rock or a sand particle may remain in contact with and wear the web, flange or head of a longit rail throughout its entire length, but wears only the top of a transverse rail. Longit rails 8 in apart wore faster than those spaced 5 in. 40-lb longit rails, spaced 5 in, were discarded after passing 9 600 000 miner's in-days of water; 40-lb transverse rails, spaced 5 in, passed 14 400 000 miner's in. 5-in spacing (c to c) proved best; different spacing might be advantageous for other grades or depths of water, but Bouery puts the economic interval between 4 and 6 in; spacing less than 4 in increases first cost; spacing greater than 6 in interferes with free passage of boulders. 45-lb rail was selected for the first experiment; 16 and 25-lb rail were considered too light; 55-lb rail had too large a web and flange in proportion to its head; 40-lb rail was finally found to be the most economical. Rails were set on a series of 2 by 6-in wooden riffles, separated by blocks (Fig 833); rails alone do not form sufficiently deep pockets, and they allow eddies which wear the sluice bottom. This system proved much more efficient for catching gold than the previous block riffles, and the gravel never packed hard between the rails. 7 spacing blocks had to be set between each pair of rails (Fig 834). Wear is greater in center than at sides of sluice, and rails bend before wearing out, unless rigidly supported. By using 7 spacing blocks, rails could be used until they were 62.5% worn. instead of 37.5%, as was the case with 3 or 4 spacers. Ends of worn rails, utilized to protect the sides of sluices (Fig 835), were held in place by nails bent over the flange of top rail, and by a 2 by 6-in plank. Side rails did not increase the duty of water materially, but decreased cost of replacing the blocks formerly used; they last 5–7 years; duty, about 30 million cu yd of gravel.

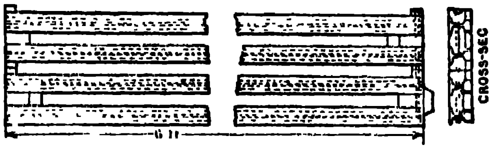

Fig 832. Longitudinal Rail Riffles (after Purington)

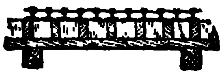

Fig 833

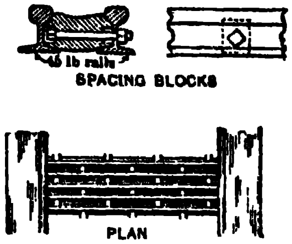

Fig 834. Transverse Rail Riffle, La Grange, Cal

Further experiments, with cast and alloy steels, showed manganese steel to be the most economical. Many forms of riffle were developed, aiming to lengthen their life and to utilize worn rails. Fig 836 shows a manganese-steel riffle considered by Bouery to have all the requisite qualities, viz: high gold-saving capac, slow wear, good setting, rigidity, and security against theft of gold. Some of them passed 52 800 000 miner's in-days of water and from 12–15 million cu yd of gravel before they were discarded. For further data, see Distribution of gold in sluices, and Bib (420).

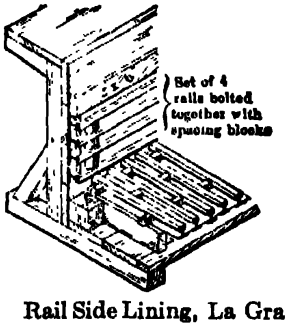

Fig 835. Rail Side Lining, La Grange, Cal

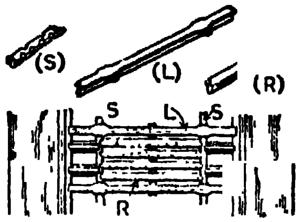

Fig 836. , Bouery Manganese-steel Riffle

Wooden Hungarian riffles, shod with iron straps, similar to Fig 829, *c*, but made of 2 by 4-in or larger scantlings, may be used where rails are not available. They resemble rail riffles in respect of gold-saving, but have shorter life and are less convenient.

Angle-iron riffles (the Evans riffle) are of the Hungarian type. They have been used chiefly in hydraulic elevator sluices (Art 126), on tables and tail sluices of dredges (Art 127) and sometimes for small open-cut work (Table 113) and hydraulicking. Size of angles varies from 1.5 by 1.5 by 1/4 in for small-sized material, up to 2.5 by 2 5 by 3/8 in. Fig 837 shows one method of holding angles in place. They are set with the vertical leg on the upstream side; clear space between them, 0.25 to 3 in. Close spacing gives a weak eddy and the "dead water" space is said to be a good fine-gold saver, assuming that the current velocity allows such gold to settle on the riffles. T-iron may be used instead of angles.

C-I grate riffle (Fig 838) has worked well in small sluices on Seward Peninsula, Alaska. It is light, easily handled, and can be set so that the long dimension of slots is either transverse or longit; the latter setting is thought best (390).

High-carbon steel plates have effected important economies at several large mines, where used as riffles and as linings for tail-sluices. They reduce friction, compared with wood block or other pavements, and are especially useful on limited grades. The steel contains 0.8–1.2% carbon; in some cases it is found that the outside skin of the plate is more resistant to wear than the interior. Plates are commonly 0.5 in thick, of same width as sluice and of various lengths. Fig 839 shows modes of supporting plates 12 ft long. A 2-in space and a 0 5-in drop is left at end of each plate. Supports *T* are 6 to 8-in logs, 12 ft long, sawed flat on 2 sides and tapered from 3.5 in at upper end to 4 in at downstream end. Plates are held down by 3 by 10-in lining boards. This made a good riffle and increased the sluice capacity about 40%; angular blasted boulders 30 in long could be sluiced, as against 20-in pieces with block riffle (412). At Waldo, Oregon, plates 20 by 30 in were set on 2 by 4-in cross joists; the plates were 1.5 in apart; no drop was used (422). The Quesnelle Co, B C, used plates 58 in sq in a 6-ft sluice, separated

by a 2-in space and a 0.5-in drop. A number of boxes at head of sluice were paved with manganese-steel rail riffles which extracted most of the gold (421). Table 120, from Gardner and Johnson (17), gives data on riffles installed in the same sluices (correspondingly numbered) as those for which other data are found in Table 116; lengths are stated only for longit riffles; width of sluice fixes length of cross-riffles.

For further data on riffles for fine material, see Undercurrents below, and Dredging (Art 127).

Side linings are required to protect the sides of large sluices; also they often furnish a means of holding riffles in place. Plank liners are common (Fig 831), 1-in for smaller sluices, 2 to 3-in for wide sluices with a high head of water. Where block riffles are used, worn blocks are placed on the sides; they serve for tail sluices, but are inconvenient where frequent clean-ups are necessary. See Fig 835 for rail linings. Height of side linings need not be more than 2 or 3 in above normal level of the stream of water and gravel.

Fig 840. North Bloomfield Undercurrent (after Bowie)

Undercurrents are intended to save fine gold which will not settle in the sluice. Fig 840 shows the North Bloomfield undercurrent, fairly typical for large Calif sluices; it is a wide sluice, set on a heavy grade at one side of and below main sluice.

Bowie gives following details: Across the main sluice, at some point where a drop can be made, is placed a grizzly, over which coarse material and some water passes; the undersize falls into a spill box and runs thence through a distributing sluice (grade 2–3%) to the undercurrent proper. The latter is a shallow box, 20 to 50 ft wide and 40–50 ft long, divided into sections by vert partitions for convenience in placing riffles and cleaning-up, and to allow better control of the distribution of material. Undercurrents are paved with small wooden blocks, cobbles, or pole riffles shod with iron; grades required for these riffles are 14, 16 and 12 in per 12 ft, respectively. Depending on location of the undercurrent, its tailing and water are discharged directly or led back to the main sluice, which extends below the drop at which undercurrent is erected. Width of undercurrent, 8 to 10 × width of main sluice. A wide undercurrent costs slightly more to clean up than a narrow one, but is often more effic; at French Corral, with a 5-ft sluice, yield of first undercurrent (20 ft wide) was 20% of yield of all; 10 ft added width increased yield to 27% of total (391).

Modern undercurrents of this general type vary widely in detail. Grizzlies in sluices 20–36 in wide are made of 8 to 12-lb rail, 0.75-in round or octagonal steel, or steel flats; spaces between members, 0.25–1 in. In large sluices, grizzlies are usually of V-shaped steel bars, either stationary or so supported that they will rock under the impact of boulders; rails are also used; openings vary in width to 2 in. Space occupied by grizzly is full width of sluice bottom; its length in direction of flow ranges from a few to 18 in, usually found by trial. Grizzly bars transverse to sluice remove sand with less loss of water than longit bars. Grizzlies are placed on grades which may be flatter or steeper than the sluice grade. Any device that will slow up the current just ahead of a grizzly is desirable, as it gives sand and gravel a chance to settle and pass to the undercurrent.

Fig 841. Undercurrent (after Ellis)

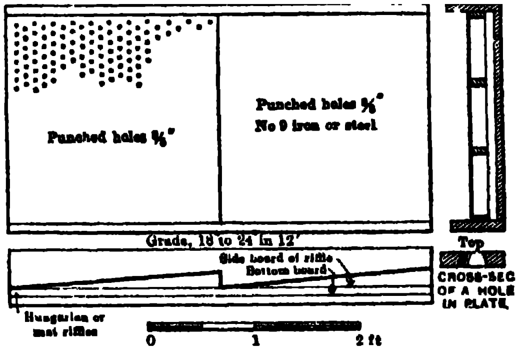

Fig 842. Caribou Undercurrent (after Purington)

Hungarian riffles of small angle iron, or of wood shod with iron, are also used for undercurrents. For saving very fine gold, carpet tufted with chicken wire, cocoa matting with expanded metal, and burlap tables, are employed at different mines. The ideal location for the form of undercurrent in Fig 840 is near the dump, so that large material need not be conducted far below the grizzly. This is not always feasible, and several other undercurrents are often built at intervals along a sluice. A min fall of about 5 ft is required where the undercurrent water returns to the sluice; the sluice grade can therefore be steepened from the grizzly to the point at which undercurrent water reenters. For further detail, see Bib (390, 391, 406, 394, 423, 424). Though the above undercurrents remove large quantities of water from main sluice, some sand and gold pass over the grizzly with oversize. In small sluices, these difficulties are partly overcome by a different type of undercurrent. Fig 841 shows an undercurrent introduced at Fairbanks, Alaska, in 1914. It greatly increased the saving of fine gold, as compared with the old type, but it was necessary to clean up the boxes every 2 days, since its effic decreased greatly thereafter. Two boxes of a string (passing a max of 150 cu yd of gravel per day) were fitted with this device; one was cleaned up each day, the blanket or cocoa matting being washed in a tub. On a claim where much fine gold was present, this undercurrent recovered 20% of the entire clean-up, and changed an operating loss into a profit (414). Fig 842 is a modified Caribou riffle or undercurrent regarding which Purington says (390): Hungarian riffles of wood or iron, carpets, plush or blankets, are placed in the sluice bottom under the screen, depending on character of the fine gold. This device affords cheapness, flexibility, and simplicity, but will not give good results with unpuddled clayey gravel. Experiments with punched plates in New Zealand showed that holes less than $^3/_8$-in diam give too small a discharge and are apt to choke; $^7/_{16}$-in holes passed too much water and material. These results were obtained in treating marine gravel containing fine shingle (425). Proper size of holes in any locality is a matter of experiment. On Snake River, Idaho, a different form of Caribou riffle and undercurrent has been used, in which the heaviest concentrates are drawn off continuously through holes in sluice bottom. This allows collection of black sand containing valuable minerals other than gold which require further treatment (426).

Bulowat Syndicate, New Guinea (458) in 1938 was working an alluvial deposit 12–30 ft deep, resting on clay and having $^2/_3$ of its gold close thereto. Gold particles are flat, and $^3/_4$ of output is of pin-head size. Deposit is ground-sluiced with 30 cu ft per sec (1 200 miner's in) of bank water at 300–700 cu yd per day, by 90 natives on 2 shifts. Sluice, 48 in wide, grade 0.6 in per ft, has 30 ft of angle-iron cross riffles spaced 3 in, and 50 ft of small riffles 0.75 in apart. Next 10 ft of sluice has $^3/_8$-in slots from side to side, spaced 3 in, followed by 20 ft of $^3/_8$-in plate drilled with 0.75-in holes on 1-in centers. These apertures drop about half the water to undercurrents, which are in duplicate, one on each side. Each is 30 ft wide by 15 ft long, composed of 15 tables 2 ft wide, sloping 0.125 in per ft. Riffles are wood, 1 by 1 in, set 1 in apart. Flow over the undercurrent is 4 ft per sec, compared with 9 ft per sec in the sluice. Use of undercurrent adds 25–30% to recovery of gold under the existing conditions.

Operators disagree as to the use and value of undercurrents. Where the gold is fine the weight of evidence is in their favor, if they are properly designed and cleaned up often enough to do effic work. At La Grange, Cal, after riffles like those in Fig 836 had been installed, undercurrents were discarded, as they clogged and the gold recovered did not pay cost of cleaning up (420). Of 39 placer mines in western U S described in (17) as operating in 1932, only 10 had undercurrents, and some were of doubtful advantage.

Use of mercury in riffles and undercurrents is quite general; amalgam is easier to handle in clean-ups than fine gold; some gold, otherwise lost, is always saved by amalgamation. Where much coarse gold occurs, mercury is omitted in a few boxes at the head of the sluice, to avoid the trouble and cost of retorting coarse gold amalgam.

When Hg is used, sluicing begins with a small head of water, until all cracks and leaks are stopped. The water is then shut off and riffles in upper part of sluice and undercurrents are charged with Hg. More is added from time to time, as needed to keep a clean surface of Hg exposed. Amounts of Hg vary; a common initial charge for large sluices is 2 to 3 flasks (76.5 lb each); for large undercurrents, 80 to 160 lb. Mercury must be clean and in charging all splashing or spattering should be avoided; otherwise minute globules are formed which float away. Loss of Hg is inevitable; it varies from 4 or 5% of the total amount used to 30% under poor conditions, averaging perhaps 10 to 15%; loss is least in well built, long sluices, provided with undercurrents (391, 394).

Cleaning-up consists in removing the riffles and collecting gold and amalgam. Interval between clean-ups is made as long as possible, to reduce the delay they cause; often the lower parts of a sluice are cleaned up only once in a season. Clean-ups are required when worn riffles must be replaced, and when much gold has collected, as in the first few boxes of a sluice handling rich gravel; danger of theft often influences frequency of clean-ups. Cleaning-up begins at the sluice head, by removing a few riffles and turning in a small flow of water. The concentrates are worked over with shovels or scoops; as they wash slowly down the sluice bottom, the gold and amalgam lags behind the black sand, etc, and is scooped up into pans or buckets. The process is repeated in next lower section. See Bib (17, 414, 391, 398).

Distribution of gold in sluices. Most gold is caught near the sluice head. Bowie estimates that an aver of 80% of total yield of large sluices is recovered in first 200 ft of length, according to results at several early Calif mines (391). In Alaskan shoveling-in or small open-cut work, the dump box and first 3 or 4 boxes below it retain most of the gold. Distribution depends upon nature of gravel, shape and size of gold, and amount of clay.

Table 121 shows results of experiments by Bouery, at La Grange, Cal, in 1910, to determine the distribution of gold of different sizes; the tests lasted 15 days (420). Value of the amalgam, \$13.50 per oz in the head boxes to \$6 in box 136. Head boxes did not show the highest saving, as they were often blocked by boulders and sand (Bulkheads, Art 124). Such experiments permit accurate determination of the point beyond which the gold recovered does not repay construction and maintenance of added sluice length.

Table 121. Distribution of Gold in Sluice Boxes, La Grange, Cal

Loss of gold in sluices can not be accurately determined. The gold content of gravel treated is not known exactly, and there is no way to sample it or the sluice tailing during operation. In large low-grade placers, as at Oroville, Cal, ample opportunity is afforded to compare aver values computed from churn-drill exploration with actual recoveries on dredges, and empirical factors have been developed for discounting churn-drill samples. Such factors represent a combination of errors in sampling and losses in gold-saving apparatus, and can not be used in other localities. Drill and shaft samples in rich Alaskan creek placers often give results widely different from recoveries obtained later by hydraulicking or simple open-cut methods (447) (Sec 25).

Purington estimates that Alaskan shoveling-in recovers 80–90% of total gold (390). Different authorities place recovery with ordinary sluices and undercurrents at 60–85%; it must vary with character of gold, as well as that of the gold-saving devices.

Sluices act as runways for material ranging from large stones to find sand. Veloc of current must suffice to sweep the coarse material along. Gold is separated from other heavy concentrate by the classifying action of irregular eddies set up by riffles; a strong "boil" is required to prevent riffles from packing. These conditions, combined with an irregular flow of water in hydraulicking and intermittent clean-ups, are not conducive to saving fine flaky or spongy gold and are responsible for losses. Undercurrents reduce this loss, if properly cared for, but no known device will force all of the fines to pass through a stationary grizzly on sluice bottom and leave enough water to carry on the oversize. Nearly all placers worked on a large scale have a very low gold content, and in spite of losses these simple gold-saving devices probably make nearly the max profit, in view of any recovery obtainable. This discussion does not apply to small gravel containing very fine gold only (as on the Snake River, Idaho, and in certain beach sands), nor to gravels containing valuable minerals besides metallic gold, which present problems still unsolved. Bib (390, 427, 424, 382).

126. ELEVATORS

Elevators of several types are employed to secure artificial dumproom at placers lacking natural facilities for disposal of tailing, and where conditions prohibit dredging.

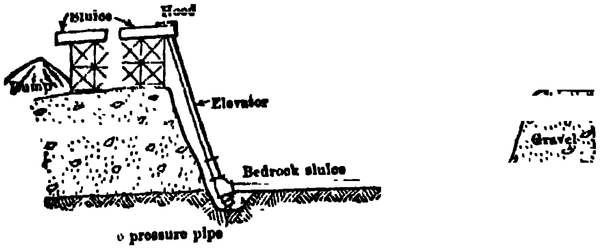

Fig 843. Elevator Pit (diagrammatic vert sec)

Hydraulic elevators (Fig 843, 844) were formerly used widely; at present, they are found mainly in isolated places where more effic power equipment can not be applied. The excavated gravel, with the giant water and seepage, is conducted in ground- or box-sluices to the foot of elevator, which delivers it to a sluice on surface leading to the dump (385, 394, 390, 397). The surface sluice is usually short, with or without undercurrents. FIELD OF USE is in flat placers lacking sluice grades and dumproom, but having ample cheap water under pressure. Depths of gravel range from a few ft to 90 ft; depths of 20–25 ft are favorable, as they allow much gravel to be mined from 1 set-up of elevator, without excessive lift. Boulders (or buried stumps and timber) too large to pass through the elevator increase operating cost, as they must be blasted or handled by derricks; if too numerous, they may prohibit elevator work. The elevator is inefficient and wasteful, but useful where necessary water is available.

Elevator CONSTRUCTION and OPERATION are shown by Fig 844. For dimensions, weights, and capacities, see makers' catalogues.

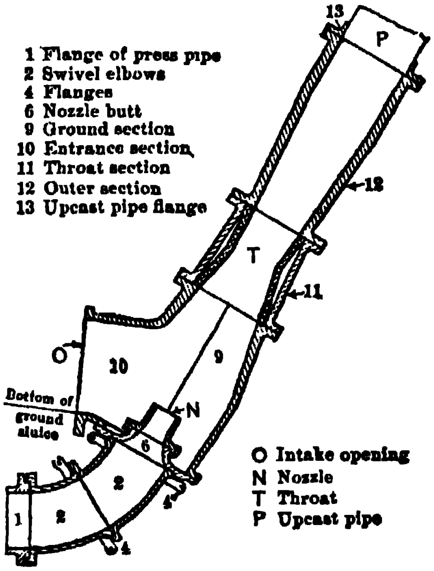

Fig 844. Hendy Hydraulic Elevator

Water under press is discharged upwards through nozzle N; in passing through the throat area, T, it sucks in water, gravel, and air through intake opening O. The force of the jet elevates the aërated column of water and gravel through upcast pipe P, the upper end of which projects through bottom of first box of the surface sluice. To prevent spattering, this box is covered and is provided with a liner ("hood") which diverts the discharge laterally. The hood and throat take the most severe wear, and are usually of manganese steel; special steels may be used for other parts. The upcast may be a riveted or welded steel pipe, with slip or flanged joints, depending chiefly on height of lift. Evans elevator has an auxiliary suction opening on each side of the main intake, to allow air to enter the elevator if main intake clogs; suction openings may also be extended by pipes to low places on bedrock and used to suck out seepage water. The SUMP at foot of elevator is usually 10 or 15 ft sq and about 4 ft deep (385). Bedrock sluices may dump into the sump, or directly into the elevator intake; latter plan is best, as the suction head should be small. The UPCAST usually has a slope of 60°–70°; makers of the Evans elevator state that it works best at 80°. Elevators are sometimes set vertically, or on slopes as flat as 42° (394).

Water required. The elevator nozzle water will lift from 0.5 to 1 × its own vol of outside water. Hence, 50–66% of the pressure water available is assigned to the elevator, and the rest to the giants; the higher figure is conservative (note experience at Swaziland, below). Distribution of water between elevator and giants is controlled by size of nozzles used on each (see Flow through nozzles, Art 123).

Max height of lift for economical operation is about 17% of the effective head at elevator nozzle. High heads are proportionately more effective than low ones; the lift is also affected by size of gravel and slope of upcast (394). Ordinary range of lift is 10–20% of the head on the nozzle water. Higher lifts may be overcome by compound or step-lift elevators; 33% of the press water is then used in the bottom lift and 67% in the upper, which has a larger upcast. This requires abundant water supply, but approx doubles the lift obtainable with a single elevator. With cheap elec power or fuel supply, the natural press of the elevator nozzle water can also be boosted by stage centrifugal pumps. These devices are rarely used. MAX SIZE OF GRAVEL depends on the throat diam. To prevent serious clogs, a grizzly is necessary in the bedrock sluice; its bars are spaced at least 1 in closer than the throat diam.

Capacity of elevators. The gravel forms at most 5% (usually 2–3%) of the total wt lifted; hence, in estimating capacities, only the water needs to be considered.

There are no exact rules; the capac in a given case varies with the ratio of pressure head to lift, the effective head and vol, regularity of flow of gravel and water to the elevator, and also with the giant-water duty. The latter is a major factor in determining size of elevator. If there is much seepage water, which reduces the capac available for elevating giant water, a WATER LIFTER (practically a small elevator, with a suction pipe instead of an open intake) is often installed to drain the pit.

Efficiency of an elevator is expressed by: $E = H(62.4W + S) \div 62.4N(H_1 - H)$, where E = % effic; H = height of lift, ft; H_1 = effective head at nozzle; W = cu ft per min of giant, seepage, and bank water; S = wt of gravel elevated per min (placer gravel normally weighs about 3 000 lb per cu yd); N = water discharged through elevator nozzle, cu ft per min (397). Effic is usually only 10–20%. Longridge cites 12 elevators in N Z, operating on lifts of 13–67 ft with water under heads of 200–448 ft, the effic of which (omitting wt of gravel) was 20–33% (394).

Wild Goose Mining Co, Ophir Cr, Council District, Alaska. Data in Table 122, contributed by W. H. Lanagan and C. H. Munro, are retained from previous edn of this book, as representing former large-scale work in Alaska. For further detail, see 2nd edn, pp 924–926. Subsequent work of that kind on Ophir Cr has been in gravel 4–10 ft deep lying mostly on slabby limestone, irregular and difficult to clean (188). Such mining has been conducted only during those parts of the working season when men and water could be spared from the Co's dredges. From 1918 to 1921 incl, a total of 96 885 cu yd was worked by elevators at aver cost of 31.3¢ per yd, excluding deprec and management, but including proportionate share of ditch maintenance. In 1919 only 11 050 cu yd could be handled, at 73¢ per yd; in the other 3 yr, the range was 21.8–29.6¢ per yd.

Little Creek, Nome, Alaska. Data from N. L. Wimmler (188) in 1927. Former large operations using elevators are now being dredged. Deposits 15–40 ft deep of medium-sized gravel containing much clay, frozen and covered with moss and muck; latter, together with 2–10 ft of barren gravel, was first removed (often elevated) by giants.

Until 1923, during each season (June 10–Oct 15) elevator mining was usually conducted in 4 pits at a time, each having a final area of 3–5 acres. Total output per season, 350 000–550 000 cu yd, or 1 000–1 500 cu yd per day from each pit. Crew for each pit, 10–15 men with 2–4 horses, working 2 11-hr shifts. Water, 750–1 000 miner's inches under 290- to 310-ft head, supplied 2 giants (3–3.5-in nozzles) and an elevator for each pit. Elevator lifts were 30–55 ft; nozzles, 4.5 in for lifts to 40 ft, larger for higher lifts; usual water consumed, 450–550 in. Tailings were stacked at intervals by a 3-in giant; boulders were hauled on stoneboats. Head box, 12 ft long, 4 ft wide, had drop of 5 in; other boxes, to total length of 150–180 ft, were of steel, 8 ft long, 4 ft wide, at grade of 0.5–0.6 in per ft; usual riffles were angles and longit 16-lb rail. Sinking of pit through gravel and 8–10 ft into bedrock, and installing elevator, took 4 days. Usual life of replaceable manganese-steel throat on elevator, about 3 mo, or 100 000 cu yd. In 1921, 4 pits yielded 550 000 cu yd at working cost of 35¢ per yd, incl 3.5¢ for ditch maintenance. Aver duty (for all water) was 1–1.25 cu yd in frozen, or 1.25–1.75 cu yd in partly frozen ground.

Inmachuck River, Alaska. Data from N. L. Wimmler (188) in 1927. Frozen deposit 20–25 ft deep, of which about half was muck, removed in advance. Elevator with 9-in throat, 4-in nozzle, 37-ft lift, under 350-ft head, handled washings from 2 or 3 giants with 3-in nozzles; stacker giant was also needed. Crew: 6 men on day (10-hr) and 3 men on night shift; 6 men on ditch. In 64 days of 1924, a pit 315 by 460 ft cost 17.2¢ per sq ft, delivering 53 000 cu yd of gravel and bedrock at 47¢ per cu yd. Aver season, 85–90 days.

Swaziland, So Af; data from J. J. Garrard in 1917 (397). Tin-bearing gravels, averaging about 18 ft deep, have been worked. Records for 12 months' operation in 1913 show that 4 elevators, with an aver lift of 23.3 ft, took an aver of 73% of the water available, leaving 27% for the giants. Best month's work showed 60% elevator to 40% giant water; the worst, 84% elevator to 16% giant water, effic of elevator, 16 58%. As the water supply was ample, its inefficient use was allowable.

Box elevator. Knox and Haley (385) describe a home-made elevator used successfully by the North Fork Salmon River Mining Co, Cal. It consisted of a steel-lined box about 18 in sq, sloping about 50°, with a 5-in jet at the bottom and 0.5-in steel striking-plate at the top, immediately over the sluice. Height of lift, 30 ft; operating head, 250 ft. Water supply was excellent; about 700 miner's in were required for elevator. Boulders to 11 or 12 in diam were handled; there was no throat, everything being lifted directly by the jet. Capac, about 1 000 yd per day.

Ruble or grizzly elevator consists of a chute inclined at about 17° and having a 10-ft aprôn to make connection with bedrock. The apron fits closely between the walls of the main chute, which is 60–90 ft long. The chute and apron are lined with 0.25-in steel side and $^{3}/_{8}$-in bottom plates. Chute is about 8 ft wide, its walls tapering from 12 ft high at the bottom to about 4 ft at the top. For the first 20 ft of the incline, the bottom is solid; remainder of incline is bottomed with transverse grizzly bars, 2.5 in apart, made of 2 by 6-in timbers covered with 0.5-in steel straps. Underneath the grizzly is a steel-lined false bottom, sloping from upper end of elevator to a sluice box, set at right-angles to elevator and directly under lower end of grizzly. The sluice, about 60 ft long and supported on light trestles, is paved with Hungarian and pole riffles, consisting of 2 by 4-in timbers shod with steel. The elevator is supported on 3 heavy stringers resting on trestle bents, which are mounted in turn on skids. It is moved by winch and cable.

Operation: The elevator giant is alined with the center line of the elevator and about 80 ft away from it. Wings, about 10 ft high and lined with scrap timber, are built out on each side, 1 wing extending to the bank; they are supported on portable frames. The cutting giant works behind the elevator giant and drives the fallen gravel along the bank to the elevator wing, where it is picked up by the elevator giant and washed in small quantities at a time up the solid portion of the incline. Care is taken to "boil out" the fines over the lower portion of the grizzly; otherwise, gold would be washed over the elevator top. When heavy stones are clean, they are washed up and over upper end of the incline. The fine tailing is piped from end of sluice by the elevator giant about once an hour. An extra tailing giant may be set up for stacking tailings when the water is not being used by other giants. When the boulder dump reaches the end of grizzly, a platform is laid on it extending outward and upward from the elevator. Thus the dump can be piled much higher than the elevator itself. These tailings are piped down periodically by the tailing giant. If the water pressure is high, a large amount of material can be worked with 1 set-up of the elevator, but the elevator must be moved to a new position when the driving limit of the cutting giant is reached, or dump room is exhausted; 5 or 6 days are required per move. This delay can be obviated only by using 2 or 3 elevators, and changing the water from one to another. At one property, such an elevator used 600–1 200 in of water under 450-ft head. The gravel was heavy, with nests of boulders weighing 1–5 tons; depth of bank, 20–25 ft. Capac of the elevator, 1 000–2 000 cu yd per 24 hr; 100 000 cu yd of gravel were washed in 4 months; total operating cost, including ditch maintenance, 6¢ per cu yd. First cost of elevator, $3 400; the mine was 90 miles from a railway. For further details, see Bib (385, 453). Two other examples follow.

Redding Creek, Douglas City, Cal. Data from Gardner and Johnson (17) in 1934. Deposit of stream gravel about 9 ft deep and 120 ft wide; insufficient natural grade for sluices (0.83%) required use of Ruble elevator. Water under 300-ft head came through 3 000 ft of 24-in pipe and supplied (through 15-in pipes) 2 giants with 5-in nozzles; one cut and swept gravel to foot of Ruble, the other driving oversize up the slope. A third giant, with 3-in nozzle, leveled off tailings pile at intervals. Ruble was 8 ft wide, 60 ft long, with lift of 25 ft; grizzly bars (iron-clad, 3 by 6-in plank laid on edge, crosswise) were spaced 2 in apart. Sluice, receiving undersize and most of the water, was 48 in wide, 48 ft long (see Ex 3, Tables 116, 120). Shallowness of gravel required Ruble and sluice to be moved 3 times during 105-day season of 1932; each move took a week for 7 men and a caterpillar tractor. Boulders were bulldozed, consuming 2 000 lb of 40% gelatin in season. For other data, see Table 117, Col I; cost of 19¢ per yd did not include ditch work, construction, interest, deprec, or amortization.

Gallia mine, Sawyer Bar, Cal, illustrates combination of Ruble elevator for discharging coarse tailings, and hydraulic elevator for fine. Data from Gardner and Johnson (17) in 1934. Gravel, 33 ft deep, contained 10% of boulders over 12 in; bedrock fairly even. Water at 265-ft head, through 2 000 ft of 36- to 15-in pipe, supplied a 3.5 or 4-in giant in pit, a 4.5-in giant at Ruble, and an elevator with 20-in intake, 30-ft lift, and 4-in nozzle. Pit giant worked intermittently, to avoid congesting the Ruble; other giant and elevator worked continuously. Ruble, 4 ft wide, elevating 25 ft, had grizzly of 90-lb rails, spaced 2.5 in, and set lengthwise. Sluice from Ruble to elevator was 120 ft long, 24 in wide, grade 4.5 in per box, and riffled with 2 by 2-in angles and longit rails. Ruble had to be moved every 3 weeks to gain dumproom, taking a week's time of 3 men. Boulders too large to go up Ruble were moved by derrick; those uncovered in cutting, by donkey engine. In 60 days of 1932 (incl moving of Ruble), crew of 3 men on each of 2 12-hr shifts treated 12 000 cu yd at cost of 17¢ per yd; pit giant could move 50–60 cu yd per hr.

Advantages of the Ruble elevator: low first cost, the fact that it can be made on the ground, and its capacity for handling heavy boulders. It is adapted to flat placers unsuitable for dredging, less than 50 ft deep, where water is available for hydraulicking. It is not suited to rough or very uneven bedrock, owing to difficulty in moving.

Use of giants for stacking tailing is possible where dumproom is ample in area but deficient in grade, and where the water will run off by gravity (406). The North Columbia Gold Mining Co, Atlin, B C, stacked coarser tailing to heights of 25 and 35 ft with giants working under heads of 110 and 140 ft (411). Where this device is used, the stacking giant can often be operated intermittently. See Bib (415).

Ellis describes an INCLINED SLUICE used in connection with giants in California, Oregon, and in Alaska for stacking tailing at the end of a sluice. On Mastodon Cr, Circle, Alaska, a 9-ft gravel bank was hydraulicked with 2 No 1 giants into a sluice delivering tailing to a sump. From this the tailing was easily driven up an inclined sluice to a height of 35 ft. A No 2 giant under a head of 100 ft was used for stacking; duty of the total water for hydraulicking and stacking was 2.5 cu yd per miner's in per 20 hr. Fairly heavy slabs of bedrock were raised by the giant. It is stated that this device used less water than would be required by an hydraulic elevator, and that it is better suited than the latter for small installations (413). INCLINES and giants have also been used in Alaska for FEEDING SLUICES which must be elevated a short distance above bedrock. A vert steel-lined back-stop is built directly behind the sluice, and gravel is banked up in front of it forming an incline leading to bedrock. Material is then piped up this incline against the back-stop, from which it drops into the sluice. No details are available (429).

Gravel pumps have been used successfully in Swaziland and Nigeria, for elevating tin-bearing gravel; elsewhere, occasionally and less successfully, for gold placering.

Swaziland. Data from J. J. Garrard (397). 8-in centrifugal pumps, with renewable impellers and linings, are direct-connected to 50-hp motors, running at 485 r p m, and deliver water and gravel to a total height of 40 ft. Pump is mounted on a pontoon resting on bedrock in the pit. The gravel is hydraulicked and washed to a sump, whence it is pumped to an elevated sluice. Suction pipe of the pump is sometimes 300 ft long; delivery pipe slopes 45°. During year ended June 30, 1915, 3 gravel pumps ran 70.9% of the time that power was available, elevating 420 423 cu yd of gravel at an aver rate of 24 cu yd per hr. Amount of water pumped, 190–230 cu ft per min; aver height of lift, 38.6 ft. Aver running cost per hr of the 3 pumps was 42.2¢, of which 23¢ was for power (cost 0.733¢ per kw-hr), 10.6¢ for renewals, 8.6¢ for repairs. This gives a cost of about 1.8¢ per cu yd. Aver effic (output ÷ input) for the 3 pumps, 27.35%.

Nigeria. Data from W. E. Sinclair (626) in 1933. For geol occurrence of tin-bearing gravels, see Art 122. Standard suction-pipe diams of centrif pumps are 6, 8, 10, 12 in;

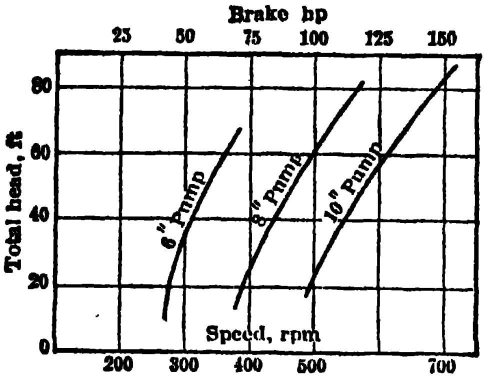

Fig 845. Recommended Speeds and Powers for Gravel Pumps under varying Heads, Nigerian Tin Fields

max lifts, 65–85 ft; 6-in pump lifts 10 cu yd gravel and 6 000 gal water per hr, under aver head; 12-in pump, 40 cu yd gravel and 24 000 gal water per hr; intermediate sizes directly proportional. Pump casings or liners are of manganese steel. Fig 845 gives power requirements of 6-, 8-, and 10-in pumps under varying heads. Pumps are mounted: (*a*) on bedrock, at lowest accessible point of deposit; (*b*) on pontoon, normally resting on bottom, while at work, but moved from place to place by temporarily flooding the pit to necessary depth; (*c*) 2 pumps, preferably of equal capac, in tandem, permitting use of smaller and lighter pumps for a given head. Max effic and min abrasion are obtained when delivery pipe slopes 40°–50°. By whatever method the gravel is broken, it is delivered to pump sump through a bedrock sluice carrying enough water to make a mixture containing about 20% solids; close control of pulp consistency is desirable. In these tin fields, ground is broken by: (*a*) ground sluicing, of soft or medium-hard ground; (*b*) shoveling-in, by hand; (*c*) digging and tramming by hand; (*d*) steam-shovel and loco haulage (see Art 122); (*e*) hydraulicking, limited to rich or unusually extensive deposits justifying large initial outlay. Table 123 gives aver cost data prior to 1933, in pence per cu yd washed, under the conditions noted; up to that time, coal at £3 per ton was usual source of power, since largely replaced by hydro-generated elec. With weekly adjustment, pump delivered 45 200 cu yd of aver gravel before requiring replacement of liners or runners. An incidental advantage of the centrifugal pump, especially important in this tin field (see p 546), is its ability to disintegrate clay and even cemented gravel without assistance from puddler or log washer.

Table 123. Cost of Mining, Pumping and Washing Tin Gravel in Nigeria (Pence per cu yd; prior to 1933)

	I	II	III	IV	V
Breaking and tramming wages	2.20	6.91	9.96	6.80	4.04
Pumping: wages				1.32	2.21
Fuel (coal)	3.10	3.54	3.60	5.05	3.79
Renewals and maint.	1.47	1.75	1.87	1.50	1.36
Lubricating oil	....	.....	.....	0.86	1.02
Sluicing and washing	(*a*)	(*a*)	(*a*)	1.19	1.40
White supervision	2.21	2.60	2.76	5.14	3.47
Overhead and general	0.86	0.65	0.85	1.99	1.46
Total	9 84	15.45	19.04	23.85	18.75

I—Ground-sluicing (no tramming). II—Shoveling-in (no tramming), breaking ground alone varied 3–10 pence, depending on distance shoveled. III—Breaking and tramming by hand. IV—Aver based on 40 846 cu yd pumped from same position in 9 mos; 8-in pump, 90-hp steam engine; total head, 65 ft; aver suction lift, 12 ft; tramming distance, 50–750 ft; cost includes pumping surplus water. V—Based on 9 090 cu yd washed in 480 hr (Nov, 1930) of which 216 hr pumping gravel; 10-in pump, 90-hp steam engine consuming 60 tons coal; total head, 79 ft; delivery pipe 90 ft long, sloping 70°; gravel, 7 ft deep, averaged 10.12 lb of 70% Sn conc per cu yd. (*a*) Not included in total.

Boe mine, Quesnel division, B C. Data from 1932 Ann Rep of B C Minister of Mines. Mine operated profitably for several years in spite of adverse conditions. Gravel, 15–20 ft deep, contained much glacial clay and required blasting. Water, from seepage only, and sufficient for only 10-hr work a day, was supplied at 45-lb press through 10-in centrif pump (steam-driven from 2 60-hp wood-fired boilers) to a giant with 3-in nozzle, at 1 800 imperial gal per min (192 miner's in). Gravel pumped to sluice from sump, protected by screen with 4 by 5-in openings, by 8-in centrif pump driven by 25-hp gasolene engine. Sluice water was impounded, settled, and returned to giant. Capac of outfit, 300 cu yd per 10-hr day. Daily expense: labor (5 men), $20; 3 cords wood, $15; 40 gal gasolene, $14.80; 2 kegs powder, $6; misc, incl amortization, $27.90; total, $83.70, or 28¢ per cu yd.

Mechanical elevators usually consist of an endless chain-bucket excavator, supported on a tower and delivering to an elevated sluice. The buckets handle only gravel; a centrif pump is also required. These elevators have been used at several mines to raise gravel mined by hydraulicking, but have failed due to: (*a*) high first and operating cost; (*b*) pump troubles; (*c*) complicated machinery, requiring services of a machine shop; (*d*) lack of mobility. Bib (385, 409, 430).

127. CHAIN-BUCKET OR BUCKET-LADDER DREDGES

By F. M. Blanchard and C. M. Romanowitz

Introductory. A placer mining dredge comprises a mechanical excavator and a screening and washing plant, both mounted on a floating hull. Dredge performs 4 functions: (*a*) Excavates the placer material. (*b*) Screens the material into 2 or more sizes, usually with a revolving screen; undersizes, usually all below 0.5 or 0.75 in, go through recovery devices, the oversize to reject. (*c*) Treats the fines to recover their metallic or other heavy components, usually on tables or jigs, or a combination of the two. (*d*) Deposits the fines from the treating unit, and the coarse rejects from the screen, to rear of dredge.

The dredge floats in an artificial pond often supplied from an outside source, by gravity through ditches or by pumping. The dredge digs at its bow and deposits washed tailings at its stern, thus carrying the pond with it as it advances. Dams may be needed to raise the water level, and it is sometimes necessary to seal the dredge tailings with sand and slimes. The chain-bucket dredge is the only type described here, as it has practically superseded all other forms, such as dipper and suction dredges, for placer mining. (For dragline dredging, see Art 129). The bucket-elevator dredge is also used for recovering platinum and tin ore, with modifications in the treatment plant to meet requirements. Size of the dredge is designated by the capac, in cu ft, of its individual bucket.

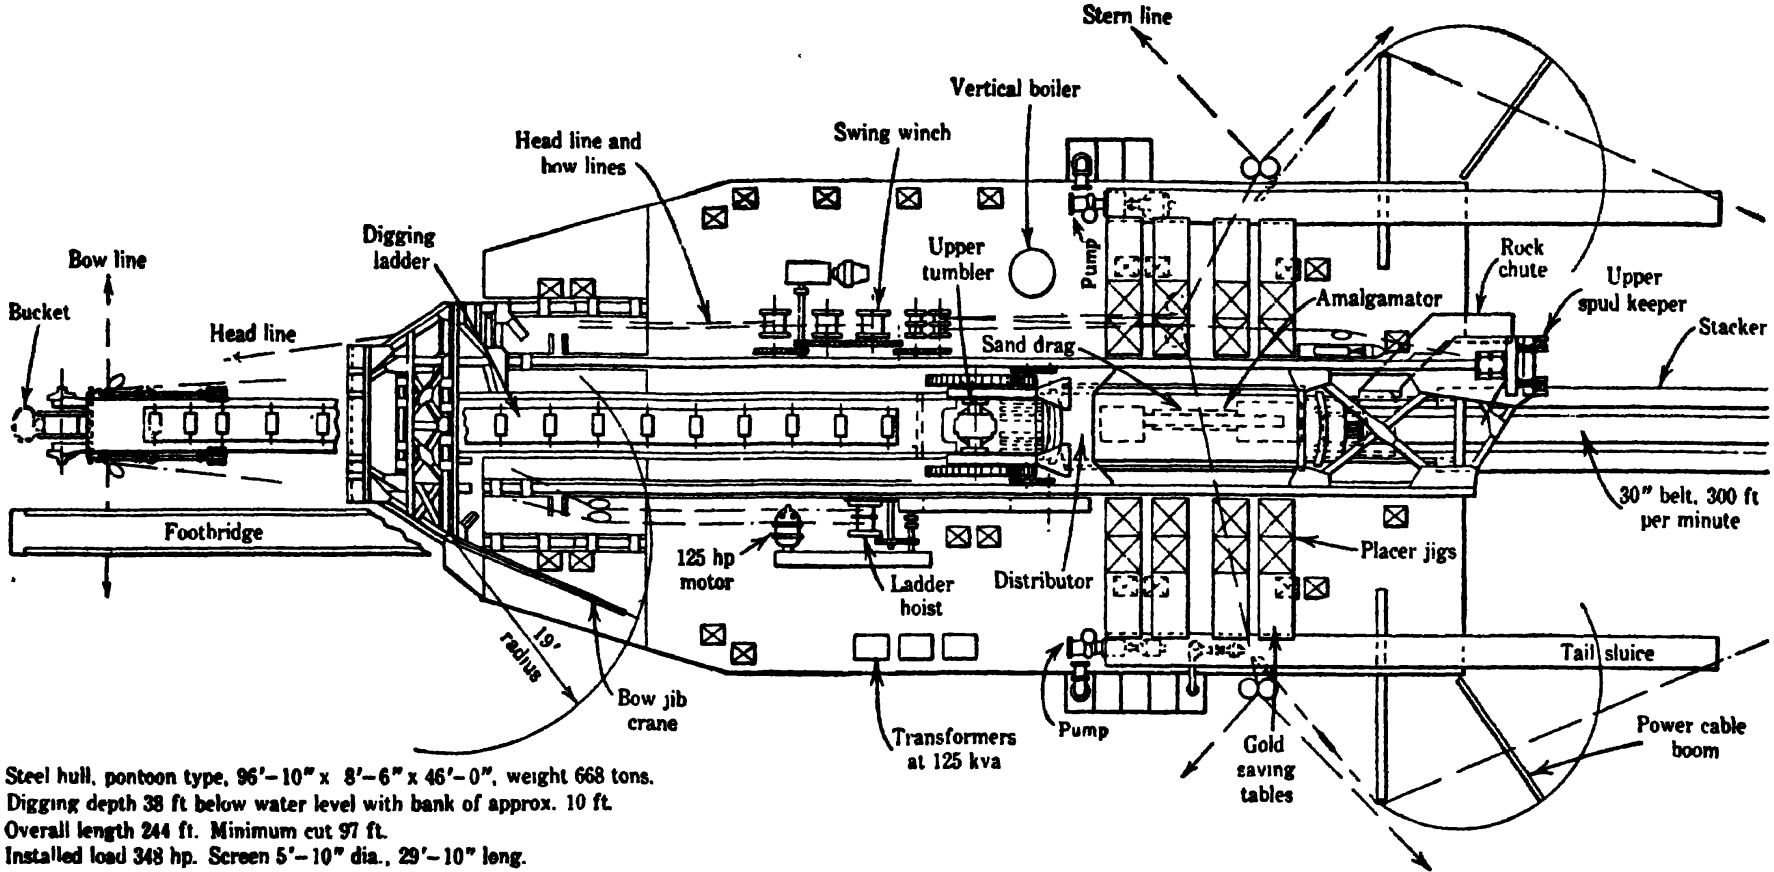
The New Zealand type of dredge, with open-connected buckets, was introduced to the U S in the late 1890's. It was successful in loose river gravels, but found unsuitable for digging "inland" where the gravel was more compacted. Development of the modern dredge began 1901 in Calif. Since then, improvements in the effic of the machines have led to their wider use, both on shallow and very deep placers. The most important improvements have been in digging capac and the treatment plant; also in the design of deep-digging dredges, and the sectionalizing of hull, superstructure, and machinery for transport by trucks and airplanes, and to facilitate rapid field erection. For notable example of dredge transport by airplane, see Bulolo, Art 128.

Factors affecting operation. Successful outcome of dredging demands (aside from sufficiency of profitable gravel): (*a*) correct and adequate prospecting; (*b*) selection of equipment best suited to the conditions; (*c*) effic management and an experienced crew. Selection of equipment is guided by: (1) Max and min depths of gravel and overburden. (2) Total yardage. (3) Amount, distribution, and character of valuable metal or mineral; its size, shape, or other features (for example, "rusty" gold) affecting its recovery. (4) Formation; tight, loose, clay, sand, cement, boulder sizes, buried timber, reefs, dykes, etc. (5) Bedrock conditions and its grade. (6) Surface contours. (7) Availability of water. (8) Special conditions to be met, as leveling, resoiling, leaving water ways, control of muddy water, etc. (9) Flood conditions. (10) Frost, frozen ground, or other conditions found in extreme North. (11) Climatic conditions, and length of working season. (12) Transport facilities and remoteness of property. (13) Class of labor available. (14) Labor and material costs. (15) Taxes and royalties. (16) Special laws to be considered. (17) Funds available.

Bucket-elevator dredge. Commonest, or "California," type is equipped with screen, tables or jigs, and a stacker to dispose of the oversize reject from the screen. Certain variations have proved useful for small placers and shallow creek deposits, as in Alaska; also for mining tin ore. (*a*) Substitution, on tin dredges, of a rock chute for a stacker to convey oversize from the screen. This simplifies the mechanical equipment and is used where proportion of oversize material is not large. (*b*) Flume dredge equipped with a screen. The screen rejects are usually larger than 6-in diam, and are passed to stern of the dredge by stacker or rock chute. Material below 6 in is delivered to a flume or sluice, 5 or 6 ft wide, carrying large volumes of water, like the sluice in a hydraulic mine (Art 124). The sluice usually has large-sized Hungarian or rail riffles. (*c*) In flume dredge without screen, all material goes directly into a sluice. This design is suitable for creeks where gravel is small in size and gold is coarse. In some cases, rocks too large to go through the flume are sorted out by a grizzly at upper end of flume and rejected into the pond, at side of the dredge.

Fig 846 is a plan, and Fig 847 a side elev of a 6-cu ft California-type dredge, for digging at 38 ft below water. Such a dredge, in 1 272 days, digging at aver depth of 26 ft and under difficult conditions, averaged 155 000 cu yd per mo; under easier conditions, a similar dredge has dug 200 000 cu yd per mo. Fig 848 is a side elev of a 3-cu ft dredge, designed for 16-ft depth; in actual performance it averaged 64 000 cu yd per mo. For an 18-cu ft, deep-digging dredge, see Fig 852, 853, Art 128.

Hull is rectangular, with bow and stern corners usually cut off diagonally to increase clearance when maneuvering; a long, narrow, open well extends back from the bow about half the length of hull



Steel hull, pontoon type, 96'–10" x 8'–6" x 46'–0", weight 668 tons.
Digging depth 38 ft below water level with bank of approx. 10 ft.
Overall length 244 ft. Minimum cut 97 ft.
Installed load 348 hp. Screen 5'–10" dia., 29'–10" long.
Jigs 8 – 42" x 42", 2 cell; 1 – 24" x 24" pulsator, 2 cell;
1 – 12" x 12" pulsator, 1 cell.

Fig 846. Plan of 6-cu ft Gold Dredge equipped with Placer-type Pan-American Jigs (Yuba Mfg Co)

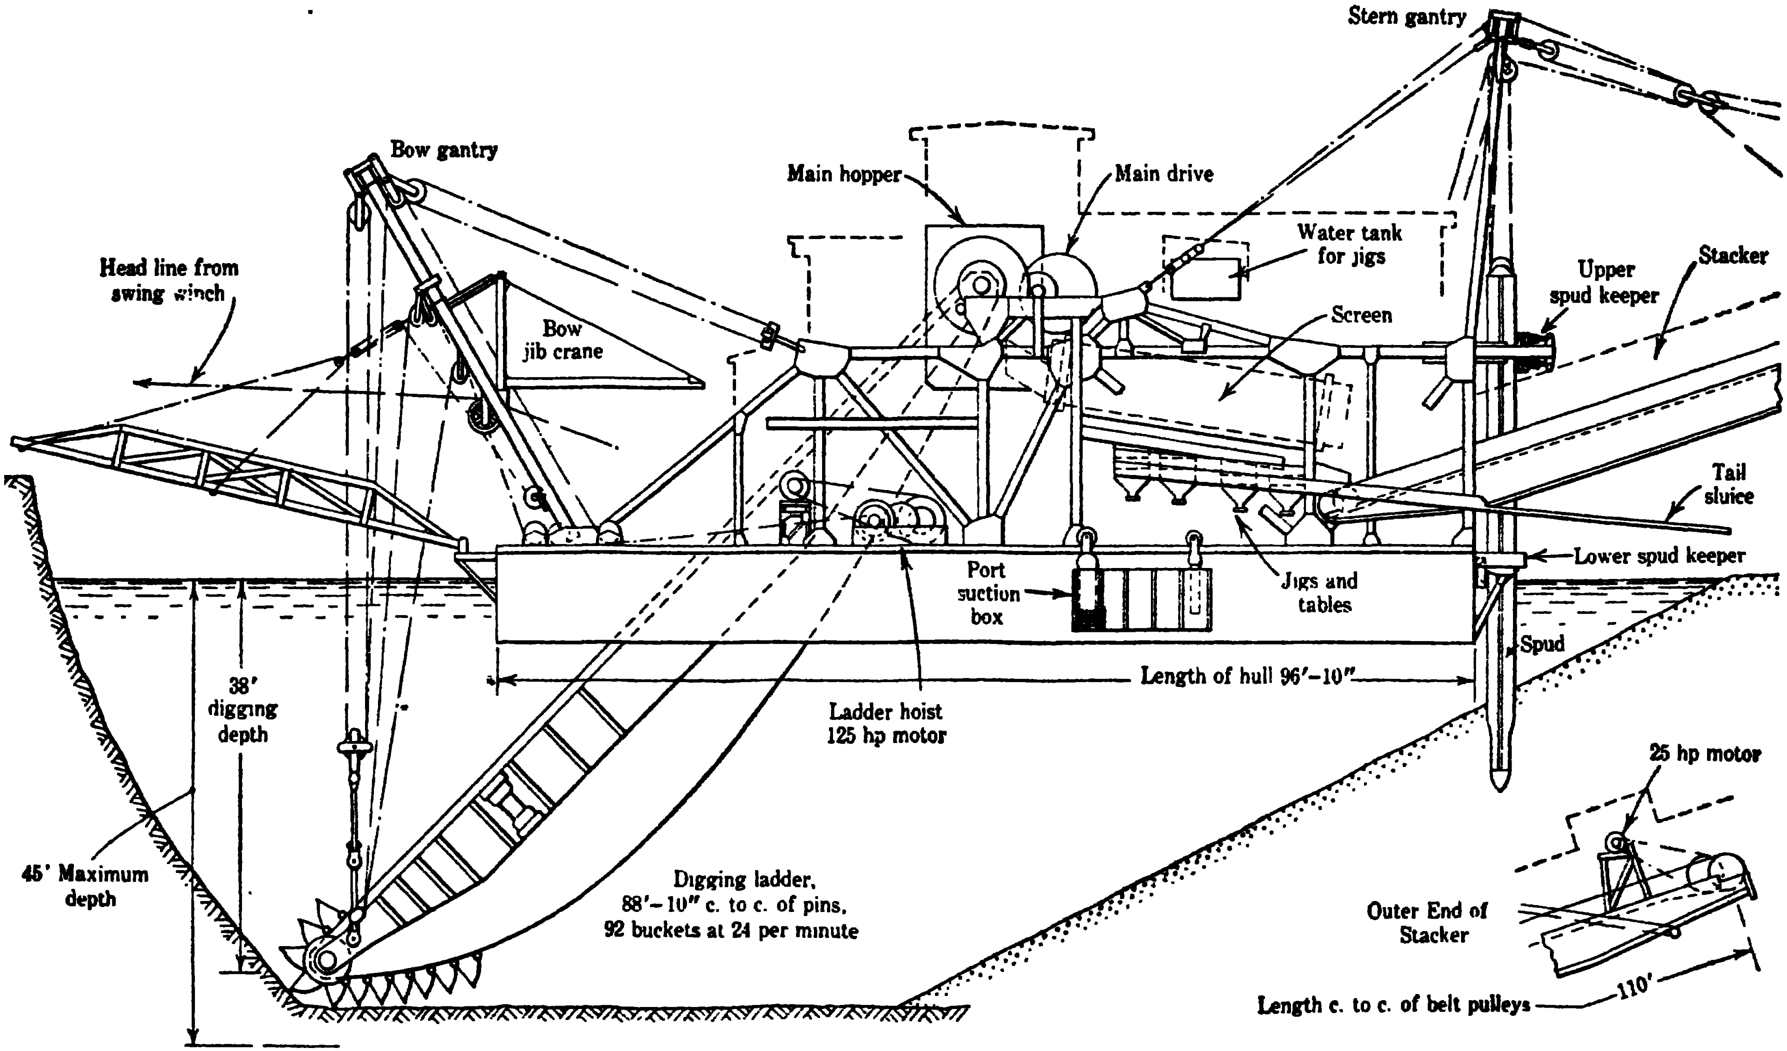


Fig 847. Side Elevation of 6-cu ft Gold Dredge equipped with Placer-type Pan-American Jigs (Yuba Mfg Co). For partial specifications, see Fig 846

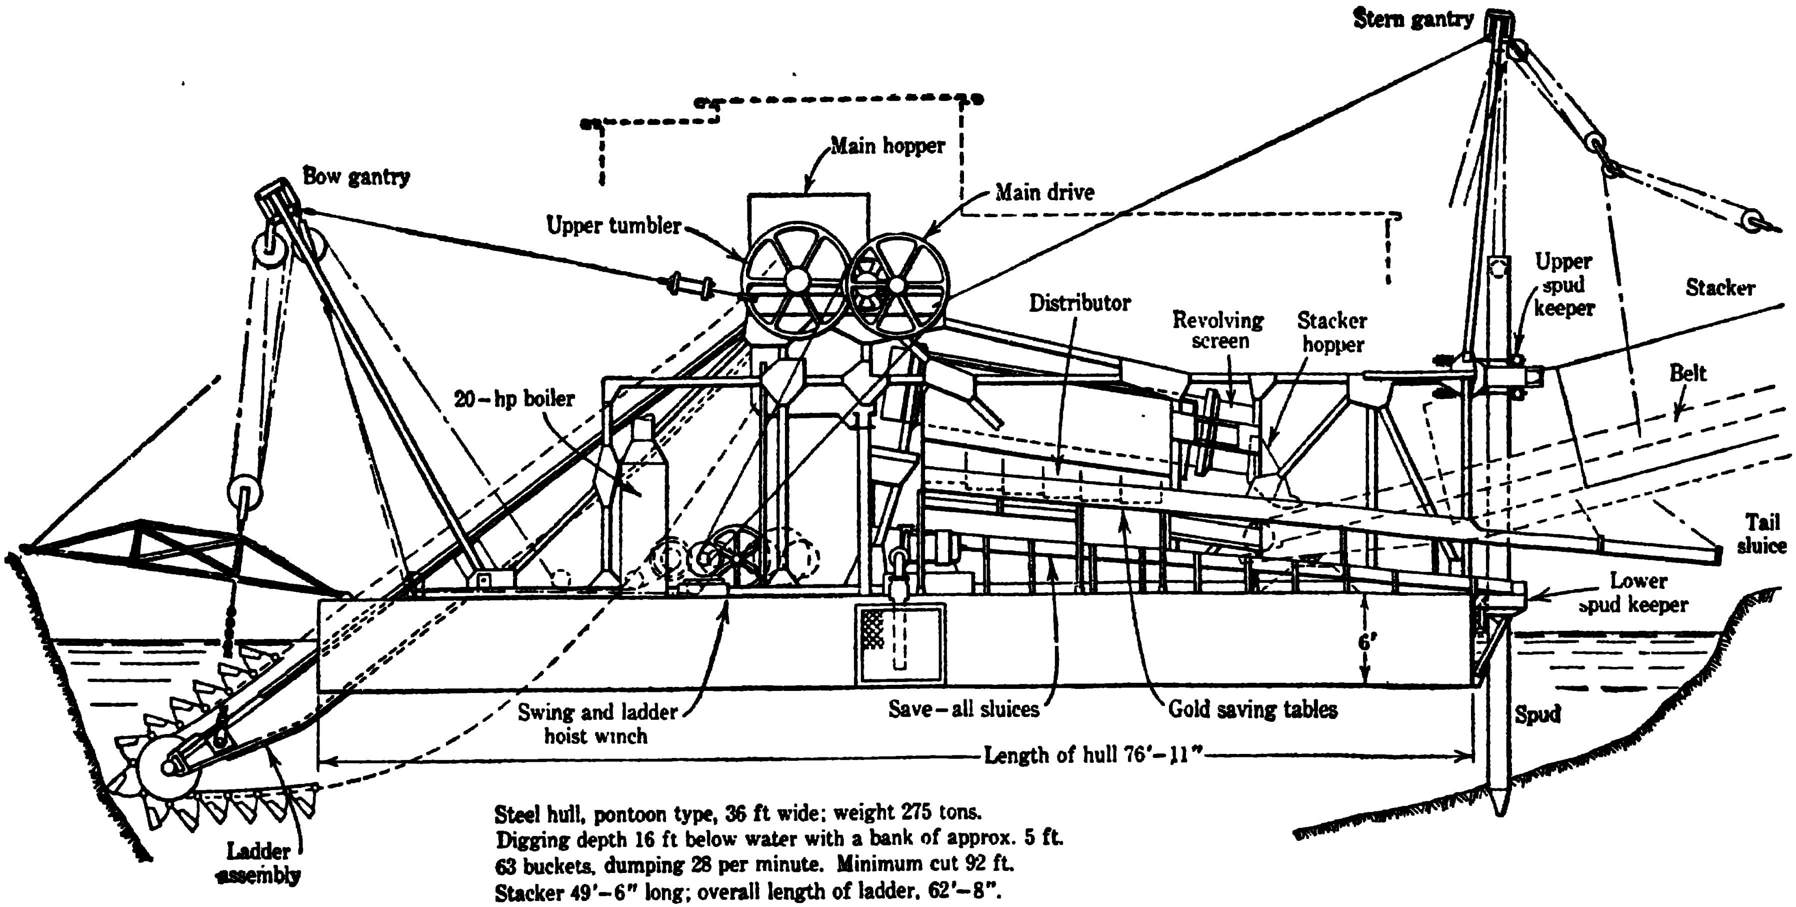


Steel hull, pontoon type, 36 ft wide; weight 275 tons.
Digging depth 16 ft below water with a bank of approx. 5 ft.
63 buckets, dumping 28 per minute. Minimum cut 92 ft.
Stacker 49'-6" long; overall length of ladder, 62'-8".
Main drive motors 50 hp. Screen 4'-6" dia., 19'-7" c. to c. of treads.
Overall length of dredge 144 ft. Installed load 159 hp.

Fig 848. Side Elevation of 3-cu ft Gold Dredge equipped with Tables (Yuba Mfg Co)

and on its center line, to provide space for the digging ladder. Depth and size of hull depend on weight of machinery and material it has to carry; amount of freeboard, which is usually 2–3 ft, depends on length of hull and change of fore and aft trim occasioned by raising or lowering the digging ladder. Width is usually 0.5 to 1/3 the length, according to area and arrangement of washing equipment. Two longit main trusses, one on each side of center line, extending full length of the hull, provide stiffness and support the heavy machinery mounted on and above the main deck. The trusses are strengthened with additional members where concentrated loads occur, and are side-braced at 3 or 4 points in their length. Hulls are fabricated or assembled in 4 ways: (1) standard steel; (2) pontoon; (3) bolted water-tight compartments; (4) wood.

Standard riveted steel hulls, of steel shapes and plates, are fabricated into convenient shipping sections, set up for inspection in the shop, then dismantled, and finally assembled on the dredging property. This is the commonest type.

Pontoon hull consists of rectangular welded steel boxes, 6 by 6 to 8 by 8 ft in section, and 15–30 ft long, corresponding to width of hull; when assembled crosswise of the hull and bolted together, the structure is practically unsinkable. When properly made, such a hull is as strong as the standard type. The pontoon hull, widely adopted since 1934, has permitted operation of many small properties where the standard dredge would be uneconomical, since this hull can be quickly dismantled and moved to another short-life property; one such dredge was moved to its third placer within 5 years. The pontoon is the only hull that can be assembled in the water, saving expense for foundations and launching; bolt holes below water line are temporarily plugged. There is also a saving in erection time. A standard hull requires 6–8 weeks for erection; the pontoon can be asembled in 4–6 days, and requires no trained mechanics. The same saving occurs in dismantling and re-erection. For example, the time for dismantling a 6-cu ft pontoon was 19 days; for re-erection, 38 days. A standard dredge of same size would take 30 days to dismantle and 100 days to re-assemble. Cost of dismantling the pontoon was $4 000, and of re-erection, $10 000; a standard dredge of this size would cost about $5 000 to dismantle, and $40 000 to re-erect. The main disadvantage of the pontoon is the bulky nature of its components, of especial interest when ocean transport is involved.

Bolted water-tight compartment type is designed to be put together in the field. When assembled, the hull consists of numerous compartments (not pontoons) the max size being adjusted to shipping conditions. As many pieces as possible are combined in the shop into a shipping unit, usually by welding, and all field connections are then bolted. This is economical for field erection and for ocean or other shipment. The hull is as strong as the standard type and practically unsinkable.

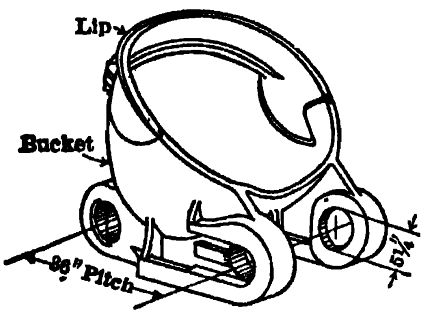
Wooden hulls were exclusively used until about 1912, when the first steel hulls were built, but are now rare except in cold northern countries, where wooden hulls deteriorate slowly. In Calif, a wooden hull lasts 10–12 yr. Wooden hulls with steel superstructure have given excellent service in Calif, Ore, and Alaska.

Gantries. At least 3 are required. MAIN-DRIVE GANTRY is centrally located and supports the upper tumbler, the main-drive gearing, the upper end of digging ladder, the main hopper, the save-all, and upper end of the revolving screen. Additional truss legs and heavy top chords with rigid braces are required here to carry both live and dead loads which must be distributed into the entire truss and hull structure. Dead load includes the main-drive gearing and half the wt of the ladder and buckets; live load is that due to thrust of the buckets while digging, and the side movement of the dredge when swinging back and forth across the pond. BOW GANTRY, at forward end of the hull, serves as a cross truss to stiffen the pontoons on each side of the well, and to support the suspension tackle attached to lower end of the ladder. Back guys of cable or steel tension members extend from its top to upper chords of the main truss. STERN GANTRY supports the spuds and the suspension for the stacker. Its lower end is usually pin-connected to top chords of main truss. Large deep-digging dredges usually have 2 stern gantries, a short one for the spuds and a higher one for the stacker suspension.

Digging end of a Calif dredge comprises an endless chain of close-connected buckets passing around tumblers at top and bottom of a ladder, which is pivoted at its top and has rollers to support the chain on the ascending side; the chain is driven by the upper tumbler. The ladder is raised or lowered by tackle hung from the bow gantry.

Digging ladder consists of 2 parallel steel-plate girders with heavy top and bottom flanges, generally of double angles and cover plates, connected by closely spaced plate diaphragms; upper edges of the latter are below the top flanges and covered by a plate, thus forming a trough to catch spillage from the buckets. Ladders are 50–225 ft long and weigh 300–3 000 lb per ft. Rollers, closely spaced along the top of ladder to support the bucket chain, are of high-carbon chrome steel, press-fitted onto forged nickel-steel shafts. Bearings are usually cast steel with replaceable C-I bushings. Different types of seals keep out abrasive substances.

Buckets are in 2 parts, a manganese-steel base and a lip. The 2 front eyes of base are not generally bushed, since the pin is stationary at those points, but the back eye has a manganese-steel replaceable bushing to resist wear at that joint. Manganese-steel lips are either riveted or rivetless, latter now being more common. A riveted lip is fastened with 10–20 large rivets, which frequently loosen and involve loss of time and expense. The rivetless lip (Fig 849) is held in place generally by only 2 bolts, engaging lugs on bucket and lip on both sides of the center. A rivetless lip weighs considerably less than the riveted, thus saving waste of metal when discarded. Bucket pins are forged from high-carbon, chrome, or molybdenum steel, heat-treated for strength and hardness; the "L" head, to prevent rotation, is almost universal.



9-cu ft bucket

Fig 849. Manganese-steel Bucket with Rivetless Lip

Upper tumblers are generally of high-carbon cast steel, body and shaft cast integral. The 6 sides of the tumbler are protected against wear by heavy liners of forged nickel-chrome steel or cast manganese steel, and bolted in place. A 2-piece tumbler, with cast-steel body shrunk and keyed to a forged-steel shaft, is often used, especially when transport is a problem.

Lower tumbler, made circular, has a high flange on each side to guide the buckets around lower end of ladder. The body, in a single piece or 2 halves, is of cast manganese steel or high-carbon chrome cast steel, with replaceable manganese-steel wearing plates. The press-fitted shaft is a nickel-steel forging. Bearings are of C I, with rubber seals or other means for excluding abrasive matter.

Idlers. Ladders digging deeper than 75 ft often have the Perry idler (Fig 853). This is suspended in heavy bearings from lower side of ladder at about $^1/_3$ its length from lower end; it reduces the drag of the buckets on the bottom, due to catenary, when the ladder is at approx 45°, and diminishes the catenary load on tumblers and pins, thereby reducing wear on bucket bushings, pins, and lower tumbler bearings. Dredges digging over 40 ft deep usually have an idler at the aft end of the well on lower deck of dredge, and so located as to engage the chain when the ladder is inclined at 35° or more below horiz. By thus keeping the upper part of the descending chain at a fixed inclination, the clearance between save-all grizzly bars and the buckets may be reduced, affording a more effic save-all arrangement.

Main drive. Small dredges drive the upper tumbler by a single set of reduction gears at one end of tumbler shaft; larger dredges have 2 sets of reduction gears, both ends of the shaft being driven. All gears, pinions, and bearings are of cast steel; shafting, forged nickel steel. A brake wheel on one end of the pulley shaft provides for emergency and for repairs to the bucket line. Recent improvements in drive mechanism: (*a*) single motor, close-coupled by V-belts to pulley shaft; (*b*) 2 motors, each driving a pulley shaft by V-belts, have proved advantageous on large dredges requiring a total of 200–600 hp for main drive. Motors are a-c or d-c; advantage claimed for latter is better control of bucket-line speed under variable load, but entailing added expense for motor-generator. Dredges working in easy ground have been speeded up to 40–45 buckets per min, but 24–28 buckets per min for dredges up to 7.5-cu ft capac, and 20–23 buckets per min for larger dredges, is usual practice.

Main hopper receives material dumped from buckets as they pass over upper tumbler; it is of steel plates and angles and has a lining of wear-resistant metal. A short half-round chute directs the material into the screen; it is lined with alloy-steel bars 2–3 in thick. When large boulders are numerous, the hopper back may have a coarse grizzly hinged at one end; on appearance of a boulder, the grizzly is lowered, mechanically or pneumatically, into position to intercept it and then raised to discharge it overboard, *via* chute or conveyer. Spill from buckets is caught on a fixed grizzly surmounting a riffled sluice, the "save-all."

Screens. Roller-mounted trommels have displaced all other types of screen, chiefly because of their vigorous disintegration of clay-bound or partly cemented gravel; disintegration is hastened by adding lifters or other tumbling devices inside the screen. Abundant water at press of 20–40 lb per sq in is supplied through nozzles or spray pipes to aid discharge of fines. Screens are from 4.5 ft diam by 24 ft length for a small, 2.5-cu ft, dredge, to 9 by 52 ft for an 18 or 20-cu ft dredge. Ends of screen are blank plates with replaceable liners; tread rings fastened outside of each plate. Rib bars (6–9-in heavy angles, bars, or channels) connect the end plates and provide longit support. The perforated plates are in sections 2.5–6 ft long and wide enough to span the gap between outside rib

bars; sections are small enough for easy handling on replacement; countersunk bolts with spring-lock washers are used for fastening. Material for perforated plates is high-carbon or other abrasion-resistant rolled steel, or cast manganese steel. Thickness is 3/8 in for small to 7/8 in for the largest screens. Diam and spacing of holes depend entirely upon character of material to be washed. To counteract excessive discharge at head of trommel, perforations at this end are often smaller and farther apart than elsewhere. A common size of hole is 5/16 in on the inside, enlarged to 3/8 or 7/16 in on the outside; tapered holes have less tendency to blind. The bridge between holes is from 0.5–1.5 in, diminishing towards discharge end of trommel. Where coarse nuggets occur, the plates at lower end of screen are usually slotted, 5/8 by 3/4 in to 1 by 1 1/4 in. The tread rings on which the trommel rotates are high-carbon or chrome-steel machined castings. The upper ring is carried on 2 idler rollers, the lower on either a central drive roller or on 2 rollers, one of which is driven. As the screen is inclined at 1–1.75 in per ft, thrust rollers are required; these engage a tapered machined face on lower edge of lower ring. The drive roller is actuated by reduction gears direct- or belt-connected to a motor; flat belts have been common at this point, but gear reducers and V-belt drives are now more frequent, occupying less space and giving higher effic. Peripheral speed of trommels is 150–200 ft per min (6–14 rpm), depending on diam of screen and kind of material being washed.

Stacker hopper. Oversize from the screen falls into a steel-plate hopper, lined, at points of greatest wear, with heavy plates or bars; it delivers to stacker belt through a chute, the discharge end of which is fitted with a mild-steel casting and manganese-steel liner shaped to change the direction and veloc of the stream to correspond with that of the belt, saving wear on the latter, The hopper often has a gate which diverts the material into a sluice discharging over the stern of the dredge; this provides a good footing behind the spud and saves power, since the stacker may be shut down meanwhile.

Stacker. The frame carrying the conveyer belt comprises 2 parallel structural-steel trusses, tied top and bottom and at each panel point with cross-braces. Its lower end is hinged on a shaft permitting the stacker to be raised or lowered. When a swinging stacker is required, an additional vert swivel allows movement of approx 15° to either side of the center line. Inclination of stacker is limited to 20°; in most cases, 15°–18° is satisfactory. Stacker is suspended from the stern gantry cap by 1 or 2 wire-rope tackles fastened at 2 or sometimes 3 points. It is raised or lowered by a line from the swing winch, or preferably from a separate small winch having a self-locking safety device (worm gear or automatic friction) which will necessitate lowering as well as hoisting by power, and thus prevent careless dropping of the stacker. The steel head pulley is lagged with rubber. Length of stacker depends chiefly on digging depth and nature of material. Knowing the swell (usually about 33%), the digging depth, and allowing clearance for outer end of stacker inclined at 18°, the required length can be computed. Due to the extreme length of hull of large deep-digging dredges, the lower end of the screen is so far inboard from the stern that a short auxiliary stacker (Fig 853) may be placed between the screen and main stacker.

Anchorage. For maneuvering dredge by spuds and lines, see "Digging procedure," below. If there are 2 spuds, they are usually placed in line with the main fore and aft trusses; a single spud (as found on many modern dredges) may be near the center line of dredge or in line with the starboard (right-hand) truss.

The SPUD is of plates and angles, or of wide-flanged beam sections with heavy cover plates. Bottom of spud has a massive cast-steel point, and its upper end carries sheaves for the hoisting tackle, which is suspended from the stern gantry cap. Lower spud keeper, acting as cushion between spud and hull, is of steel with a self-adjusting rocker element to accommodate changes in position and maintain a broad bearing against the spud. Resistance to twisting is afforded by heavy brackets fitted with replaceable liners. In the upper keeper, tendency of the spud to move away from the dredge is counteracted by an outside cross-beam connected to the upper truss members by heavy rods and compression springs. A HEADLINE, sometimes replacing a spud in very easy digging, is a wire rope about 1.5-in diam, fastened to a deadman 500–1 000 ft ahead, and held taut by a winch on the dredge. Where the dredge is making a wide cut, a number of "pennant" lines are spaced across the full width, and the headline is attached to these in most convenient positions. SIDELINES, one at each corner of dredge, are anchored ashore, and control lateral movement by winches on the boat.

Winches are for: (*a*) adjusting inclination of ladder and buckets, the "ladder hoist"; (*b*) control of side lines (the "swing winch"); (*c*) hoisting of spuds; (*d*) adjusting slope of stacker; (*e*) holding pull on headline; (*f*) miscel purposes, as handling of heavy machinery. Grouping of winch drums, and their power, vary with size of dredge. SMALL DREDGES, to 5-cu ft capac, have a combination ladder hoist and swing winch, including 2 drums for bow lines, 2 for stern lines, 1 or 2 for spud hoists, 1 or 2 spares, and the ladder-hoist drum. Gearing is so arranged that each may be operated individually, and each drum has expanding-type friction and a band brake. On LARGER DREDGES, the swing winch includes all drums except for the ladder hoist. Either the bow or stern lines, spud, and spare lines may be operated as a unit. Instead of combining all drums in one winch, some dredges have independent bow- and stern-line drums; spud and spare drums are then in another unit, thus requiring 3 motors (usually a-c). Several dredges have had d-c motors for the bow-line winches, with automatic elec control to maintain constant pull on bow lines. LADDER HOIST, on the larger dredges, is a separate unit actuated from the main-drive motor, through pulleys and clutches, or from an individual motor through V-belts or a gear reducer. The drum is divided by a central flange, and 2 ropes lead off to the suspension; on smaller dredges, only 1 rope is required. For DEEP-DIGGING DREDGES, with very heavy ladders and long bucket lines, the ladder winch has 2 separate drums, driven by 400–500-hp motor, direct-connected to a gear reducer, coupled to an intermediate shaft by herringbone gears. A herringbone pinion drives the first drum, the gear of which engages a pinion on an idler shaft driving the second drum. The motor has an elec brake; a heavy wheel with band brake on the idler shaft may be pneumatically controlled from the winch room. An automatic control electrically connected with the motor control is used on many modern dredges, to limit the high and low positions of the digging ladder and the max speed at which the ladder may be lowered.

Pumping equipment usually includes a high-press, a low-press, and a small auxiliary pump, all centrifugals. The high-press pump discharges at 60 to 80-ft head into the screen at both ends, or from a pipe with adjustable nozzles, extending through full length of the screen. The low-press pump discharges at 30 to 40-ft head opposite the head of each cross sluice. Pump sizes depend upon amount and kind of material washed; ratio of water on the tables should be 8–12 times the solids. Auxiliary pump, 2.5 to 4-in diam, at 60 to 80-ft head, is used for washing deck, fire outlets, and priming the larger pumps. In dredging clay or other sticky material, an extra 6 or 8-in pump supplies water at about 120-ft head for nozzles directed against the buckets as they dump into main hopper. Pumps should have liners, as the pond water may contain abrasive matter. Pumps are direct-connected by flexible couplings to motor on same base, each having a suction check valve above water line.

Combination MUD AND MONITOR PUMP is used on dredges digging 80–125 feet deep and with a high bank, where tailing sludge tends to flow out along the bottom of the pond to the bucket line. This pump is about 8-in diam, developing 250-ft head. For extracting mud, the suction extends to a point near the lower ladder tumbler, the discharge pipe passing aft to the end of the stacker. (Fig 853). When serving a monitor, suction comes from the strainer box and the discharge supplies a nozzle at the dredge bow; this washes down a bank which does not cave by itself, to avoid a cave-in which might bury the digging ladder.

Strainers protect suction inlets against floating debris or water-logged material. A frame covered with galvanized wire cloth with 3/8 in openings is usually adequate, but removable perforated plates may save some labor. A self-cleaning, revolving suction box is satisfactory. It consists of a wheel, 10–14 ft diam by 3–4 ft wide, framed of angle-iron and covered with wire cloth. Buckets around the inside periphery are filled from a small nozzle for turning the wheel. Debris outside the screen may be scraped or blown off as the wheel revolves.

Power for elec motors reaches the dredge, from shore, by rubber-covered or steel-armored cable, supported on floats. Voltage, 6 900–2 200; 3-phase, 60-cycle current is usual. Operating voltage on the dredge is 440, delivered by 3 single-phase transformers.

Starters are usually distributed among 3 boards, 1 in winch room for the main drive and swing winch, 1 on main deck for the pumps, and 1 at stern for the screen, stacker, and sand elevators. Pump motors are constant-speed; those for main drive, winches, screen, and stacker, of variable-speed, reversible type. Control is by a breaker and a starter for each motor, the variable-speed motors have C-I resistance grids. Main-drive has a magnetic reversing controller, with line protective, primary, and secondary panels. Motor controls include a thermal overload protection device with a push button for resetting. In isolated places without elec power, dredges have 440-volt Diesel-elec generators. Motor equipment as above.

Digging procedure. Digging starts at top of the ground ahead of dredge. Forward end of ladder is swung slowly from side to side of intended cut by the side lines. At end of a swing, the ladder is lowered for a deeper cut on the return trip; bedrock, when reached, is scraped if its nature permits. On raising the ladder, the dredge is moved ahead for the next cut. To make the forward movement, and maintain position while digging, the dredge may have (*a*) 2 spuds, (*b*) 1 spud, (*c*) headline; side lines are always necessary. For "stepping ahead" with TWO SPUDS, the dredge swings to right of the cut, turning on the "digging" spud as a pivot; the port ("stepping") spud is then lowered and the other raised; after swinging to left, the digging spud is lowered, stepping spud raised, and dredging proceeds.

With a SINGLE SPUD, the stern lines are anchored well ahead of the dredge; by pulling on them, after raising the spud, the dredge is moved. This method is quicker than with 2 spuds, due to fewer operations, but not always applicable. HEADLINE stepping (and digging) is practicable only under easy digging conditions, as in Malayan and other tin fields (Art 132); rarely on gold dredges. When operating from a headline, swinging as usual by the side lines, hard ground offers difficulties in keeping the buckets efficiently at work.

Gold-saving equipment, treating undersize from the screen, includes: (*a*) distributer; (*b*) riffled tables; (*c*) roughing jigs, preceding or following the tables; (*d*) clean-up box or jig; (*e*) mercury trap or other form of amalgamator; (*f*) retort and melting furnaces; (*g*) sand wheels or elevators sometimes aid disposal of tailings. **Fig 850, 851 show alternative flowsheets, with and without jigs.**

Distributer is a steel housing enclosing the trommel. Its sloping bottom is partitioned into pockets corresponding in number to the tables; partitions have adjustable gates to equalize distribution; when wide open, the gates facilitate cleaning-down the bottom of distributer. If gold is coarse, riffles are customary instead of partitions, discharging overflow into an outside longit distributing sluice; this has the advantage of spreading the flow more thinly over more tables than could be grouped close to the screen distributer (Fig 850-B). In the usual type of distributer, sand discharges from its bottom, on both sides, by water applied at 15-lb press through 1.5-in nozzles in headers fed by low-press pump; a short sluice opposite each nozzle leads to adjoining table or roughing jig; uniform distribution aids effic of recovery.

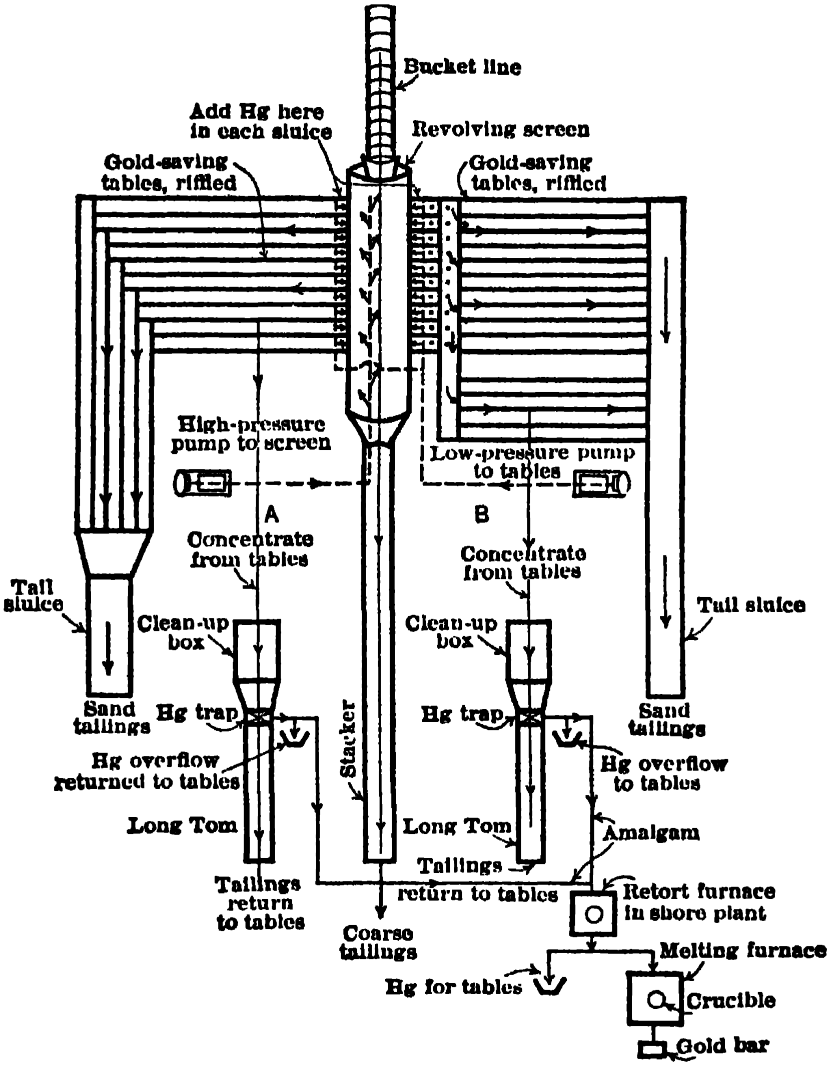


Fig 850. Flowsheets of Gold Dredge equipped with Tables. A—Conventional type. B—Improved Arrangement

Tables are rectangular steel sluices, 21–32 in wide, placed crosswise of the hull and sloping 1.25–1.5 in per ft outwardly toward both sides. In Fig 850, 851, the alternative arrangements are only for illustration; a given dredge will be equipped symmetrically. Total table area, in absence of jigs, depends upon size and character of gold, fine gold requiring more area; recent dredges have 200–500 sq ft per cu ft of bucket capac.

Enlarged table area, for large dredges, may be secured without proportionate increase of hull area, in 3 ways: (*a*) Double-bank tables, having an upper deck permanently fixed 6 ft above the lower, requiring corresponding increases in height of upper tumbler and length of digging ladder and bucket line, entailing added wt. (*b*) Double-deck riffles; sluice has a false bottom of 10-gage plate, supported from the sides about S in above true bottom and similarly riffled. (*c*) Telescoping or nesting sluices; upper sluice fits between sides of the lower; it is hinged at one end and can be raised by tackle, the 2 decks being similarly riffled; this allows faster clean-up than the false-bottom sluice. Outer ends of all tables discharge into longit sluices carrying tailings to stern of hull and dropping them 15–20 ft overboard; bottoms of tailings sluices are often riffled to catch escaping gold or amalgam.

Wooden Hungarian riffles (Art 125) are almost universal. Common size, 1.25 by 1.25 in, spaced 1.25 in; tops protected by steel or rubber strips $^3/_{16}$ in thick by 1.5 in wide, the 0.25-in overhang being on the downstream side. Riffle bars, usually 6, are made into frames about 13.5 in wide; length corresponding to width of table. The frames are held to bottom by 1.5-in sq battens, wedged under angle-iron brackets riveted along sides of table. Mercury trap riffles are usually placed at intervals along a table.

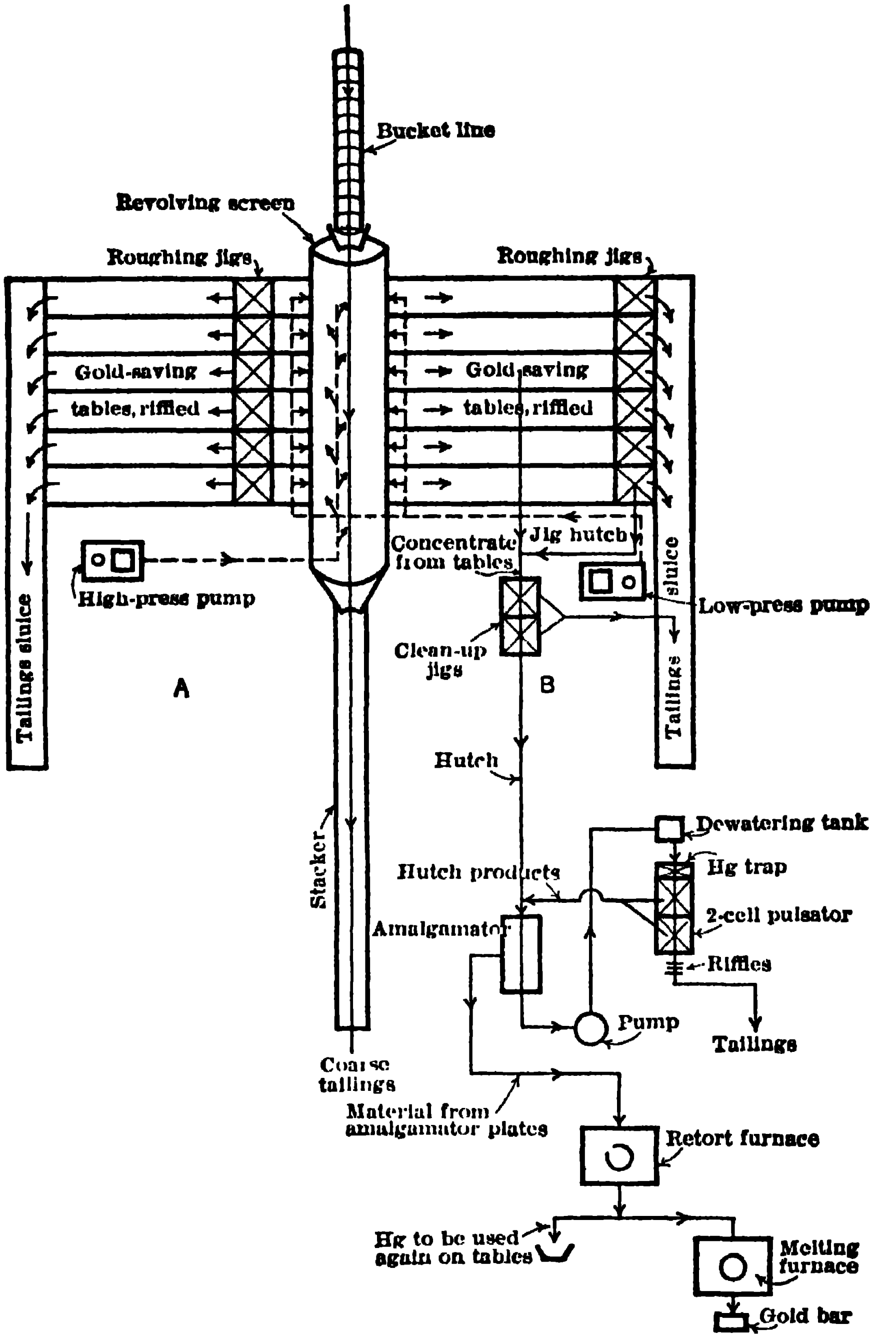

Fig 851. Flowsheets of Combination Jig and Table Dredge. A—Roughing jigs ahead of tables. B—Roughing jigs following tables. Arrangement of cleaning jigs is same in either case.

Jigs are especially useful on gold dredges (common also on tin dredges, Art 132), when gold resists amalgamation or is largely in scales or very fine particles. Jigs are designed for large capac in small space (Fig 846, 847), made possible by the extremely small ratio of concentrate to feed, as compared with ore-concentrating jigs (403).

Fig 851 shows alternative positions of roughing jigs with respect to tables. In either case, the hutch product, and concentrate from riffled tables, is re-treated on 2 cleaner jigs, the second re-treating the hutch from the first, both discharging tailings. Final product may pass through a small ball-mill amalgamator; final recovery of gold is usually on amalgamated plates. Black-sand concentrate containing metals of platinum group, resisting amalgamation, is treated separately.

Clean-up of sluices. After stopping the flow over a table, the riffles are removed, washing any adhering material into the sluice. With a small stream of water the material is washed to the lower end, which is fitted with a wooden stop about 3 in high; here most of the light sand is scraped or washed off; the rest, mostly black sand and amalgam, is shoveled out and transferred to the "clean-up box," a steel or wooden receptable of about 1-cu yd capac, which collects concentrate for further treatment. From an orifice in lower end of this box, the concentrate is washed, a little at a time, over a sloping plate, to extract heavy foreign matter, and thence into a mercury trap. Excess of free Hg collecting here is tapped off and re-used, the heavier amalgam being removed by hand for subsequent treatment (Sec 33). Sands overflowing the Hg trap then pass through a Long Tom (Art 119), 12–15 ft long, riffled on cocoa matting; discharged sands return to the initial tables, or may be further treated in a ball-mill, or by smelting.

Sand tailings. Tailings sluices usually empty into the pond behind and from both sides of dredge; when working a high bank consisting largely of sand, tailings so discarded may interfere with floating the dredge stern, and must then be disposed *via* the stacker. In such case, the tailings sluices discharge into sumps, from which water overflows to the pond while sands are lifted by wheel or bucket elevator and delivered by chutes to the stacker. Sand wheels, with light steel frames, are 12–16 ft diam; buckets, 2–3 ft wide; they are chain driven from 7.5–10-hp geared motors. Bucket elevator, of either chain or belt type, occupies less space and permits a higher lift when necessary.

128. GOLD DREDGING

Introductory. Gold dredging is a subject of great detail; for a general discussion, see (385, 403, 409, 437, 438, 614, 627). In the U S, gold dredging began about 1898; by 1927, with price of gold at $20.67 per oz, the known areas suited to dredging were largely worked out, thereby forcing a search by American companies for dredging ground in foreign countries, such as for tin placers in the Malay States (Art 132) and gold placers in Colombia, Central America, New Zealand, and elsewhere. The increase in price of gold to $35 per oz in 1933 stimulated activity in gold dredging in the U S. In recent years, the relatively inexpensive dragline dredge (Art 129) has been widely applied to small and shallow deposits, but the chain-bucket dredge (Art 127) is best for large operations in low-grade gravel. Recent improvements in design have also permitted the chain-bucket dredge to work gravels at much greater depths than were formerly considered accessible.

Requirements and limitations. Deposits suited to dredging are extensive river-bar and gravel-plain placers (Art 117), occurring chiefly in geologically old districts. Requirements as to bedrock, character and size of gravel, effect of boulders, cemented gravel and buried or standing timber, ordinary limits of dredging depth, water for dredge ponds, etc, are summarized in Art 118 and Sec 25, Art 7. Other considerations affecting choice of method and operation and design of dredge are: CHARACTER OF GOLD. Very fine flaky gold, like that on Snake River, Idaho, requires addition of special equipment (usually jigs) to the other gold-saving devices. Coarse gold sometimes modifies the form of apparatus required. "Rusty" gold may entail special methods of recovery. GRADIENTS. Dredging is inherently applicable to large flat deposits, where lack of grade prevents hydraulicking; small topographic irregularities and flat surface or bedrock gradients affect only the height of bank carried above water level. Some dredging has been done on grades as steep as 6%, requiring dams to maintain a pond (431). FROZEN GRAVEL must be thawed before it can be dredged (Art 131). FLOODS. Dredging in beds of torrential streams is precarious, due to danger of being wrecked. CLIMATE determines length of working season and hence the annual output and return on investment for a dredge of a given capac. Min gold content of workable gravel is higher where the season is short than where operation is continuous. Cold climate increases costs, because the dredge must be heated and its equipment protected from accumulations of ice. See Bib (408, 432, 409) for description of successful winter work. TRANSPORT FACILITIES are more important than for other forms of placer mining. Weight of the machinery is large, even for small dredges; attempts to sectionalize a dredge for muleback transport have not been successful, but sectionalizing into units capable of transport by trucks and aeroplanes (see Bulolo) has been accomplished. High first cost where good roads are lacking militates against construction of large boats in remote regions (385, 433). LABOR. A small crew can handle a large yardage; all but a few roustabouts are skilled men. Cheap POWER is essential. TOTAL YARDAGE must be sufficient to amortize the initial investment and yield desired profit. A choice often exists between use of one dredge, or several of different sizes, with corresponding alternatives in first cost, rate of return, and life of property (Sec 25, Art 14). Closer estimates of this kind are possible on well explored dredging ground than on any other form of mining property. An attempt is usually made to adjust the rate of working, and hence life of property, to the LIFE OF DREDGE. This is practically the life of the hull, as the machinery is repaired or renewed as necessary. The machinery is often dismantled, after working out an area, and installed elsewhere at moderate cost on a new hull. Constant running at max capac is essential to low working costs; hence construction and operation of a dredge must be planned to minimize delays. Following examples illustrate dredge work under various conditions.

Central Calif. Data in Table 124, relating to 10 dredges in the Folsom and Oroville districts, were supplied originally by R. G. Smith, Mgr of the Gold Dredging Dept of the Natomas Co, in 1917. Table 124 has been condensed, by F. M. Blanchard, from 4 tables on pp 938–941 in 2d edn of this book (revised only as to history) Mr Smith submits following comments in Feb, 1940, concluding that present aver operating costs per cu yd are slightly lower than in 1917, in spite of increased prices for labor and materials. WAGES per hr on Calif dredges, 1940: winchmen, 82.5¢; oilers, 67.5¢; laborers, 55–60¢; compared with 1917, these wages represent increases of 83% for winchmen, 93% for oilers, 84% for laborers. Total labor charges have increased by 85%, about equal to increase in hourly rates. MATERIALS. Comparison of unit prices is not practicable, but total costs for materials have increased 30% over 1917. POWER RATES to large consumers, equipped to take service at high voltage, have been reduced about 20% since 1917; but total power charges have increased about 23% with longer hours and larger yardage. WATER CHARGES have risen 175% since 1917. GENERAL EXPENSES show apparent increase of about 90% in total, possibly explained in part by changes in accounting methods, some general expenses having formerly been charged to operation. TOTAL OPERATING COSTS have increased by more than 50% since 1917. ANNUAL YARDAGE. Dredges of nearly all sizes have greatly enlarged their yearly output since 1917, through increased speed, longer running times, and improved mechanical effic; increase in yardage, though widely variable, has averaged about 70%. COST PER CU YD. Balancing the above items indicates a slight decrease in operating cost since 1917. TAXES and INSURANCE have increased about 70%, and AMORTIZATION allowance should be 90% greater. Finally, Federal INCOME TAX is an item much more oppressive now than in 1917 (see Sec 24).

Oroville, Calif. Data from C. M. Romanowitz in 1940. Dredging conditions in this field are considered unusually favorable. One 9-cu ft dredge (a frequently adopted size) during a period of 1 363 days averaged 290 000 cu yd per mo from depth of 50 ft. Others of same size, under favorable conditions, have handled 3 500 000 cu yd in a year.

Calif "deep-digging" dredges. Data from C. M. Romanowitz in 1940. Two notable examples of 18-cu ft dredges operate in the Yuba River field, at Hammonton; Yuba No 17 began July 17, 1934, and No 20 on Apl 24, 1939. No 17 has dug 112 ft below water, with bank of 56 ft; No 20 digs at 124 ft below water, with same height of bank as No 17. During a 1 363-day period, No 17 averaged 310 000 cu yd per mo, from aver depth of 110 ft. Usual max depth dug by other dredges in same field is about 80 ft; one such dredge, of 18-cu ft capac and digging in easy gravel at aver depth of 68 ft, handled 415 000 cu yd per mo during a period of 1 287 days. Another, of same size, but with more modern digging facilities, during 704 days averaged 450 000 cu yd per mo from 75-ft depth in tougher gravel. Below 90 ft, the formation at Hammonton is tighter and harder (though not cemented) than at shallower depth. These deep-digging dredges require special design and equipment. Fig 852 and 853 are respectively plan and side elev of an 18-cu ft dredge designed to dig 124 ft below water. The Perry bucket idler and the Yuba mud-pump system (Art 127) give good results. While these dredges are effic, they can not mine as large yardages, in proportion to their bucket capac, as those working at shallower depths, chiefly because the operator can not "get the feel" of the work as well as on smaller dredges. The longer time the buckets take in traveling to the surface makes it impossible to determine promptly whether they are digging to full capac. The unit operating costs of these deep-digging dredges are higher than those of shallower dredges, due to smaller yardage and higher cost of replacements. F. C. van Deinse, V-Pres of Yuba Consol Gold Fields, states that costs for operating the deep-digging dredges are 1.33¢ more per cu yd than for shallower dredges in the same fields.

Table 124. Operating Data and Costs on 10 Dredges, Folsom and Oroville Dists, Calif, 1912–16

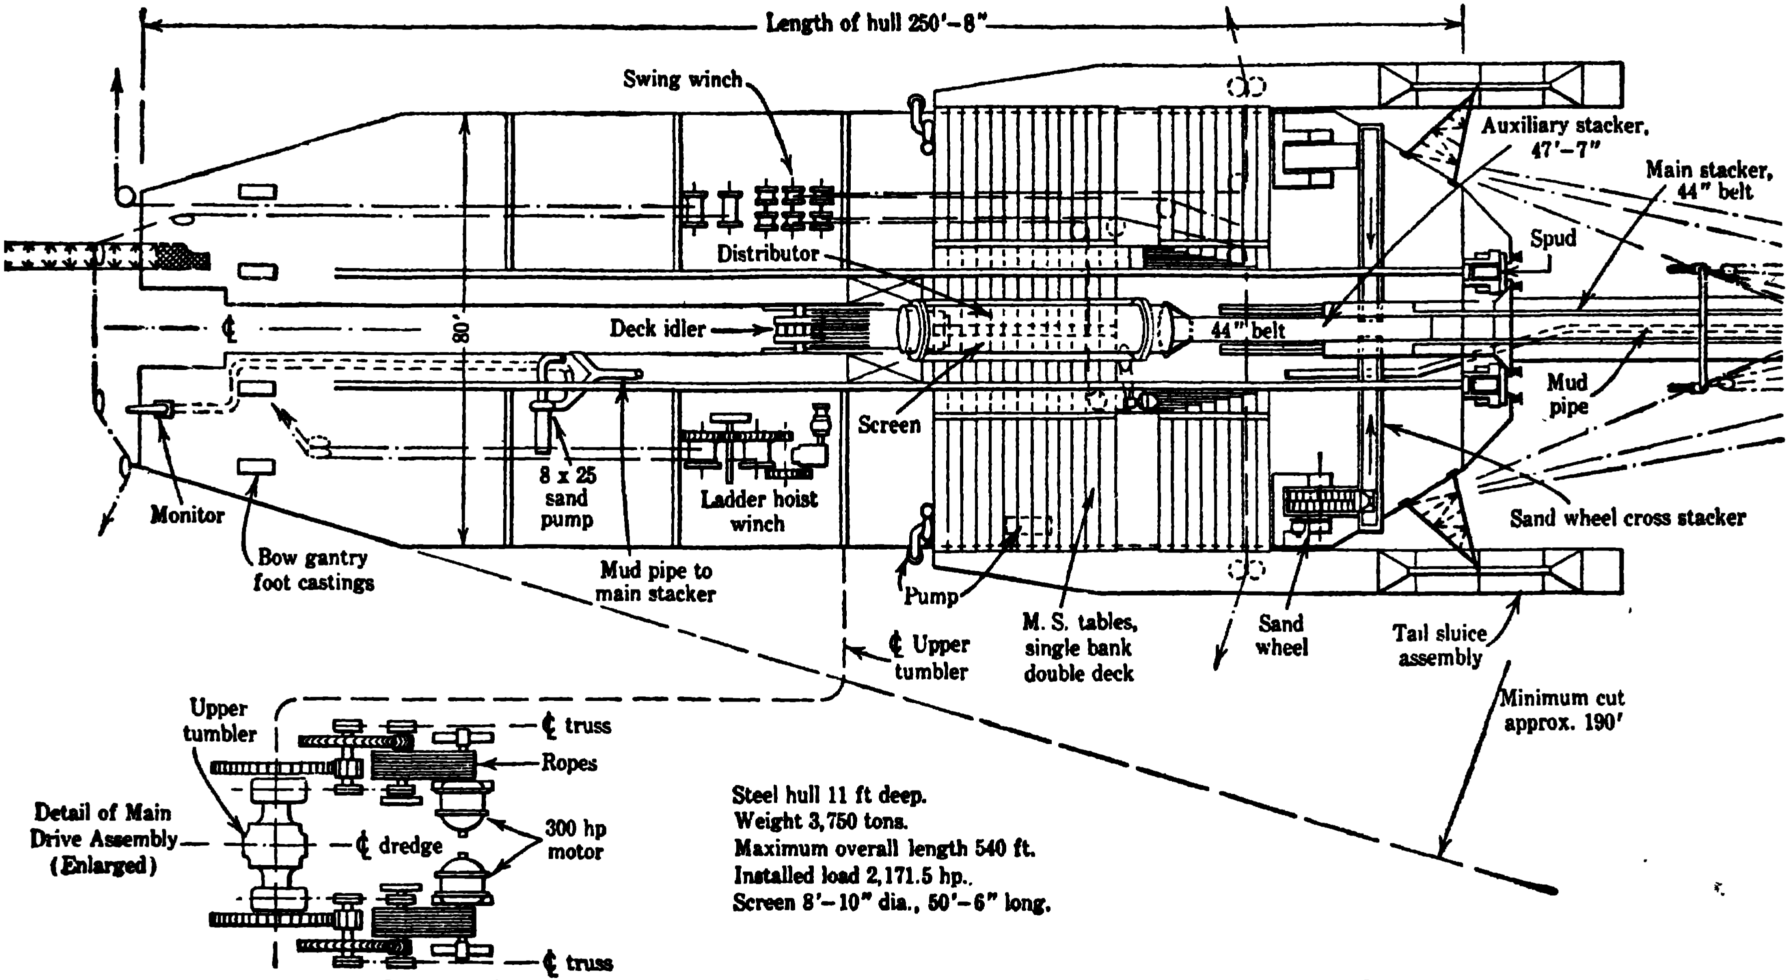
* Dredges *C* and *J* in Oroville dist, all others in Folsom dist. Dredges *F*, *G*, and *H* were designed for same conditions as *D* and *E*. Dredge *I*, of large capac, was designed for shallow, easy digging; *J* similar to *G*, and worked in easier but deeper ground than *I*. To June, 1914, a suspense acct was carried for large items, as bucket lines, tumblers, etc, these costs being distributed *pro rata* over the life of parts in question. Thereafter, when such parts were put into use, their full cost was charged to operating. Wages on all dredges: winchmen, 45¢ per hr; oilers, 35¢ per hr; laborers, $2.50 per day. Operating costs do not include taxes and insurance, amounting to a yearly charge per dredge of $2 740 to $4 970; aver, $3 600 for all dredges but *I*. For the latter, annual taxes, etc, were $5 500 to $6 760. † First dismantled and rebuilt in 1916; finally dismantled in 1922. ** Not exact totals of tabulated items, due to dropped decimals.

(*a*) Loose sand and gravel on lava bedrock; very easy digging.
(*b*) Loose sand and gravel, with considerable topsoil, on lava bedrock. Bottom gravel, fair size and generally not easy digging. Considerable drift mining done in former years.
(*c*) Loose sand and gravel river bar; much sandy soil; easy digging.
(*d*) Tight clay and gravel, with 5–6 ft topsoil, 4–8 ft hardpan of varying hardness, and soft lava bedrock: similar to (*f*) and (*g*).
(*e*) Tight clay and gravel; some difficult hardpan digging; lava bedrock. Ground like (*d*), (*f*), (*g*).
(*f*) Tight clay and gravel, with 8–10 ft topsoil; like (*d*) and (*g*).
(*g*) Like (*d*) and (*f*). Prospect shafts stand for years with little caving.
(*h*) Worked in 3 benches; much maneuvering; tight clay and gravel, some hardpan. Both soft lava and hard bedrock.
(*i*) Loose sand and gravel, with 4–8 ft topsoil; soft lava bedrock. Very little clay, and bank not subject to excessive caving.
(*j*) Very loose sand and gravel on soft lava bedrock; no clay; considerable topsoil.



Steel hull 11 ft deep.
Weight 3,750 tons.
Maximum overall length 540 ft.
Installed load 2,171.5 hp..
Screen 8′–10″ dia., 50′–6″ long.

(*a*) New hull; some used machinery. (*b*) Incl labor, materials, power, ordinary taxes, and general expenses, but excl deprec and royalty. (*c*) Covered with rubber strips instead of usual iron. (*d*) Two 8-in pumps at 40- and 60-ft heads. (*e*) Some 1 3/16-in steel angles, some wood, shod with steel or rubber. (*f*) Compressing air for operating winch. (*g*) Excl deprec and royalty. (*h*) Machinery mainly of sizes usually installed on dredges with larger buckets, due to difficult digging. (*i*) Not reported.

Centerville, Idaho. Data from O. H. Metzger in 1938 (428). Gravel, 20–25 ft deep; deposit, 800–1 000 ft wide; 80–85% of material is finer than 0.5-in; largest boulders 6–8 in. Gold is mostly concentrated in 3–5 ft of gravel on granite bedrock; about 1 ft of bedrock is excavated where possible, but in places it is so hard that only a few inches can be taken. Dredging is carried full width of placer bed upstream. Dredge is all-steel with 2 spuds. Bucket line has 79 6-cu ft buckets, dumping at 22 per min; rated capac, 6 000 cu yd per 24 hr. Dredge takes a 6-ft cut and makes a sweep of about 100 ft. Trommel undersize goes to Pan-American jigs, where most gold is recovered; jig tailings are riffled. Payroll for the three 8-hr shifts (1937): 1 dredgemaster (salary); 3 winchmen @ $6.25; 6 oilers @ $5.00; 1 mechanic @ $6.50; 2 extras @ $6.00. A manager and an electrician are the only employes besides the regular dredge crews. Table 126 shows costs for dredging 1 596 000 cu yd in 1936.

Fairbanks, Alaska. Data from H. W. Rice, V-Pres U S Sm, Ref & Min Co, referring to operations in 1931, and quoted by Gardner and Johnson (18). Co was then operating

3 dredges on Goldstream Cr and 2 on Cleary Cr, respectively 14 and 25 miles from Fairbanks, where the company's steam-driven, elec plant of 8 125 kva capac was situated. Power distributed to dredging areas at 33 000 volts. All the gravels were permanently frozen, and covered with frozen muck to 120 ft depth. Moss, tundra and as much muck as would thaw naturally were stripped hydraulically with water brought 90 miles by ditch, siphons, and a 4 000-ft tunnel; capac of water system was 5 000 miner's in (delivering at press of 80–160 lb), practically all of which was used in stripping. Gravel thawed by cold water (Art 131), between about May 10 and Sept 20. Gravel 35 ft or less in depth was thawed by driven points at 16-ft c-c, requiring about half a season; in deeper gravels, points were set in churn-drilled holes 32 ft c-c, and thawing might not be completed in a whole season. Normally, enough gravel was thawed ahead of each dredge to provide a full season's work, usually about 210 days; re-freezing during winter penetrated only 7–8 ft, which depth thawed naturally early in summer. In season of 1931, stripping amounted to 7 011 000 cu yd, or 52 000 cu yd per day; thawing, 8 133 000 cu yd, or 64 000 cu yd per day; the 5 dredges dug 6 916 000 cu yd of material, or 30 800 cu yd per working day. Gravel contained few boulders over 12 in, and little clay. Gold was mainly close to bedrock, and might penetrate 5 ft into it, if of blocky schist. Table 127 gives construction and operating data on the dredges. Following additional features were common to all: hulls, all-steel, assembled in the field; housings, stacker, and ladder all heated; each hull had 2 spuds in the stern; bucket-chains, close-connected; trommels, pitching 1 $^5/_8$ in per ft, had successively $^3/_8$-, $^1/_2$-, and $^5/_8$-in holes in upper 3 segments, followed by 2 segments with $^7/_8$ by 1 $^1/_2$-in and 1 $^1/_8$ by 1 $^3/_4$-in slots; nearly all of gold was finer than 8-mesh, with a few nuggets up to 1 oz; transverse tables sloped 1.25 in, and longit tables 1 $^1/_8$ in per ft; Hungarian riffles were 1–1.25 in deep, 1 in wide, 2.25 in c-c.

Yukon Consol Gold Corp, Ltd. Data from W. H. S. McFarland, Gen Mgr (434) and G. R. F. Troop, Direc and Sec'y-Treas (435) in 1939. Accompanying statistical and cost tables were contributed personally by Mr. McFarland in 1940.

General. Co, with headquarters at Dawson, Y T, controls about 1 000 sq miles of placer claims and leases distributed along Klondike River and tributaries, and along several north tributaries of Indian River, south of the Klondike. Of 92 000 000 cu yd of gravel (containing gold worth $41 000 000) proved and in reserve at end of 1938, all except 8 000 000 cu yd of hill and bench gravels (to be hydraulicked or draglined) lies in creek valleys adapted for dredging. About two-thirds of the tested area was worked previously by drift or hydraulic mining; of 10 dredges operating in 1939, six were reworking such gravel. Only 2 dredges, those farthest downstream on the Klondike River and Bonanza Cr, worked in naturally thawed gravel; elsewhere, the gravel was almost completely frozen. Gravels in Dawson dist rarely exceed 10-ft depth, except in Klondike valley where max depth is 45 ft (aver, 30 ft). Gold, free and relatively coarse, is mainly in bottom of gravel and upper 4 ft of bedrock; if latter is blocky or slabby, as much as 10 ft of it is sometimes dug. Overburden of frozen, totally barren muck is 10–65 ft deep, usually covered by moss, sod, and brush. Working season is short. Preparatory work on dredges begins about Apl 1; first dredges (usually the larger, or those in richer ground) start towards end of Apl, followed by others as rapidly as increasing water supply develops necessary power at the central hydro-generating plant, until all are operating by mid-May. After Nov 1, diminishing water supply for power, with increasing freezing, lead to suspension, first of the smaller, and later, of the larger dredges; in the exceptionally favorable 1938 season, 2 dredges worked until Dec 24. During the summer, Co employs 600–675 men, of whom only 90 are retained through the winter. Min wages for common labor, 50¢ per hr, plus keep, totaling $7.28 for 10-hr day. Cost of supplies includes freight charges of $55 (for machinery) to $135 per ton from Vancouver to Dawson, *via* Skagway and Whitehorse, plus local transport by truck and tractor, until recently costing about 50¢ per ton-mile.

(*a*) For depth of muck at those sites where thawing was required, see Table 149. (*b*) 1 in-day = 1.5 cu ft per min for 24 hr. (*c*) Cu yd, per in-day. (*d*) Itemized costs for some examples are in Table 130.

Stripping of frozen muck is done as in hydraulic mining (Art 123), with water supplied under press from ditches, or by pumping from local streams; suitable press, 50–120 lb per sq in. After providing channels for run-off into nearest natural outlet, a row of 8 or 10 No 2 giants with 3.5-in nozzles is so arranged that consecutive portions of the area can be stripped in rotation, with

little moving of the giants. When the thawed muck has been removed from one portion, the next giant is put into action, leaving the first area to thaw naturally. By the time the last giant in the row has finished its work, the area adjacent to the first will have thawed enough to allow removal of another layer. Distance, in ft, worked from a giant is roughly 1.5 times the water press in lb per sq in. Tailings piles, often complicating the procedure, are removed by a special set-up of a giant before attacking the muck. **Pumps** for stripping are 10-in centrifugals, rated at 3 000 US gal per min at 150-ft head, suitable for a 3.5-in nozzle; each is driven by 150-hp 2 300-volt, synchronous motor. Each unit, with starting equipment, is

(*a*) Rebuilt. (*b*) Direct charges include: Wages; Mess and camp expense; Repair parts; Other supplies; Machine and electrical shops; Transportation; Power. (*c*) Indirect charges include: Stripping; Thawing; Prospect drilling; General expense; Bullion expense; Engineering; Supervision; Sundry. (*d*) Itemised in detail in Table 132.

housed in a portable building, 18 by 10 ft, mounted on skids. Active stripping is feasible only between mid-May and end of Sep; preparatory work begins about a month earlier. Table 129 gives operating data, and Table 130 itemizes costs of such stripping at 7 of the Co's dredge sites.

Thawing is applied to the frozen gravel exposed (as completely as practicable) by removing the muck; the cold-water method is employed. For details and costs, see Art 131.

Dredging. At end of 1939, Co was operating 10 dredges (No 2–11, incl; No 1 was dismantled in 1938 after 33 yr service on 3 sites). All have wooden hulls, and are elec operated. Table 131 gives data and costs for 3 yr on 6 dredges, No 2–7. No 8, a 7-ft Yuba dredge, handled 455 453 cu yd in its 161-day season of 1938, at total cost of 21.72¢ per yd. No 9 is a 5-ft Bucyrus, re-built in 1938; No 10 and 11 are both 7-ft Yubas, built 1939. A new 7-ft dredge in the Klondike costs about $350 000, exclusive of camp buildings, power-line connections, roads, and stripping and thawing equipment; to justify such installation would require about 10 000 000 cu yd (on basis of aver value of present reserves) or a life of 15 yr. Table 132 gives itemized costs for 1938 at 2 dredges selected to represent: (No 3) a large-scale operation in naturally thawed ground on Klondike River; and (No 6) a smaller operation in ground which had to be both stripped and thawed. The 9 dredges working in 1938 dug a total of about 8 500 000 cu yd and produced gold worth $2 131 000 (25.1¢ per yd); 2 of these dredges were working in unproved ground. These 9 dredges, with accessory thawing and stripping equipment, power plant, camps, buildings, and ditches, represent an investment, at cost, of $6 750 000.

Hydro-elec power plant, of 15 000-hp, is situated on Klondike River about 28 miles above Dawson. Its three 5 000-hp turbines, at 220-ft head, drive one 4 690-kva, and two 3 000-kva generators, delivering at 33 000 volts. First water supply came from the North fork of the river, through a 6-mile ditch; added supply of 10 000 miner's in from the South fork was obtained by a 16-mile ditch. The high-tension line is 94.3 miles long; distributing lines, at 2 300 volts, 37.4 miles. Table 133 gives costs of operating and maintaining the power plant.

Bulolo, New Guinea. Contributed by C. A. Banks, Mng Dir, in 1940; for earlier and more detailed data, see Bib (436). Operations are noteworthy because entire equipment of 8 steel dredges and 2 hydro-elec plants delivering 8 000 hp was transported by aeroplane. Beginning in 1931, 30 000 short tons of machinery and supplies were flown up to 1940 without fatal or disabling personal accident, or loss of any equipment. Airline distance from aerodrome at Port Lae to 2 landing fields 5 miles apart on property is only 35–40 miles, but an intervening 5 000-ft range with lowest pass at 4 000 ft, and difficult jungle conditions, made land travel by 110-mile road slow and costly; air transport is estimated to have saved 2 years' time. Flight from Lae to Bulolo takes about 40 min, and the round-trip, incl loading and unloading, about 2 hr. Elev at property is 2 250 ft. TRANSPORT EQUIPMENT includes 3 Junker G–31 aeroplanes, each with three 550-hp Pratt & Whitney Hornet engines. Cargo compartment is 24 ft long, 77 in wide, 69 in high except over the hatch, where height is 82 in; hatch opening, 60 by 141.5 in. Planes were designed for pay-load of 7 000 lb, but 8 000 lb have been carried safely; loads aver about 5 000 lb. Heaviest single pieces (upper-tumbler shafts) weighed 6 950 lb each for the first 4 dredges, and 7 550 lb for No 5. Total capital outlay for air transport was considerably less than would have been required for construction of suitable road and purchase of vehicles. UNIT COST OF AIR TRANSPORT has declined with increasing tonnage and introduction of certain economies. During 54 mos prior to 1937, cost for 14 341 short tons was $49.94 per ton, plus amortization then estimated at $11.85 per ton. During 3 yr to end of 1939, costs on basis of 420 tons monthly were as in Table 134. Gasolene cost about 32.5¢ per Imp gal (27.1¢ per U S gal). Now that the property is fully equipped for

a life estimated at 16 yr, future transport will be limited to a reduced tonnage of supplies and replacements. Extra cost for design and erection of the dredges, incurred by necessity for sectionalizing, was estimated as 10% for the hulls and 5% for the machinery. DREDGING started in Mch, 1932, with 1 dredge, which was followed by 2 others within the next 2 yr; No 4 began dredging in Aug, 1934. Two more were added at intervals, putting 6 dredges at work by mid-1938. First 4 dredges all had 10.5-cu ft buckets, and dug respectively 29, 35, 52, 59 ft below water; to May 31, 1936, they had handled 32 600 000 cu yd. Costs for 6 fiscal yrs, and aver costs for period, are in Table 135, in U S cents per cu yd. GOLD-SAVING EQUIPMENT on all dredges (as of 1937) includes double-deck tables 21 in wide, 12 ft long, with Hg in wells at top and on riffles. Table tailings go to jigs. Hutch product, 100–150 tons per day, or about 1% of gravel treated, passes through rubber-lined tube-mill 11.75 ft long, 50 in inside diam, loaded with about 1.5 tons of 1.5-in steel balls, and then over amalgamated plates. A flotation cell was installed on 1 dredge, with good saving, but was later found unnecessary when jigging was adopted.

Colombia. C. A. Banks, Managing Director Pato Consol Gold Dredging, Ltd, contributes data on operations of the 3 largest and most typical of Co's 5 dredges, working a property which extends 16 miles along the Nechi River, Zaragosa dist. Equipment includes 2 hydro-elec plants, totaling about 12 000 hp. Table 136 gives costs, in U S ¢ per cu yd, for fiscal yr ended Apl 30, 1939. Each dredge has 13.5-cu ft buckets, and was designed to dig (at 24–26 buckets per min) 3 500 000–4 000 000 cu yd annually; max digging depth is 75–80 ft on Boyacá dredge, 65–67 ft on the others. Jobo dredge has been operating partly on ground covered with 40 ft of barren clay and partly on a bench where a high bank was unavoidable. San Francisco dredge (during yr stated) worked mostly in tailings, with some patches of virgin ground which escaped earlier dredges; digging was relatively easy. Boyacá dredge operated in a low, swampy area, with 50 ft of sand overburden; digging moderately easy. All dredges are equipped with Placer rougher and Pan American pulsator cleaner jigs, treating overflow from riffled tables. Final jig concentrate passes over amalgamated plates, tailings going to a scavenger jig, hutch product of which is ground in a 2 by 4-ft ball mill and returned to the cleaner cells.

Bright, Victoria, Australia. H. S. Elford, in 1935, gives mechanical details and operating costs of a steam-driven, flume-type dredge working in gravel averaging about 24 ft deep (439). Buckets are of 7.5-cu ft capac. Ladder has overall length of 78 ft 9 in; wt, 35 tons. Dredge digs 35 ft (max) below water line. Hull, of $^5/_{16}$-in riveted steel plate, is 111 ft long, 38 ft 9 in wide and 7 ft deep; draft, 5 ft 3 in. Bucket drive is from a compound, condensing, 125 hp Marshall engine, running at 110 rpm and driving the first-motion shaft through eight 1.75-in manila ropes. By reduction gears, top tumbler is given a speed of 4 rpm, delivering 18 buckets per min.

Steam at 150-lb press is from a wood-fired, multi-tubular boiler, burning 200 cords of eucalyptus per mo; delivered cost of wood, 13 sh per cord. Main winch is driven by a 12-hp, twin-cylinder engine. Dredge buckets deliver into a chute feeding a duplex shaking screen, set at slope of 1.25 in per ft, and making 70 8 75-in strokes per min; holes in upper section are $^3/_8$- and $^1/_2$-in; in lower section, $^{11}/_{16}$-in. Oversize material is delivered by "stone chute" 25 ft behind the boat. This chute has semi-circular section, 3.5 ft diam, and is lined with 4 by 0.75-in steel wearing plates. It is suspended by wire ropes from an 8 by 4-in channel 3 ft above bottom of the chute. Screen undersize passes to gold-saving sluices, lined with coconut matting under expanded metal. Most of the gold is caught in the first 6 ft of sluices, the upper 12 ft of which is covered with a steel plate locked in place to prevent theft of gold. Sluice tailings pass into a single launder discharging 42 ft behind the dredge, or 17 ft beyond the stone chute. On clean-up, dredging stops, and expanded metal and matting of all launders are removed. Concentrate is washed out of the matting in a launder and collected behind temporary riffles; then transferred to an amalgamator. Aver capac of dredge is about 16 000 cu yd weekly, from 0.42 acre. Table 137 gives working costs for three 4-week periods in 1935.

Lakekakamu, Papua. Data from J. W. Hinks in 1937 (440). Operation of Tiveri Gold Dredging Co, Ltd, is noteworthy for diminutive size of dredge. Bucket line has 34 buckets of 1.25-cu ft capac, and gross wt of entire plant is only 59 tons; wt of individual parts was limited to permit transport by native carriers; heaviest single part, 725 lb. Bucket ladder can dig 15 ft below water level. Dredge has a steel hull, 50 ft long, 20 ft wide, and 3 ft deep, divided into 6 water-tight compartments.

Power supplied by two 40–60-hp Industrial Marine engines, with clutches permitting either or both to be used. Fuel is producer gas, but engines will operate, without alteration, on benzene or kerosene. Working for 2 yr on producer gas, fuel consumption was 40 lb charcoal per hr; charcoal is from kiln-burning the jungle timber First recovery is in a sluice 36 ft long by 3 ft wide, with angle-iron riffles and slotted plate over coir matting. Discharge from sluice passes over a grizzly from which the fines return over sand tables covered with expanded metal over coir matting. Oversize discharges behind dredge through a flume. Results for 2 yr ending June 30: In 1936, 154 824 cu yd and in 1937, 158 135 cu yd, cost 8 pence per cu yd.

Resoiling. In normal operation, a dredge destroys the value of land for agriculture, but sometimes, where all conditions were favorable (see below), resoiling has been successful, though at added cost. In most cases, some manual or mechanical work has been needed to complete reconditioning the surface. A dredge operating with headline (Art 127) spreads its tailings more evenly than a spudded dredge, but will still bury the topsoil unless special methods are adopted. A resoiling dredge, with spuds, was developed by the Natomas Co for service in Calif, but proved uneconomical under existing conditions. A similar dredge, by Yuba Mfg Co in 1918, operated satisfactorily in valuable rice lands of Korea, abundant cheap labor being available for final leveling; such land is said to be ready for a crop 6 mos after dredging. C. M. Romanowitz enumerates following conditions for successful resoiling: (*a*) bedrock fairly smooth and level; (*b*) bedrock at nearly uniform depth below surface, within area to be dredged; (*c*) gravel fairly shallow, and water level in pond only slightly below ground surface; (*d*) deep topsoil; (*e*) cheap labor, or effic mechanical methods for final leveling; (*f*) land, or gravel, must be worth enough to justify added cost (above normal dredging) of at least 1¢ per cu yd.

Newstead, Victoria (441). An area of 381 acres on Loddon River, estimated to contain 15 000 000 cu yd of gravel averaging 3.64 grains gold (26.6¢ with Au @ $35 per oz) per cu yd, to aver depth of 24.5 ft, was to be dredged (beginning early 1938) in such manner as to restore surface for farming while avoiding discharge of silt into river. Gravel is covered by 12–13 ft of loam and sandy clay. In its digging, screening, and gold-saving features, the dredge design is conventional. A close-connected chain of 9.5-cu ft buckets is carried on a ladder 72 ft long between centers of tumblers; at 45° inclination, digging depth below water is 27.5 ft; by raising the ladder until bottom tumbler is out of water, a bank 16 ft above water can be dug separately. At 21 buckets per min, output of dredge is 175 000 cu yd per mo. For full details of construction, see Bib (441).

Special features required for resoiling (Fig 854): (*a*) Receiving end of stacker belt, 42 in wide, is moved forward to a point in front of the high end of the trommel; passing under the latter, the belt rises from the stern at 18° and discharges 25 ft above and 104 ft behind the deck; total length of stacker-conveyer, 160 ft. (*b*) Chute from bucket-discharge hopper to trommel has a removable bottom segment, under which is another chute which delivers the entire bucket-discharge to the tailings stacker, by-passing the screen; this is done while ladder is working in dry soil above gravel. (*c*) Chute delivering screen oversize to stacker belt also has a removable bottom segment, through which the coarse tailings can be dropped (*via* another chute) into the pond 15 ft behind the stern. (*d*) Longit sluice boxes terminate in 4 tail chutes discharging sands 25 ft behind the stern. These modifications reverse the usual order of depositing tailings, the coarse now being on bottom, sands in middle, and soil on top. AVOIDANCE OF SILTING. Tract was prepared in advance by building levees 35 ft wide at base, 4 ft wide at top, and averaging 9 ft high, or 2 ft above highest recorded water level of river. A settling dam was provided at elev above highest flood water. To this, dirty water from dredging pond was to be pumped, clarified water returning to pond, makeup water being pumped from river.

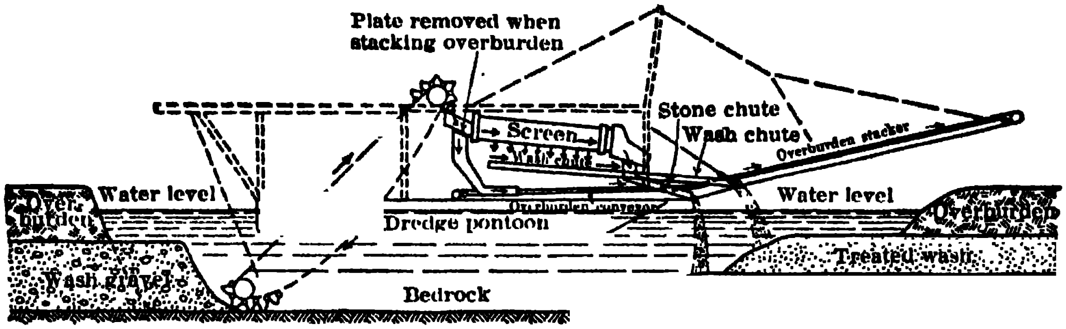

Fig 854. Dredge Equipped for Resoiling, Newstead, Victoria

129. DRAGLINE DREDGING

By CHARLES WHITE MERRILL, U S Bur Mines, San Francisco

General. The washing plants are mounted on scows or pontoons to which gravel is delivered by dragline excavators standing on dry land; for analogous methods employing stationary or movable washers on land see Art 122. The excavator retreats as it cuts away the bank on which it stands; the washer is floated into the newly-dredged pond. Early installations included a plant built in Siberia by American engineers in 1910; after 2 seasons' operation, the washer was converted into a bucket-ladder dredge. Present practice began in 1933, when 2 plants were built almost simultaneously near Oroville, Calif, and Helena, Mont. Table 138 shows the great expansion of the method in Calif since 1933; many plants are now at work also in Alaska, Ida, Mont, Ore, Colo, Ariz, Nev, and the Philippines. Recent changes in the method and its expanding production have made much of its literature obsolete. The rapid advance of the industry resulted in part from the need for a new method, but the coincident rise in price of gold was a major factor in its widespread acceptance. The special field of the dragline dredge is in working deposits too small to warrant installation of bucket-ladder dredges (Art 127, 128).

Table 138. Dragline Dredging in Calif, 1933–1938. (Minerals Yearbook, 1939, p 235)

Year	Production units		Material treated	Gold recovered		Aver value per cu yd, ¢	% of total Calif placer gold
	Mines	Dredges	Cubic yards	Fine oz	Value		
1933	2	2	11 500	75.26	$ 1 924	16.0	..
1934	4	4	604 000	3 466.04	121 138	20.1	1
1935	24	24	3 906 000	22 191.47	776 701	19.9	6
1936	30	31	10 016 000	49 976.54	1 748 864	17.5	12
1937	51	55	19 364 000	94 142.00	3 294 970	17.0	20
1938	77	80	24 560 000	118 108.00	4 133 780	16.8	21

Requirements for successful operation. (*a*) Easy-digging gravel, with few boulders (dragline lacks the digging power of a shovel or a bucket-line). (*b*) Max depth below water, about 30 ft; general aver has been 10–12 ft; ideal digging, 16 ft (working depth of gravels has increased steadily). (*c*) Fairly smooth, soft, unfissured bedrock; dragline digging under water is less effective in recovering bedrock gold. (*d*) Gravel of sufficient richness (including in the average such barren gravel as must unavoidably be handled) to pay expenses about 50% higher per cu yd than those of a bucket-ladder dredge. Direct working costs of dragline dredges in the U S in 1937 were 6–15¢ per cu yd (165); aver gold recovery in Calif in 1938 was 16.8¢ per cu yd. (*e*) Sufficient yardage of profitable gravel to cover amortization of equipment (cost of plants is from $40 000 to $200 000); the whole yardage need not be contiguous, since the plant is readily moved from one deposit to another; provision for moving expenses (Table 139) must be included in cost estimates. (*f*) Topography not much rougher than for bucket-ladder dredges; if the gravel will hold water, by using bulldozer and dragline on ditches and levees, ponds can be made that enable a washing plant to climb slopes as steep as 5%, but they generally work on much lower gradients.

(*a*) At Redding, 25 tons of parts were added before rail shipment. (*b*) All in Calif except Realito, Sonora, Mex. (*c*) Customary to make convenient repairs during assembly, without segregating their cost; above estimates include no such repairs.

Usual equipment. Dragline EXCAVATORS commonly have 1.5–2.5-cu yd buckets (max to date, 5 cu yd), 45–65-ft booms, and are driven by 125–150-hp Diesel engines (a few have elec or gasolene drive); buckets, especially where gravel is tight, are usually 0.25–1 cu yd less in capac than that for which the rest of the machine is designed. Usual output is 90–125 cu yd per hr of working time. WASHERS (Fig 855) mounted on steel pontoon or wooden scows 25–40 ft wide, 35–50 ft long, and drawing 30–40 in of water, have gold-saving equipment practically identical with that on bucket-ladder dredges (Art 127). Dumping from a dragline bucket, however, requires addition of a hopper, 10 or 12 ft square at top, and about 15 ft above water. The intermittent feed is equalized as far as possible before reaching the tables by: (*a*) making the hopper with low-sloping sides, on which powerful water jets impinge; (*b*) by equipping the first section of the trommel as a scrubber; (*c*) by using screens, retards, lifters, and Archimedean screws in the trommel; failure to equalize the flow of gravel is a prime cause of poor recovery. Recommended total area of tables on a washer receiving 150 cu yd per hr and discarding about 50% of screen oversize is at least 500 and preferably 600 sq ft; width of a single table should not exceed 30 in, due to interference with its smooth flow by careening of the scow when a load of gravel is dumped into hopper. Stackers are 40–60 ft long, with belts 24–36 in wide. Diesel engines of 50 to 100-hp are commonest source of power for driving pumps, trommel, stacker, and jigs; usually the power requirement of the dragline excavator slightly exceeds the total needs of the washing plant. Most plants include tractor with bulldozer, one or more trucks, portable pumping unit for fresh water to pond, a blacksmith shop, and welding outfit (when digging is difficult, the replacing of bucket teeth is a major expense). Stripping barren overburden by scarifier, carryall, and bulldozer is often economical. Table 140 gives data on 6 typical dragline dredges operating in Calif in 1937, from Gardner and Allsman (165). Boulders over 12 in were absent in all cases. Sluices were at grade of 1.25–1.5 in per ft; upper ones had iron-topped wooden riffles (except No VI, which used 1.25-in angles); lower sluices (in all but No VI) were riffled with expanded metal laid on carpet, matting, or burlap.

Cost of dragline dredges. Setting up the outfit is mainly a matter of selecting and assembling large units of ready-built machinery; excavators and buckets, trucks, and bulldozers are always ready-made. Washing plants can be bought ready to assemble or are designed and built at the mine. Table 141 gives prices for 4 typical outfits built in 1939.

General procedure. Most gravels worked by dragline dredges are recent stream deposits. If channel is not more than 50–60 ft wide, its full width generally is taken in 1 cut (Fig 856-A), the washer following close behind and discharging tailings behind itself, screen oversize by stacker, and sands into the pond. A wider channel may be worked in successive cuts parallel with the stream, but it is better (Fig 856-B) to take successive 15 to 20-ft cuts back and forth across the channel. (Compare with land dredge at Atlantic City, Wyo, Art 122.) One advantage of latter plan is that the bedrock can be scraped (with improved recovery) in more than one direction. By either method, position of the boat is adjusted by 4 wire ropes anchored to deadmen on shore and held taut by winches on the boat; spuds (Art 127) are usually unnecessary. Following examples illustrate practice as of 1936–1938.

Wyandotte Cr, Oroville. Data from J. F. Magee (442) in 1936. GRAVEL is in 2 beds; upper, loose and easy to dig; lower, slightly harder; both well rounded and of medium size (60% on $^3/_8$-in). Gold is fine; bright in upper gravel, less so in lower. Depth to false bedrock (decomposed volcanic ash easy to scrape), 4–25 ft, aver 12 ft; max depth dredged, 24 ft; usual working depth 9.5 ft, leaving lower bed intact when necessary. Parts of area have up to 2.5 ft of overburden. DRAGLINE, Lima type 601, caterpillar-mounted; Diesel 102-hp engine; 60-ft boom, 1.25-yd bucket; on aver digging, it delivers 2 heaping buckets per min, or 150 cu yd per hr. WASHER is on a wooden scow drawing 25 in of water when fully loaded (displacement, 65 tons). Hopper, 10 by 10.5 ft at top, has bottom sloping 25°; water jets regulate discharge of gravel. Trommel, 25 ft by 48 in, has 4-ft scrubbing section and 5-ft blind lower end; middle 16 ft has $^3/_8$-in holes, 1 $^1/_8$ in c–c throughout; slope, 1.5 in per ft. Cross-sluices, 7 on each side, are 27 in wide and discharge into a 4-ft sluice on each side; all grades, 1.5 in per ft; total sluice area riffled (iron-topped wooden cross-riffles), 480 sq ft; extensions of side sluices deposit sand tailings 12 ft behind rear of scow. Stacker for screen oversize, 45 ft long, with 24-in belt. Wash water, delivered by centrif pump with 7-in discharge at 1 200 gal per min, is distributed: 84% to trommel sprays, 14% to hopper chute, 2% to skimmer jet to keep the strainer free from floating trash. Purchased water, 40 miner's in. Whole washing plant is driven by 50-hp, 4-cyl Diesel. OPERATION is similar to that in Fig 856-A; pond is 70 ft wide and about 75 ft long. During first 3 mos of operation, all delays amounted to 34.5% of possible time, largest single source of lost time being the moving of dragline, which was then on soft ground. COSTS of Wyandotte operation are compared in Table 142 with those of 2 others (localities not stated), practically identical equipment being employed at all 3 places. Digging and washing conditions differ as follows: At Plant *A*, gravel (9.5 ft deep) is finer (30–40% on $^3/_8$-in), but harder both to dig and wash; bedrock, of decomposed granite, digs easily but is difficult to distinguish from bottom of gravel. At Plant *B*, gravel (6 ft deep) is loose and sandy, with much coarse (60–75% on $^3/_8$-in) making for easy washing; bedrock favorable and easily recognized when reached.

Milton Gold Dredging Enterprise, Milton, Calif. For geol, structural, and operating data, see Table 140, col VI; following added information is from Julihn and Horton (57) in 1938. Installation is one of few dragline dredges operated entirely by elec. Trans-

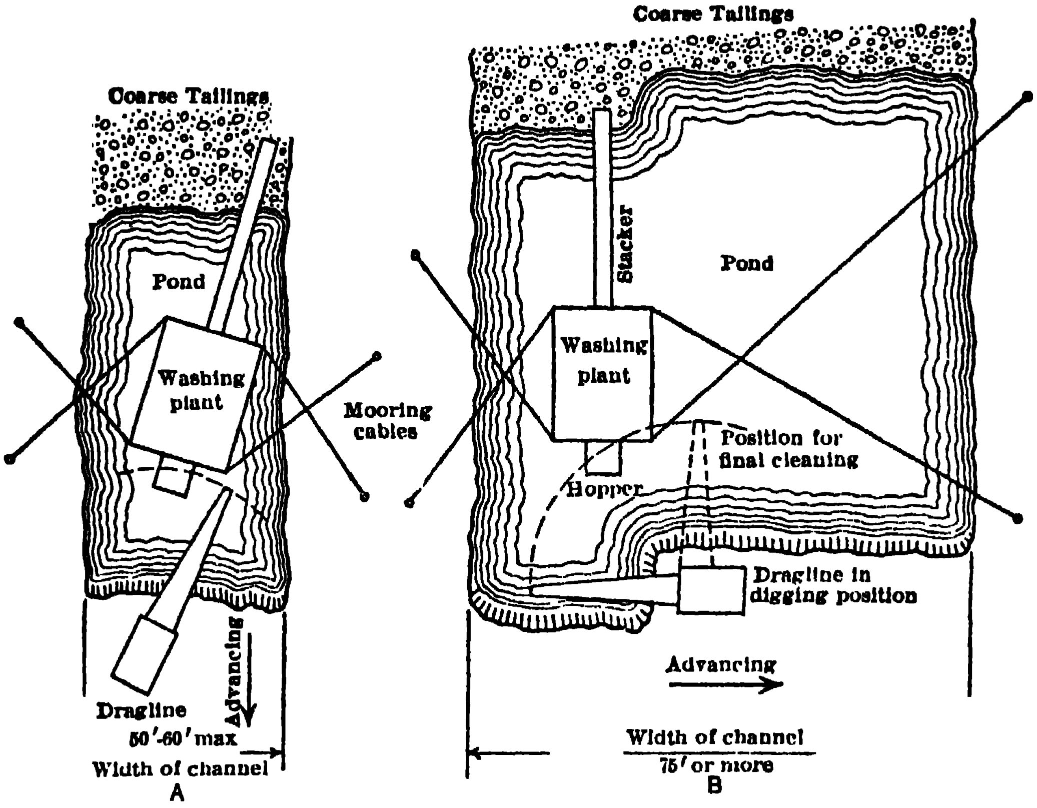

Fig 856. Two Procedures in Dragline Dredging

formers (4 000–440 volts) are mounted on a wheeled trailer. Ground was carefully prospected with 7 pits to bedrock per acre, each being groove-sampled on up-stream and down-stream sides; no factors to cover bedrock or washing losses were applied. Dredge cuts, surveyed monthly, coincided approx with blocks as used for estimating (Art 11); aver recovery from over 1 000 000 cu yd was 0.2¢ or a little more than 1% above estimate. Crew for 3-shift work comprised 12 men and foreman at (weighted) aver wages of $5.75 per day. Water (50 miner's in) cost 11.25¢ per day-in. Power (at 1.1166¢ per kw-hr) for a typical month's operation was 29 500 kw-hr on washer, 20 200 kw-hr on dragline, 900 kw-hr for welding, lights, and shop. During first 2 yr, all time lost (incl several groundings and a sinking of washer) was 30.8% of elapsed time. Aver total cost, on basis of 1 234 908 cu yd (bank measure) handled in 2 yr ending Aug 31, 1937, is itemized in Table 143.

Lilly mine, Camanche, Calif. Data from Julihn and Horton (57) in 1938. Gravel, 4–18 ft deep, is uncemented, and contains no boulders; bedrock, volcanic tuff. Gold fine and flaky. Similar gravel in adjoining tract averaged 16¢ per cu yd in test pits. Dragline, Diesel-powered, has 60-ft boom and 2-yd bucket; normal output, 100–125 cu yd per hr. Washer is on 50 by 36-ft scow, composed of 5 wooden pontoons drawing 2 ft of water. Trommel, 32 by 4.5 ft, has 8-ft scrubber, 18 ft of $^3/_8$-in, and 2 ft of 0.5-in holes. Wash water, 3 200 gal per min. Stacker, 50 ft long, with 26-in belt. Total (Hungarian) riffled area of 16 cross-sluices and 2 lateral sluices, 1 500 sq ft. Clean-ups, every 10 days; mercury supplied during interval, 225 lb; loss of mercury, 6–7 lb at each clean-up.

Fresh water for pond is pumped 2 miles through 8-in pipe against 420-ft head. Washer equipment driven by individual elec motors: 30-hp for trommel, 40-hp for wash-water pump, 7.5 hp for stacker. Crew for 3-shift work: 3 operators, 3 washer attendants, 3 laborers; 2 blacksmiths on day shift to maintain bucket teeth, wear on which is very severe. Of 2 close neighbors of the Lilly mine, one suspended operations owing to expense of saving rusty gold, the other because the gravel proved too hard for a 100-hp gasolene dragline with 1.25-yd bucket.

Boise Basin, Idaho. Data from O. H. Metzger (428) on 2 dragline dredges operating in 1937. (*A*) On Grimes Cr, above Pioneerville. Stream gravels 75–100 ft wide, 6–8 ft deep; little overburden (gravel previously worked by hand) but heavy brush, which was cleared by caterpillar tractor. Excavation by Diesel-driven 1-yd dragline. Washing plant, on steel pontoons, had 4-ft trommel in 4 sections with $^3/_8$-in holes; tables covered with carpet and expanded metal. In 3 mo, plant advanced 1 mile upstream, treating 75 000–85 000 cu yd of gravel. (*B*) On a tributary of Fall Cr, west of Granite. Bench gravel about 15 ft deep, more firmly consolidated than stream gravel, with 5 ft of topsoil which was stripped and piled at sides. Excavation by Diesel 3-yd dragline with 65-ft boom, delivering 75 yd (aver) per hr. Washer was on six 8 by 36-ft steel pontoons assembled from $^3/_{16}$-in plates at the property; it had a 5-ft trommel in 10 3-ft sections ($^3/_8$-in holes differently spaced), delivering to 10 tables on each side, covered with Brussels carpet and expanded metal (which proved better than Hungarian riffles). Individual motors for trommel, 2 centrif pumps (10- and 5-in), stacker, etc, were supplied by 100-kw Diesel-driven generator on boat. Labor, 3-shift: 3 operators, 3 oilers, 2 shoremen, 1 dredgemaster.

Mill Gulch, Tenabo, Nev. Data from W. O. Vanderburg (443) in 1939. Ravine deposit of sand and medium-size boulders, 200–300 ft wide, is 10–45 ft (aver 30 ft) deep; gold, both fine and coarse, is mostly close to bedrock. Link-Belt dragline has 60-ft boom and 1.75-yd, heavy-duty bucket. A caterpillar tractor-bulldozer is used for grading. Washer is on wooden scow, 30 by 40 ft, with 3 additional steel pontoons; draft, 40 in. Estimated (3-shift) capac, 1 500 cu yd per day. Trommel, 24 ft by 54 in, is in 2 equal sections; upper, unpunched, has spiral disintegrating flights; lower, $^3/_8$-in holes. Six cross-sluices on each side are 30 in wide by 12 ft long; total (Hungarian) riffled area, 460 sq ft. A 6-in centrif pump circulates wash water, pumped to the pond from a well through 15 000 ft of 8-in pipe against 500-ft head. Stacker is 70 ft long, with 24-in belt. A 160-hp, 8-cyl Diesel supplies all power. Crew, 16 men, 3-shift. Clean-ups daily.

130. DRIFT MINING

Drift mining is the exploitation of placers by underground methods. It was one of the early types of mining in Calif, reaching its peak between 1870 and 1880; thereafter it declined and almost ceased (57). Since 1933, due to higher price of gold, a revival of drift mining has occurred.

Field of use is in mining rich paystreaks of moderate thickness, where open-cut methods are impossible or would yield a smaller net return. Large boulders must usually be blasted; if numerous, they may increase cost to a point which is prohibitive. Drift mining has been practiced chiefly in the ancient buried channels in Calif, the buried beach placers at Nome, Alaska, and the deep leads of Australia (Art 117). Alaska creek gravels, where frozen, are often drifted, especially by small operators. In early Calif and Alaska mining, many placers were drifted for rich streaks by miners with small capital, later the same deposits were profitably hydraulicked or dredged (385). Drift mining costs more than open-cut work, hence requires richer gravels to yield a profit. Ordinary thickness of gravel mined is 5 to 8 ft; up to 10 or 15 ft in rare cases, and down to 3 or 4 ft, which is about minimum for economic work in flat openings.

General plan. The methods of OPENING are the same as for other underground mining (Art 14–16), with emphasis on a mode of entry that will drain the workings and eliminate equipment and costs for hoisting and pumping. But tunnel or drift entries are limited to bench gravels or other elevated deposits like the old Calif channels. Details of LATERAL DEVELOPMENT (Fig 857–859) vary widely with local conditions. In general, a central haulageway is driven from the point of entry close to the long axis of the paystreak, and on or partly in bedrock; in Calif and Victoria, this opening is sometimes entirely in bedrock and connected by chute-raises with the workings in the gravel above. Crosscuts are driven from the central drift to the RIM of the channel, or limits of the paystreak; auxiliary drifts also are driven in wide deposits. These openings have both a mining and an exploratory function, latter often predominating in fixing the dimensions of the blocks of ground. MINING is done by a form of longwall-retreating (Art 108), called "breasting"; advancing longwall has been used in a few cases. Ground is broken with picks where possible; by hand drilling and blasting where necessary. Frozen gravel is usually thawed before it is excavated; for exceptional case, see Idaho Mining Co, below. The roof of working places is temporarily supported by timber; posts and head boards serve in firm, cemented, or frozen ground; spiling or forepoling may be necessary in loose gravel. Barrows are best for transport in small mines or under low roof; otherwise tracks are laid along the working faces and the gravel shoveled into cars. Tracks are shifted bodily after the face has advanced 6–8 ft. Equipment for haulage, hoisting, and pumping is the same as in metal mines of similar area and output.

Fig 857 typifies early work in Calif in WIDE deposits (456, 457). Main haulageways *H* are 6 ft by 6 or 7 ft in the clear, often requiring heavy drift-sets and close lagging. Some of these mines covered large areas, making the maintenance of haulage openings a serious item. Crosscuts *C* and auxiliary drifts *D* are 5 by 6 ft or 6 by 6 ft, timbered and lagged in soft ground, but not in as permanent a manner as the main haulageway. Crosscuts *C* may be driven at an angle to the bedrock slope to secure the desired haulage gradient. Breasting begins at the ends of drifts *D*, and retreats towards the crosscut from which they were driven. Successive positions of the working faces are indicated by dotted lines *S*. Short breasts (Fig 857) allow partial control of roof press by regulating speed of advance and distance apart of working faces. In compact gravel requiring blasting, little care was taken to keep breasts "faced-up" evenly; it was cheaper to break from the corners of blocks. Fig 858 shows breast timbering at the Hidden Treasure (457); it is the usual form for soft gravel.

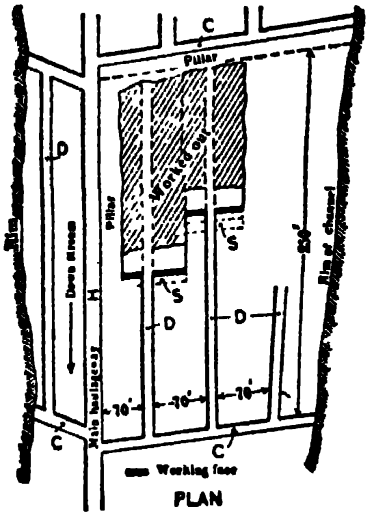

Fig 857. Layout of Wide Drift Mine, Calif

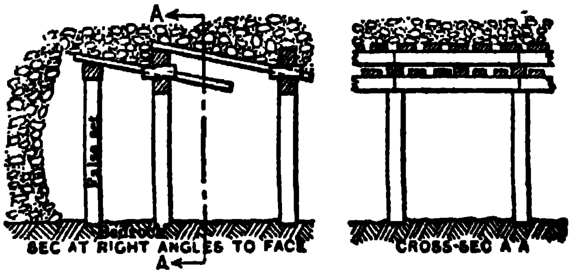

Fig 858. Breast Timbering, Hidden Treasure Mine

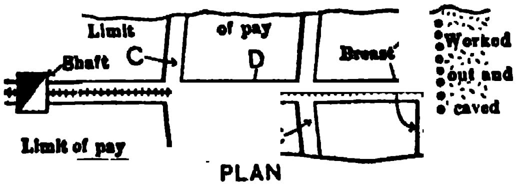

Fig 859. Layout of a Drift Mine in a Narrow Paystreak

Fig 859 shows a layout for paystreaks 75 to 100 ft wide, typifying early work in Alaska; also that in NARROW paystreaks in Calif. Central drift *D* may connect with a shaft or an adit; it usually requires timbering even in frozen ground. Prospecting crosscuts *C* are driven at intervals; in frozen ground they are generally untimbered. Breasting is carried the full width of the pay, retreating towards the point of entry. Breasts are timbered with sets in heavy ground, with posts and caps in moderately firm ground, or left untimbered in solidly frozen ground.

Fig 860 shows an advancing method of breasting. It has been applied in Alaska and Calif to narrow, irregular deposits where straight haulage drifts, driven ahead of stoping, are not feasible. A gangway is kept open through the worked-out area by timbering with light 3-piece sets and tight lagging (459).

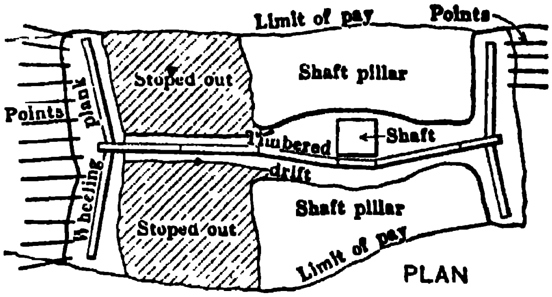

Fig 860. Advancing System (after Ellis)

Washing gravel. At mines opened by a drift or tunnel, cars are dumped at the portal into a bin feeding a sluice. Sluicing is rarely continuous; bin is flushed out periodically by a small giant working under low head. At shaft mines, gravel is usually hoisted high enough above surface to give headroom for sluices and tailings disposal. Gravel may be dumped directly into a box (Fig 828) at head of an elevated sluice, or into a bin for intermittent sluicing. Latter plan is usual at small mines and where water is scanty or costly. Bins hold a day's output; upper sluice boxes are cleaned up after each run; frequent clean-ups are advisable due to relative richness of gravel. In the far North, sluicing is impossible in winter; gravel is stacked on surface and sluiced in spring and summer. In Calif, tough cemented gravel is crushed in stamp mills fitted with coarse screens, and then sluiced. Gravel containing much sticky clay may be passed through trommels or puddled, before sluicing.

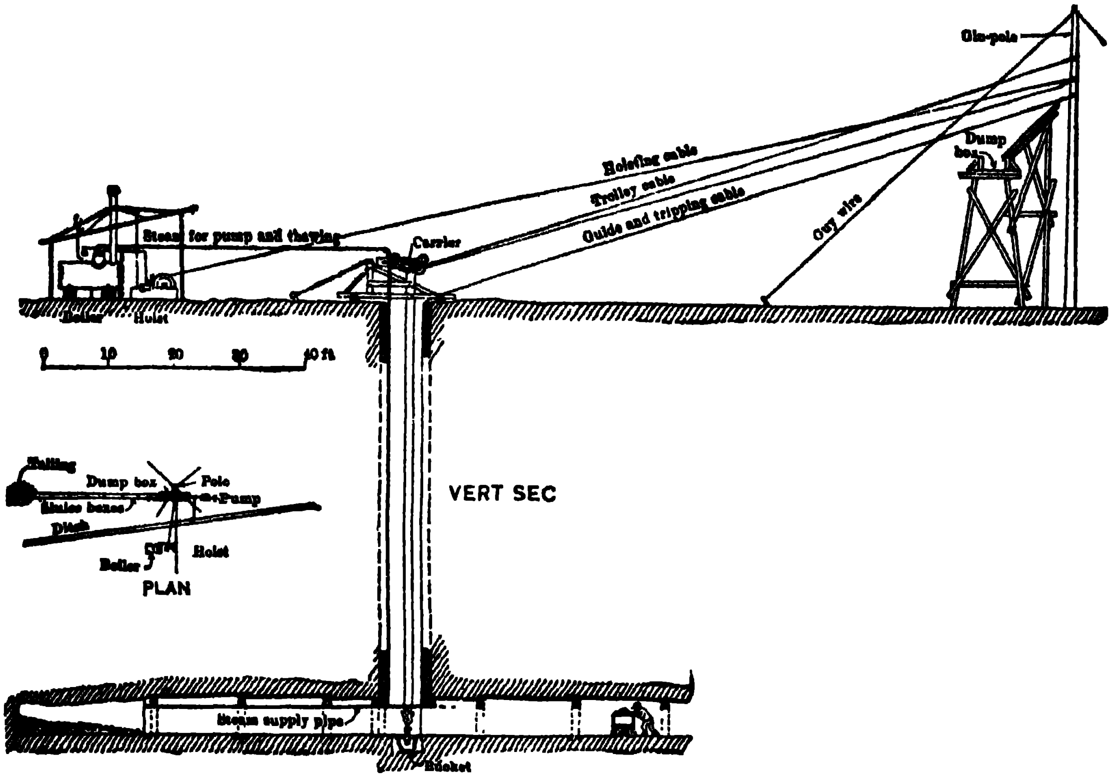

Fig 861. Arrangement of Self Dumper (after Katz)

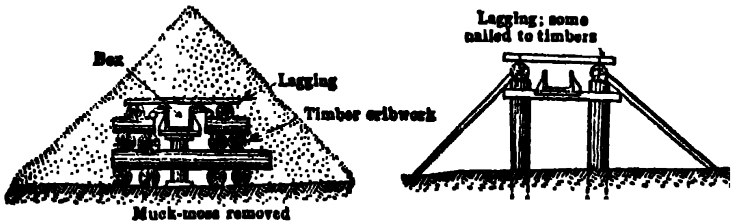
Surface plant at Alaskan drift mines is marked by wide use of inclined cableways, the bucket of which descends into the shaft (Fig 861). For winter work, the structure shown for supporting the dumpbox is replaced by a sluice, built near the ground, and supported as in Fig 862. The carrier dumps in a conical pile over the sluice; hence, much of the winter dump can be fed to the sluice by gravity assisted by nozzle water in the spring.



Supporting dump over sluice by cribbing, so that settling will not affect sluice

Supporting dump by posts set in holes thawed in muck

Fig 862. Methods of Protecting Sluice under Winter Dumps (after Ellis)

Examples of drift mining.

California, EARLY WORK (to 1890). Cost of 6 by 7-ft main haulageways in hard gravel, requiring blasting, $4–$7 per ft; smaller crosscuts and drifts, $3–$5. In ground less difficult to drill, and in picking ground requiring timbering, main tunnels cost $3–$4 per ft; auxiliary openings, $1.75–$3. Table 144 shows effect of local conditions on costs at 4 typical mines (456, 460).

Table 144. California Drift Mines Operating about 1888 to 1890 (Brown)

		Hidden Treasure	May Flower	Paragon	Red Point
Character of pay gravel		*Lo*	*Hc*	*Hc*	*Mc*

Aver total cost, mining and milling (*e*)		$1.10(*f*)	$3.25	$3 25	$2.00
Aver gross yield per ton gravel (*g*)		$1.75	$7 00	$10.00	$2.50

Lo = loose. *Hc* = hard cemented. *Mc* = medium cemented. *Pc* = picking and caving. *Db* = drilling and blasting. *Sl* = sluicing. *Mi* = milling. (*b*) Includes surface and underground labor, but not management. (*c*) Tons of pay-gravel per man-day computed from table. (*d*) Per ton. (*e*) Aver cost of labor and supplies for mining and milling (or sluicing) per ton gravel delivered during active operations on aver gravel breast, not including management, improvements, additions to plant, nor dead-work during periods of non-production. See (*f*). (*f*) Includes management. (*g*) Pay-gravel delivered at surface. (*h*) Large stones thrown back from face.

Vallecito-Western mine, Angels Camp, Cal. Data from C. E. Julihn and F. W. Horton (57) in 1938. A segment of Central Hill channel, 40-150 ft wide, aver 6 ft (max, 14 ft) deep, is opened by a 153-ft vert shaft and bedrock tunnel extending 4 300 ft upstream. An abrupt rise of 5 ft occurs in bedrock 300 ft from shaft, beyond which the tunnel, after following bedrock grade of 1.25% for about 2 300 ft, gradually works into and under the bedrock, which thereafter rises at a slightly steeper grade. The downstream portion, within about 1 700 ft of shaft, and while tunnel was still on bedrock grade, was mined from 2 parallel drifts, one on each rim of channel, connected by crosscuts 100-150-ft apart. Breasting method (Fig 863) was applied to one 240-ft block in 1932; for details, see Bib (461, 18).

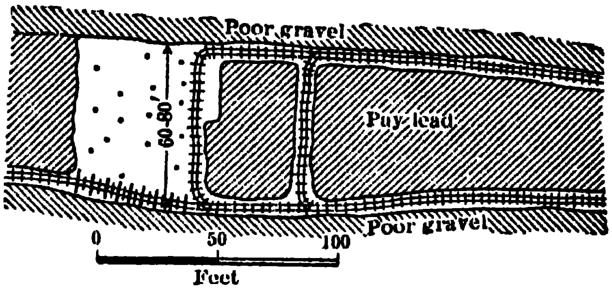

Fig 863. Development for Breasting, Vallecito Western Mine (18)

Following notes from Bib (57) relate to subsequent work (1933-36) upstream. Where gravel lay above tunnel, it was attacked through raises spaced according to the vol of gravel accessible to them; where channel was 100-150 ft wide, spacing might be 50 ft, increasing to 125 ft in narrow parts. Gravel, not cemented but requiring blasting, was well rounded and heavy, with many boulders, some 6-10 ft diam; of ground mined, about 30% consisted of boulders left underground. Gold was coarse (90% on 20-mesh, with frequent nuggets up to 0.5 oz) and 75% of it was within a foot of bedrock, of which 1 or 2 ft was usually taken up. Gravel was mined by breasting across full width of channel. Two rows of 6-ft holes, spaced 4 ft horiz, one row 1.5 ft, other 3.5-4 ft, above bedrock, each hole loaded with 3-4 sticks of 40% dynamite, broke to height of 5 ft; another row gave added height, if wanted. Posts 10-12 ft apart, with headboards, were all the roof support usually required. Broken gravel loaded into wheelbarrows, dumped down nearest raise, discharged into 1-ton cars, hauled in 4-car trains by storage-battery loco to transfer dump 300 ft from shaft, loaded into other cars, and trammed by hand to 1.5-ton skip in shaft. Waste, of deep bedrock cuttings and boulders for which

storage space was temporarily lacking, amounted to 31% of all material hoisted. Headframe bin discharged directly into 2-ft sluice 12 ft long, with only enough water to move 4 to 5-in stones; larger ones were picked out by hand; this sluice recovered 50–60% of the gold. Discharge from sluice passed into a disintegrator-trommel yielding plus 1.5-in (to dump), 1.5–0.5 in, and minus 0.5-in sizes; 2 latter were washed separately on sluices 12 in wide, at 4% grade, riffled with flat iron cross-bars, 2 in wide, sloping 45° upstream. In Aug, 1936, 25 men on 3 shifts mined and washed 80 tons per day. During 45 mos, ending Aug 31, 1936, hoisting 40 967 tons of gravel and 18 102 tons of waste, direct mining and washing cost was $4 58 per ton of gravel; indirect and marketing, $0.51; total $5.09. Recovered value, $5.68 per ton of gravel.

Calaveras Central mine, Angels Camp, Calif. Data from Julihn and Horton (57) in 1938. Company said to control 3.5 miles along the Tertiary Central Hill channel, and has developed 3 roughly parallel paystreaks of different ages (others known in reserve), lying on slate or schist bedrock and buried to depth of 250–350 ft by alternating beds of gravel and tuffs. Pay gravel is normally limited to 3–4 ft above bedrock (21 ft in one case) and 1–3 ft of the latter is usually taken up. Gravel is coarse, well rounded, and tightly cemented; boulders numerous; gold mainly coarse (over 10-mesh), associated with considerable pyrite and a little black sand. One paystreak (mainly worked in 1932–33) was 50–70 wide; other 2, 150–200 ft wide, of which only one was actively worked in 1934–36. Aver recovery from 138 750 tons of gravel and bedrock washed in 4.5 yr, $4.94 per ton, incl some low-grade gravel moved in exploration; 1935 aver, $5.17 per ton washed. Development is through 3-compt vert shaft 350 ft deep, and a cross-cut tunnel in bedrock passing underneath the 2 channels now mainly developed; another 240-ft shaft affords ventilation.

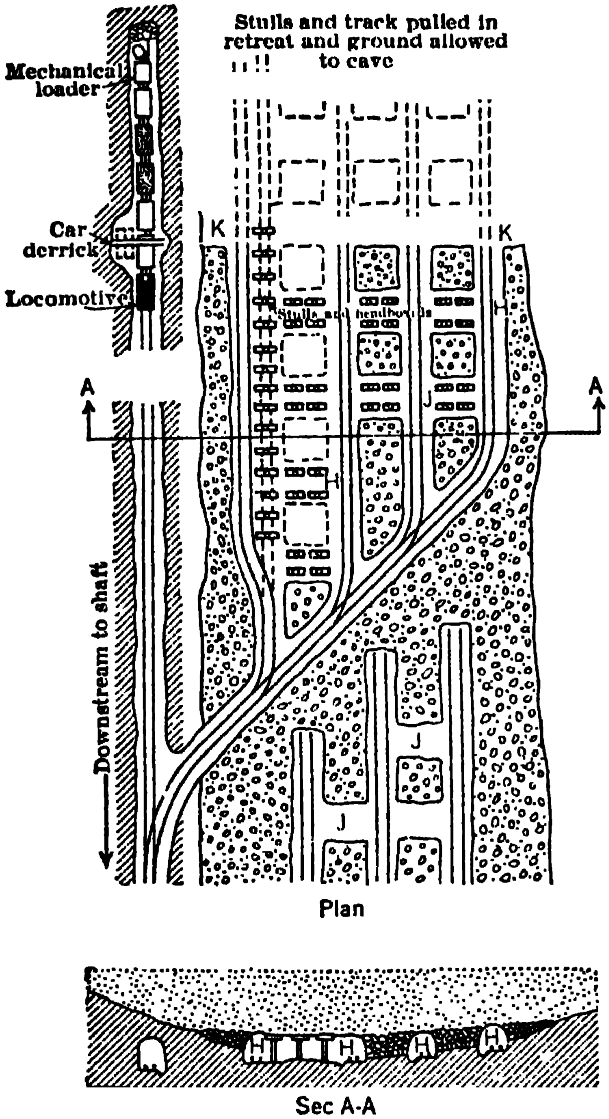

Fig 864. Room-and-pillar Drift Mining, Calaveras Central Mine

Drifts up and down stream from tunnel follow the 2 principal channels, developed (1936) for a total length of 4 000 ft, with about 30 000 ft of workings. Haulage drifts, 7 by 7 ft, on 1% grade, are advanced about 6 ft per shift by 2 men, drilling with light drifters, shooting 8–10 holes with light charges of 40% dynamite, and loading 2-ton cars with Eimco-Finlay loaders. Use of a "car derrick" facilitates movement of cars at face without switches or side tracks. Fig 864 shows one method of mining. Here the haulageway is beneath the rim of the channel. Parallel headings *H*, 7 by 7 ft, are advanced like bedrock drifts; breakthroughs *J* divide the long pillars into square blocks: nearly all material from these operations is loaded by Eimco-Finlay loader. Most pillars are recovered on retreat. For longwall work, as at *K*, the same type of loader is employed by shifting the track close to the wall before blasting, so that most gravel will be thrown onto the track in better position for the loader. Caterpillar-mounted Nordberg-Butler shovel has also been used with advantage where a train of cars can be placed near the gravel pile. All gravel is loaded, including boulders (except a few of the largest, and these are not piled) since the cost of piling by hand exceeds that of loading, tramming, and hoisting them. Boulders too large for the loaders are sledged or bulldozed. Enough bedrock is taken up and treated as gravel to insure recovery of gold in its crevices. Drag scrapers

have been used experimentally, loading into cars through a hole in a raised platform. Under favorable conditions (a large area of well drained and previously broken or caved gravel) scrapers were expected to be advantageous for handling low-grade gravel, provided haulage, hoisting, and washing facilities were adequate for the enlarged output. Trains of 4–6 2-ton cars are hauled by storage-battery locos to shaft pocket, loading into balanced 2 5-ton skips which dump into mill bin. Waste from bedrock drifts, 25–30% of all material hoisted, is handled similarly, but discarded at surface by a 200-ft stacker belt. Mine water, 150 000 gal per day, pumped by 50-hp turbine from shaft to a tank above the mill, supplies an ample quantity for washing. COSTS. During 1933–34, gross output (gravel 75%, waste 25%) was 83 419 tons (aver, 114 tons per day) at cost of $1.89 per ton for mining and washing, excl deprec, depletion, and general overhead. Costs per ton varied inversely with monthly output, from $1.40 on 6 507 tons (209 tons per day) to $3.04 on 1 271 tons (41 tons per day). These costs, largely the result of mechanization, compare favorably with those of earlier years when abundant cheap labor was available.

Dakota mine, Rivulet, Mont. Data from E. D. Gardner and C. H. Johnson in 1935 (18). Deposit was only 6–20 ft wide, under 80-ft cover; 7 ft of gravel was mined, of which much was boulders. An adit was started in the face of old hydraulic workings and driven 150 ft through previously drifted ground to reach virgin gravel. Thereafter face was advanced full width of deposit, with round-timber sets, 4 ft c-c. Caps, 12–15-in diam, were usually 10–14 ft long, depending on width of channel; min width of 10 ft was required to stack boulders; posts, 9–12 in; girts, 6 in. Top lagging, 4.5 ft long, of split poles, was driven ahead as ground was picked out. All rock over size of man's fist was stacked on sides of opening, except large boulders for which there was no room; boulders too large to handle were blockholed. Dry walls, built on each side of 18-in gage track, left only enough room for passage of an 8-cu ft car, 3 ft wide. Two men worked on each of 2 shifts, mining and washing 30 cu ft (1.7 tons) per man-shift. Labor cost (@ $4 per shift), $2.35 per ton; total cost, incl supplies, about $2.60 per ton of material trammed.

Alaska. Wimmler (188), in 1927, stated that drift mining had then become practically obsolete at Nome and elsewhere in Alaska, except in the Yukon-Tenana valley and a few other interior districts. Formerly, a large drift mine would employ 30–50 shovelers and clean 100 000–200 000 sq ft of bedrock in a season; by 1927 there were less than a dozen mines employing as many as 15–20 men and cleaning 50 000 sq ft; but at numerous places 2–6 men, with old and inefficient equipment and working 1 shift, were cleaning 10 000–30 000 sq ft of bedrock per season. Most drift mining in Alaska has been in permanently frozen gravel, at depths of 25–200 ft. They are developed through shafts, usually 7 by 7 ft, which can be sunk by 2 men at 5–8 ft per shift, after thawing; thawed muck can be bailed out. Cost, if little or no timber, $6–$12 per ft; if close cribbed with round timber, with a framed set at bottom, $10–$20 per ft; some deep shafts in bad ground, $25 or more per ft. (For thawing, see Art 131). Aver duty per man picking, shoveling, and wheeling 200–300 ft from working places to shaft, 75–125 barrow loads in 8 hr; equivalent to 20–40 sq ft of bedrock underlying 5–6 ft of gravel; aver, 25 sq ft (5 cu yd). Cost is often stated on basis of bedrock area cleaned. During chief activity at Fairbanks, some costs were 40¢ per sq ft; a few at Nome, only 25¢; usual costs at Fairbanks in 1927 were 60¢–$1 per sq ft; aver about 75¢. In Tolovana dist, 50¢–75¢; 32¢ at one specially favored mine. In Ruby distr (1922), where channels are narrow (about 75 ft) and other conditions adverse, 60¢–$1 25, aver 85¢ per sq ft or $5 per cu yd, of which 45¢ per cu yd was for thawing and 35¢ for sluicing. Central Alaska and the Yukon are essentially high-cost regions due to high wages, scanty supply and high prices of many supplies (incl large transp costs), and short working season of 3–5 mos. Most mines pay wages plus board; general labor in 1926 ranged from $6.50 in larger and more accessible districts to $12 at more remote; board cost $1–$4 per day. Some mines paid a bonus of 50¢ per shift to men who stayed during a whole season. Old system of lower wages in winter was not in effect in 1926. Underground mines usually worked 2 8-hr shifts.

Nome, Alaska; data by A. Gibson, 1914 (454, 462). Table 145 shows data for 5 successful drift mines in frozen gravel. All thawing was done during night shift; mining, in day shift only. Water for sluicing was pumped by independent distillate engines; mines No 2 and 3 were under same management with a common pumping plant; head on pumps about twice that at mines No 4 and 5. Other conditions affecting costs were as follows. Mine No 1: All mining done in winter; 1.5 ft of bedrock mined. As much as possible of the winter dump (6 520 cu yd) was hydraulicked into sluices, the rest shoveled in; sluice tailing was removed with horse scrapers. Water was pumped day and night for 18 days in larger amounts than necessary. Mines No 2 and 3: All summer work; 1.25 ft of bedrock was mined. Gravel was dumped into bins and sluiced intermittently (about once a day). Mine No 4: Preparatory work was done in early spring; all mining and sluicing in the summer; 1.5 ft of bedrock was mined. Gravel was handled on the surface as at No 3. Mine No 5: Spring and summer work as in No 4. Pay-gravel averaged 2 in above, and 2 ft in, bedrock. Gravel was dumped into a mud-box; sluicing was continuous, hence pumping was continuous on day shift. The bedrock in No 1, 2, 3, and 4 was mica schist; at No 5, black slate. The waste or overburden at No 1, 2, and 3 was coarse sand; at No 4, sand and clay; at No 5, light gravel or sand.

Wild Goose mine, Nome, Alaska. E. E. Fleming (681) describes a system of caving in blocks employed in 1905, after typical Calif method (as at Hidden Treasure) had proved dangerous from caving, and costly, from loss of all timber (@ $60 per M, plus frt from Nome). Channel was 80–110 ft wide and nearly straight; mining took out 1.5–2 ft of mica-schist bedrock and 2 ft of gravel, unfrozen and loose. From shafts 69–140 ft deep, usually 40 ft and never less than 25 ft outside of deeper edge of channel, crosscuts were driven to about center line of channel, and turned both ways

Table 145. Data on Drift Mining, Nome, Alaska, in 1914 (Gibson)

	Mine No.	1	2	3	4	5

Duty, laborers only, 8, 12.06, 15.12, 14.28 and 16.36, respectively, for the 5 mines. (*d*) Foreman, engineer and laborers. Duty, laborers only, 5, 6.7, 8.41, 10, and 7.87 cu yd, respectively. (*e*) All labor but manager included. (*f*) 10 men employed per day while upper part of winter dump was being sluiced; 21 men per day during time it was necessary to shovel-in.

into drifts 300 ft long; a crosscut both ways from end of each drift then divided the channel into sections 600 ft long. Beginning at outer ends of most remote crosscuts, blocks never more than 10 ft square were extracted as in Fig 865, using 8 by 8-in posts at 3 ft c–c, with 3 by 12-in headboards; no headboard was permitted to rest on 2 posts. Runs of gravel from sides were stopped by temporary lagging. When No 1 block was finished and floor cleaned, its 2 gravel faces were close lagged behind posts with 2 by 6-in plank, and all other posts were pulled out; roof usually caved at once, filling block solidly. Block No 2 was then worked back towards No 1, the intervening posts and lagging being drawn before pulling posts in No 2. Successive blocks were mined in the order indicated. A second crosscut had meanwhile been driven 20 ft back, and its 10-ft blocks were removed in same way. This system provided 4 working places at a time, besides crosscut headings, tributary to shaft, keeping hoist busy. Loss of timber in one 600-ft section, full width of channel, was only 5 000 bd ft; shaft timbers were recovered when walls froze in winter.

Fairbanks, Alaska; data from J. F. Newsom; see also Bib (400). 80% of productive deposits are at depths of 40–260 ft; all lie in valley bottoms with flat gradients; most of them solidly frozen. Transport difficult and water supply meager. Work covered by Table 146 was done prior to 1909.

Idaho Mining Co, on Little Eldorado Cr, Fairbanks, Alaska, made successful use of wet jackhammers for working solidly frozen gravel at 165-ft depth (188); mining took 3.5 ft of gravel and 1.5 ft of bedrock. Gravel was tight, containing numerous large and hard boulders, but only about 5% of ice. Drilling was applied first to holes for "sweater" pipes (Art 131); 1 man could drill 20 9-ft holes and put in their sweaters in 8 hr, at cost of 65¢ per hole, whereas (under previous method of point thawing) 2 men could set only 4–6 points in 8 hr, due to difficult driving. Thawing for 40–45 hr under steam and 24 hr standing usually reached 18 in beyond end of pipe, or 40 sq ft per sweater. The Co next used drills for blasting unthawed gravel, following typical Calif system of breasting from crosscuts, which (as also the drifts) required no timbering. A man could drill and shoot 150 ft of holes per shift, breaking 100 sq ft or 17 cu yd; cost for explosives (0.4 lb per sq ft) was 60¢ per cu yd. Broken gravel was dragged from faces by 12-cu ft bottomless scraper and loaded into cars. Exceptionally small proportion of ice in this gravel made thawing before sluicing unnecessary.

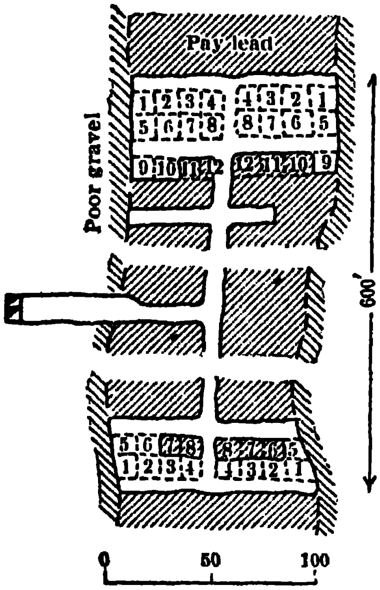

Fig 865. Block System, Wild Goose Mine

Victoria "deep leads," Australia, are old river channels under 250–400 ft of alluvium, frequently capped with basalt flows, and sometimes as much as 2 000 ft above level of present streams. Workable gravel, not always in deepest part of channel, is up to 15 ft (aver 3 ft) thick; gold mainly confined to lower 1–1.5 ft of gravel and upper 0.5–1 ft of bedrock, usually kaolinized; bedrock gradient, 20–40 ft per mile. **Drainage** of channel is first requisite and development is planned accordingly. Shafts are usually in bedrock at side of lead, to avoid costly sinking through loose, wet sand (Fig 866). From shaft bottom, 80–100 ft below channel, a "main reef" crosscut *C* is driven under the lead. From a point under the middle or deepest part of the lead, drifts *D*, called "main reef drives," are driven in both directions under center line of channel; they are on an up grade, for drainage and haulage. Main reef drive *D* is usually timbered with 12-in round timber; caps 5.5 ft long; posts, 8.5 ft. At 50-ft intervals along drift *D*, holes are drilled upward into the water-laden gravel. Later, usually at 300-ft intervals, raises

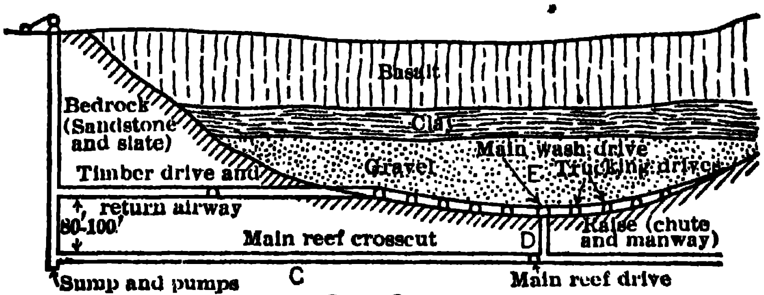

Fig 866. General Scheme of Development, Victoria Deep Leads

are put up to finish drainage and to serve as orepasses and manways; complete drainage may require 3–5 years, pumping 2–6 million gal per day. Fig 867 shows usual DEVELOPMENT in "wash" (gravel), cutting area into rectangular blocks, drifts and crosscuts being advanced by spiling. Posts in "main wash drive" *E* are 7 ft long; caps, 4–5 ft. In "trucking drives" *F*, posts are 5.5 ft long; caps, 3–4 ft. MINING in 1935. Two methods used: (*a*) "blocking," (*b*) "paneling." BLOCKING METHOD is adopted where wash is very loose, with large boulders, or where thickness of pay gravel is over 4 ft. Development divides wash into strips 40 ft wide (Fig 867); distance between crosscuts, usually 300 ft. Midway between crosscuts, "blocking drive" *G* is driven 20 ft at right-angles to length of strip. At same time, a similar drive is put in from trucking drive on other side of strip, the two holing at the center. Drives *G* are timbered with 8 to 9-ft caps on 3.5 to 4-ft posts (6 in round). Spiling "laths," 8 by 2 in, are driven ahead, gravel is dug out, and next set erected; sets are at 4 to 5-ft intervals. Floor of *G* is at about same elev as that of *F*. Gravel is shoveled into cars and dumped into nearest raise. On completing one blocking drive, another is started alongside, working successively toward the wash crosscuts at both ends of strips, as indicated by numbers in Fig 867. No timber is salvaged from the workings, which soon cave. PANELING is employed where gravel is finer or where gold is confined to bottom 2 or 3 ft of wash. Principle is same as in blocking, but trucking drives are 32 ft apart (instead of 40) and "panel drives" are 4.5 ft wide (instead of 9 ft). Panels are closely timbered with 8 by 2-in caps, 4.5 ft long, supported by props of 2.5 to 3.5-in split timber (Fig 868). Gravel is shoveled back to mouth of panel drive and into car in trucking drive. On "main reef" level, elec locos are customary. Ventilation is important in deep-lead mining, as foul gases tend to exude from the gravels (628, 682, 683).

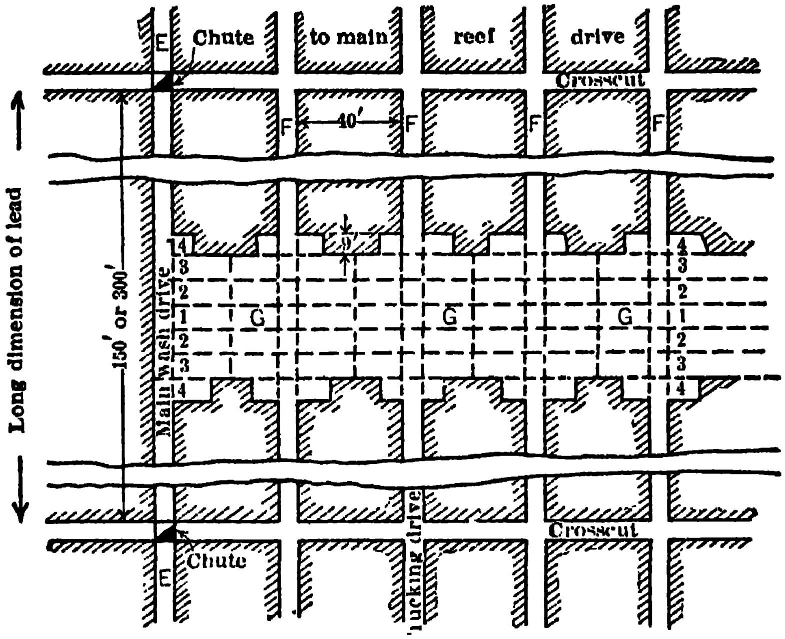

Fig 867. Development and Mining of Victoria Deep Leads by Block System

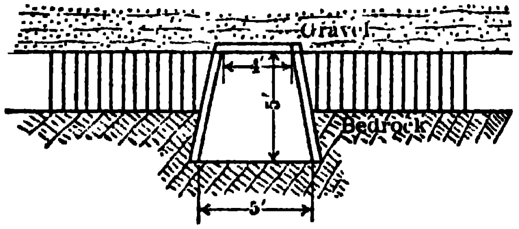

Fig 868. Paneling, Victoria Deep Leads

131. THAWING FROZEN GRAVEL

General. In Alaska, Yukon and Siberia, the earth or muck overlying most placer deposits, and usually the gravel itself and underlying bedrock, are permanently frozen. Such ground gives little trouble in deposits that can be hydraulicked; the muck is thawed by allowing water to run over the surface; frozen ridges left between channels thus formed thaw naturally, or may be thawed and stripped more quickly with giants. When a pit has been opened, bank and giant water aid in thawing gravel faces and new surfaces are constantly exposed to solar heat. In drift mining (Art 130) no stripping is necessary, but the paystreak must be thawed. In dredging (Art 128) the muck must be thawed and stripped and the entire gravel bank thawed. Adequate (not necessarily perfect) thawing is essential for successful dredging (435) to save excessive wear on machinery, permit effic digging, and to avoid loss of gold encased in frozen lumps rejected by the screen. While most gravel can be sufficiently thawed in a short time to permit dredging, it is best to allow thawed ground to stand several months, during which small isolated frozen patches may continue to thaw.

Thawing methods were developed in drift mining. Early shaft sinking and drifting in Alaska and elsewhere were done with wood fires and hot stones; these are still used by prospectors, but boilers light enough to be carried by 1 or 2 men are now obtainable, and permit steam thawing for prospecting and exploration in remote districts (386, 390, 408, 455). Steam-thawing, introduced about 1898, developed rapidly; steam is carried into gravel through pipes terminating in a bit or "point" (Fig 870); the method was soon applied to thawing frozen ground ahead of dredges. Numerous experiments have been made with hot water instead of steam, but with indifferent success; C. Janin in 1922 traced the development of thawing methods, and summarised available data in Bib (629). Since 1917 cold water has largely replaced steam for thawing dredging ground.

Physical properties of frozen gravel (Table 147). Extensive tests in 1912 by H. M. Payne, on permanently frozen gravel in the Klondike, gave following results; temp (F) of bedrock, 2°-14°; of gravel, 17°-22°; of black muck, 17°-24°; of sandy muck, 19° - 24°. Mean temp of frozen ground depends solely on the kind of material and not on its depth, depth of frost line or water level, nor on presence or absence of muck overburden. A. Gibson states that the temp of perpetually frozen ground on Seward Peninsula is about 28° F, except when near thawed ground; he estimates the sp heat of gravel at 0 2. Nearly all the heat required to thaw frozen ground is that needed for converting ice into water; hence percentage of ice in gravel should be determined in estimating probable fuel or water requirements (454, 451, 629).

Table 147. Physical Properties of Frozen Material (393)

Aver of tests on 46 samples		Black, sandy muck	Gravel and sand	Bed-rock

Comparison of thawing media. Experiments by J. H. Miles, of Alaska Mines Corp'n, in 1917-1918 at Nome, in thawing deep dredging ground with steam, hot water and cold water, are described by W. S. Weeks (644) as follows:

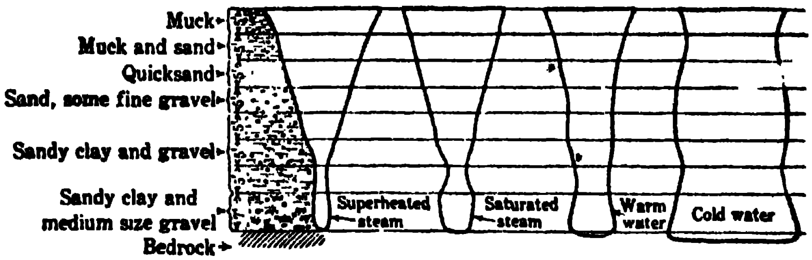

Fig 869. Comparison of Thawing Media

Depth of ground, approx 42 ft; character is shown in Fig 869. Thaws were made with superheated steam, saturated steam, hot water and cold water; in each case the thawing agent was introduced at bottom of a churn-drill hole In following winter, when surface water was frozen, shafts were sunk on these holes and the thawed volumes computed. Fig 869 shows cross-sec of a thaw of each type. Results (Table 148) show relatively high utilization of heat available for thawing with cold water and very low utilization for steam and warm water. Tests with superheated steam indicated that most of its heat was expended in heating a relatively quiet pool of water around the pipe. Also, steam failed to penetrate clay layers appreciably, while clay did not impede action of cold water. Hot water gave uniform thawing, but was ineffic; this test was shorter than the others and its results are not strictly comparable. Miles obtained a patent (U S, No 1 339 036) in 1920 on his cold-water thawing method. Alaska Mines Corp'n made further tests with cold water on a working scale in 1919 and adopted the method; in 1920 this Co thawed 88 807 cu yd of frozen ground with cold water, at aver cost of 11.5¢ per cu yd (629).

Table 148. Tests on Thawing Media, Alaska Mines Corp'n, Nome, 1917 (644)

	Super-heated steam	Saturated steam	Warm water	Cold water (*a*)
Length of test, hr.	156	98	67	192
Oil burned, gal per hr.	11.25	9	6.04	......
Temp of steam or water at points, deg F.	590	250	105	52
Temp of water at surface.	140	104	70	(*c*)
Volume thawed, cu yd.	109	83	81	511
Rate of thawing, cu yd per hr.	0.7	0.85	1.21	2.66
Effic of heat utilization, % (*b*)	3 8	5.80	12.30	57.40

(*a*) 20 gal per min supplied under 40-ft head. (*b*) Computed for steam and hot-water tests as: [heat units required to melt the ice in the gravel (about 10% of its wt)] ÷ [heat units in fuel burned × 50% boiler effic]. In cold-water test, the divisor in the above ratio was taken as the heat units available in the vol of water used, between 52° F, the temp of entering water, and 32° F. (*c*) Temp of outgoing water varied during test; at end of 192 hr it was 36° F (644).

Steam points. Fig 870 shows typical head and tips. STEAM THAWING IN DRIFTING (Art 130). The point is pressed firmly against the face, and steam turned on. In a few minutes, the point begins to sink into the face; it is gradually worked in to its full length, being alternately rotated, driven with a hammer, and allowed to stand. Points can not be driven faster than the gravel thaws ahead of them; heavy blows are avoided, except where required by tight ground, as they may injure the point.

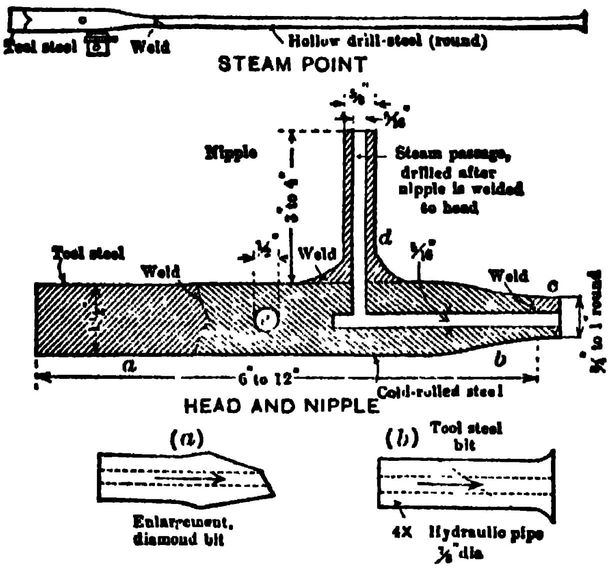

Fig 870. Steam Points (after Ellis)

H. I. Ellis gives following data at Fairbanks in 1915 (455). Diamond or square bit (*a*), Fig 870, is used in easy-driving ground, where stones can be pushed aside. Chisel bit (*b*) is for hard driving, requiring actual drilling; a cross-bit (as for rock-drills) is used where chisel bit is hard to turn. Steam points are 8, 10, 12, 16 and 20 ft long (some 5–7-ft points are also needed); 8-ft is commonest; deep holes start with short points. For thawing breasts, the points are driven near bottom of face and spaced 2–4 ft apart across it (Fig 860). There are 2 modes: (*a*) Enough points are driven to thaw required length of face; steam is usually kept on 6–10 hr; points then withdrawn and gravel allowed to "sweat" before being picked down. (*b*) Only 1 point is used on a face; after driving it home, it is withdrawn and replaced by a "sweater" of 1/4 or 3/8-in pipe (Fig 871). Before turning on steam, the pipe is plugged in collar of hole with gunny sacking. This is repeated for holes over the entire face. Plan (*b*) is replacing (*a*); sweaters cost much less than steam points and obstruct shovelers less if gravel settles during thawing and prevents withdrawing the sweaters. In easy ground, 2 men working separately can drive more points than 2 working together; but they usually work in pairs, one striking, while the other rotates the point. Depending on character of gravel, 1–6 pointmen can thaw gravel for 16 shovelers. At Nome good pointmen, working under plan (*a*), often drove 20 5-ft points in 10 hr.

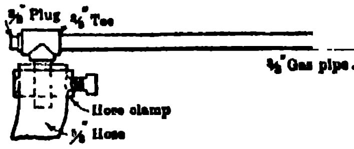

Fig 871. Sweater

Steam is distributed in uncovered 3/4-in pipes, carried on posts of haulageway sets and laid on the breast floor about 10 ft back from face. Points and sweaters are connected by crossheads (Fig 872). Ordinary press, 90–100 lb. Thawing time varies with depth of thaw, spacing of points, character of gravel and effective steam press. Ellis says that at Fairbanks a 5-ft paystreak of loose gravel, relatively free from clay or sediment, can sometimes be thawed to depth of 9 ft in 10 hr, using 8-ft points under 100-lb press. W. H. Sirdevan states that at Nome a 5-ft point, thawing for 6–10 hr under 90–100 lb press and followed by a sweating period (without steam) of about 20 hr, will thaw a block of gravel 6 ft long by 3 ft wide by 3-4 ft high, or 2-2.5 cu yd. In drifting in Klondike, 6-ft points aver 3.75 cu yd per 10 hr (408). Boiler capac varies locally, but is about 1 bhp per point. When drift mining on Third Beach at Nome was at its height, the bhp per point was 1-2, aver 1.5; attention to detail reduced this figure. See Art 130, and Bib (390, 408, 451, 455, 454, 629).

Steam-thawing dredging ground. Steam points are driven vertically to bedrock, advancing as fast as thawing ahead of point will permit. Methods of Yukon Gold Co, described by Perry in 1915 and McCarthy in 1914 (451), illustrate good practice at that time. Points, as in Fig 870, were of extra heavy pipe 0.75-1 in diam; driving head was drop-forged; tips, of tool steel, had $^5/_{16}$-in discharge opening. Points, set in holes made with crowbars to frost line, were alternately struck with a 4-lb hammer, rotated and allowed to stand. Boulders were drilled by a cutting bit on the point, or by withdrawing the point and using a jumper. Aver rate of thawing, about 2 ft per hr; points were driven as deep as 40 ft; points had to be driven 4-6 ft into bedrock; then allowed to steam 12-48 hr. Boiler plants comprised 2 or 3 loco-type 150-hp boilers; the aim was to carry 25-lb press at the points; fuel, wood. Steam lines were asbestos covered and cased in wood boxes packed with sawdust; branch lines were 1.5-in and often several hundred ft long; at 8-ft intervals along them were nipple connections for $^5/_8$-in armored hose, leading to the points. Batteries of 150 or more points formed a unit. Costs varied locally, with depth and character of ground, driving troubles, time of steaming, cost of fuel, etc, from 12 to 20¢ per cu yd. See Bib (629).

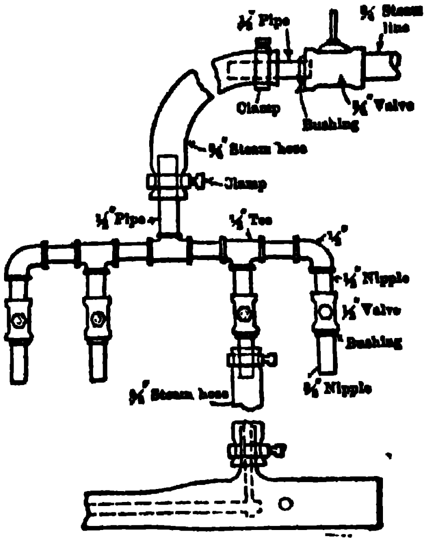

Fig 872. Crosshead (after Ellis)

N. L. Wimmler (188) gave following data on Alaska practice just prior to 1927. (1) Otter cr, Iditarod. Gravel, 14 ft deep; 150-hp boiler supplied 95 points; thawing cost, 30-45¢ per cu yd. (2) Same location; 200-hp boiler for 110 points thawed 100 000 cu yd in 1 season; cost 33¢ per cu yd. (3) Candle cr, Kuskokwim. Gravel 15-18 ft deep and less than half was frozen; muck removed previously; 100-hp boiler for 80 points spaced 6 ft c-c; fuel per day, 12 cords wood @ $10; employed 10 men per shift and thawed 100 000 cu yd in 1 season, at 25¢ per cu yd.

Cold-water thawing is done by injecting water at normal surface temp and under press (from ditch, if possible, otherwise from pumps) into the gravel through pipes resembling steam points, Fig 870, or sweaters, Fig 871. The water returns to surface through the ground surrounding the pipe; as thawed ground tends to settle, it opens a channel for the rising water along the under surface of still frozen ground, thus promoting effic of operation. Presence of former drift workings often complicates procedure. Water points or sweaters, driven to bedrock like steam points, have been widely used on dredging ground in the North.

Alaska. N. L. Wimmler gives following general information (188) in 1927. Alaskan surface waters reach 50° F or over only during 3.5 summer months; occasionally 65°-70° for short periods; water may be 6°-8° colder at night than in day. Best thawing results when water rises from points at not less than 36°-38°; only about 8°-15° of available temp can ordinarily be utilized; effic is highest at start of thawing. Amount of water varies widely; one case at Nome, thawing 60 ft deep, supplied 1-1.75 miner's in of ditch water per point, at 30-80 lb press; another pumped 1 000 gal per min to supply 100 points at 17.5 lb press; Yukon Gold pumped 3 500 gal per min for 100 points. Excessive press may cause pipes to rise, but 60 lb is more effective than 40 lb. Water thaws more slowly than steam; hence 2 men can manipulate twice as many water points as steam points, say 10-25 or more, depending on difficulty of ground and temp of water; aver advance of water point, 0.75-1.5 ft per hr.

Water points are usually staggered in straight rows, on 8-16-ft centers; in 60-ft gravel at Nome, with slabby boulders on bedrock, holes at 32-ft centers were churn-drilled in winter and thawed next season. Under aver conditions, points at 8-ft centers finish thawing in 4-8 days; at 10 ft, in 8-12 days; at 16 ft, in 10-14 days; at 32 ft (Nome) in 10-12 weeks. Thawed gravel freezes to depth of only 2-5 ft during a following winter. Water-thawed gravel is easier to work than that thawed naturally or by steam, especially if much clay is present, since circulating water assists in disintegrating clay. In general, water thawing costs 7-15¢ per cu yd; Yukon Gold, having to pump water, thawed for 10-14¢ per cu yd; at Fairbanks Cr, with small and erratic supply of ditch water, cost was 10-12¢ per cu yd.

Yukon Consol Gold Corp. Data from W. H. S. McFarland (434) and G. R. F. Troop (435) in 1939; statistics and costs from Mr. McFarland in 1940. Company aims to gain at least 2 years' reserve of thawed ground ahead of a dredge, requiring operation of 5 or 6 "units" of 400-700 (usually about 600) points each. Thawing season begins about

May 10 (preparation, nearly a month earlier) and ends about Sep 25. Equipment is mainly like that at Nome and Fairbanks.

From its main source (usually a pump), water passes through a 12-in gate-valve into a line of flanged pipe reducing in steps from 11 in to 8 in; this line has 6-in outlets, each with a gate-valve, spaced 27 ft 7 in apart; aver "unit" has 12 such outlets. Header pipes, one for each outlet, are 6-in and 4-in slip-joint pipe in 16-ft lengths, each length having a 2-in threaded outlet at center. By combination of bushings, nipples, T's, or crosses, water is finally delivered through individual cocks to 1-in hose, 16 ft long, feeding the points; usually 2 (occasionally 4–6) points are supplied from each outlet in the header; usual press, 20 lb per sq in. Normal spacing of points is at corners of 16-ft equilateral triangles; sometimes reduced (when much muck remains to be thawed) to 4 ft. Points are of 0.75-in extra-heavy pipe in 10-ft lengths, with a chisel bit of high-carbon steel welded to lower end. Points are driven by hand, using a cyl slotted weight to fit around the point, and kept in place by a $^{3}/_{8}$-in crossbar which also serves as handle. The weight strikes a collar firmly clamped to the point by swing-bolts; a wooden handle bolted to the clamp serves to twist the point. For rate of driving, and thawing duty of water, see Table 149. Extra-heavy $^{1}/_{2}$-in pipes, without cutting bits, are sometimes driven at intermediate positions, but usually not to bedrock. Thawing water has to be circulated, due to scarcity; settling basins are arranged, from which water, after straining through 7-mesh screen, is pumped back into the pipe line The water from stripping muck (Art 128) can not be sufficiently clarified for use in thawing gravel, and precautions are often required to prevent contamination of the thawing water. Standard pump is a 12-in centrif, rated at 6 000 (US) gal per min under 100-ft head, and driven by 200-hp synchronous motor. Each of the 11 such portable units in service is housed in same manner as those supplying water for stripping (Art 128). A "unit" block of Klondike gravels can usually be thawed by this method in 1–3 mos; progress is examined by driving steel bars into the ground about midway between points. Table 150 gives costs of thawing at 7 of the company's dredge sites, during a period of organization and expansion; lower costs are anticipated. For stripping and dredging on same sites in Klondike distr, see Art 128.

(*a*) Work on the Australia-Sulphur ditch. (*b*) Costs high due to necessity for re-thawing much of the 1937 area, for which no credit was allowed in 1938.

Points on 10-ft centers, staggered on rows 10 ft apart, were driven to bedrock under full water press (19–23 lb), then withdrawn, and replaced by sweaters; latter could sometimes be put down without preparation by points. Four men on each of 2 10-hr shifts bottomed 40 points and set sweaters for 4 000 sq ft, each working on 21 points at a time. Temp of inflowing water, usually 42°–44°; max, 69°; usual drop on return, 10°–12°. Thaw finished in 10–12 days (4–5 days when water was warmest). Aver daily labor cost (wages including board @ $3 per day) was: 8 pointmen @ $9, $72; 1 day foreman, $12; 1 night foreman, $10; 1 ditchman, $9; ½ blacksmith and helper, $10.50; total $113.50. In 10 days, this crew set 391 points, thawing 21 722 cu yd (39 100 sq ft, 15 ft deep) at 5.25¢ per cu yd for labor and repairs. Former cost by steam thawing was 35–45¢ per cu yd. Equipment (excluding old ditch) cost about $10 000.

Water thawing without points. A different application of cold water for thawing was employed on Candle Cr, Fairhaven dist, Alaska, by E. E. Pearce in 1921 (558). The gravel lay in and alongside a creek, with no muck cover. Length, 1 025 ft; aver width, 60 ft; depth to bedrock, 9 ft; depth to frost line, 3.5 ft. The creek was diverted into 2 parallel ditches, one along each edge of area. A 5 by 5-ft shaft, sunk in middle of the area, about 235 ft from the down-stream end, was timbered tightly to a point 2 ft above bedrock. Timbering extended above surface water; coarse gravel was thrown in at bottom and around the sides of shaft. Water entering shaft bottom was pumped out (at 250 gal per min) by a 2.5-in centrif pump, driven by a 4-hp gasolene engine. Creek water seeped through thawed surface gravel to the shaft, thus creating circulation along the frost line. Aver temp of creek water, 64° F; of shaft water, 48°. Whole area thawed in 15 days; pumping time, 80 hr. Cost, excluding equipment and overhead, 1.4¢ per cu yd. Previous work with water points only, in same type of gravel (water pumped), cost 9.5¢ per cu yd.

132. MINING ALLUVIAL TIN DEPOSITS IN MALAYA

By John Branner Newsom, Mining Engineer

a. General Conditions

Tin occurs as cassiterite, associated with heavy minerals of Fe, W, etc, over large areas in Malaya. Fig 873 shows types of deposits; alluvials and residuals, occurring separately or in combination, are worked by placer methods and yield the bulk of Malayan tin production. Bedrocks are decomposed granites and soft schist, with areas of very hard irregular limestone. Tin-bearing pay-streaks are locally called "karang"; heavy associated minerals, "amang," correspond to black sands in gold placers. Occasional large pieces of cassiterite occur, but approx 90% of ore grains pass 10 mesh and stay on 150 mesh. Essential differences between these deposits and gold-placer gravels are: (*a*) sp gr of cassiterite is lower than gold,

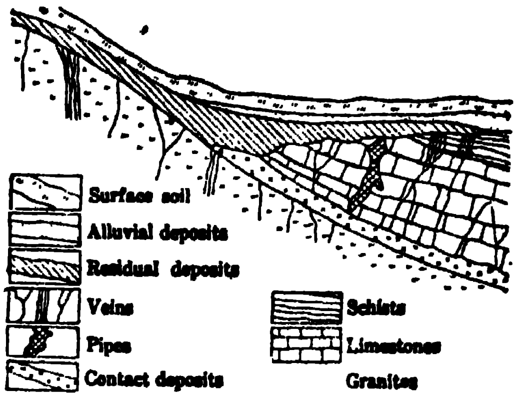

Fig 873. Types of Malayan Tin Deposits. Ideal Sec

making it more difficult to save; (*b*) fully 95% of deposit is fine sand and clay, with a few stones and boulders (Table 151); (*c*) fluctuating price of tin.

To handle a given vol of material, these conditions require larger areas in sluices and more water than in gold placers; sands in sluices must be agitated artificially to prevent packing; clay puddled, to release included mineral and prevent sluice-robbing; some deposits are worked intermittently, as price of tin varies.

While some ground is very rich, production is mostly from deposits carrying 0.5–1.5 lb tin per cu yd; with prices for tin in 1937, usual open-cut methods operate profitably with Chinese labor where values are 1 lb per cu yd; dredges work profitably under favorable conditions with values as low as 0.3 lb per cu yd; clay and difficult bedrock increase minimum profitable values; normally, 0.5 lb per cu yd is considered good dredging ground. Wages: Chinese common labor, 30–50¢ (U S) per 8-hr day; skilled labor, 75¢–$1.50; much work is on contract and tribute systems. Methods include use of small- or large-scale handwork, ground sluicing, hydraulicking, hydraulic elevators, gravel pumps, mechanical haulage on inclines, and dredging.

Table 151. Sizing Tests of Typical Bank Materials

Screen		Per cent weight on screen	
Mesh	Aperture, mm	*A*	*B*
20	0.90	20.5	27.6
40	0.38	19.5	17.8
60	0.21	8.7	8.6
80	0.16	5.2	3.5
100	0.13	2.9	2.0
−100	0.13	42.7	39.7

A. Ampang Selangor. *B*. Sungei Linggi, Negri Sembilan. Note. Voids in alluvials in place vary from approx 38% in pure clay to 23% in material containing 50% sand. Per cent voids in pure clay and sand is higher than in mixtures.

In all cases, a rough concentrate carrying 15–50% tin is made; this is rewashed to the standard grade for the district, which is 73–75% tin and is sold to local smelters. Rough concentrate may contain 50% or more "amang"; finished concentrate is called "ore," a term applying loosely to all kinds of concentrate.

Foreign engineers often fail to recognize the low costs and large outputs attained by Chinese hand methods, through their ingenuity and low cost of labor. A fixed idea of Chinese operators is to avoid expense for equipment wherever possible. Prior to 1900, with possible exception of a few small hydraulic mines, all Malayan placers were worked by hand; still true for certain work involved in present methods using power. In early days, extensive drifting (Art 130) was done by Chinese, but this has almost stopped.

In 1931 the International Tin Control scheme went into effect. Under it, the Malayan quota has varied from low of 25% of rated capac in 1932 to 80% in 1937. In 1936, 87% of world production was controlled and the Straits region, comprising Malaya and Netherlands East Indies, produced 55% of world's tin, valued at $99 000 000 (U S), practically all by placer mining. Malaya furnished 68% of this. Malayan placer mining is the most extensive placer work now being done.

b. Washing Devices

Simple hand-washing devices are important in the industry, being always used to clean rough concentrate. For use of jigs, see Dredging, Art 132g.

Dulong is a wooden bowl, about 24 in diam by 5 in deep, corresponding to the gold miner's pan or batea and used similarly. Aver dulong operator handles 1.25 cu yd of sandy material per 8 hr. In 1918, dulong miners produced 3 365 tons of 73% concentrate, or 8% of total Malay output, but in recent years encroachment of other methods of primary concentration has reduced this figure. For final concentration, the dulong is operated as for rough concentrate, but work is much slower.

Lanchute is a coffin-shaped sluice box, varying from dimensions in Fig 874 to 35 ft long. Material enters by gate *A*, being puddled first if necessary. As the sand streams down the box, a coolie pulls it back with a hoe ("changkol," Fig 875); the water swirling around sides of hoe carries off light sand; heavy sands settle. 1 man operates a lanchute of size shown in Fig 874; 2 or 3 coolies for larger ones. Ratio by vol of water to sand is about 10 : 1; recovery, about 90%. Duty per man-shift, 12 cu yd of well puddled material. Lanchute and changkol are auxiliaries in all large-scale work, to bring rough concentrates up to standard grade.

Clay puddling is done as follows: (*a*) In small-scale work, with digging changkols (Fig 875), in puddles at lanchutes (Fig 874). A coolie puddles 0.3–0.5 cu yd of tough clayey material per hr. (*b*) By "stage" working in small open pits. About 60% of water by vol is added to the karang on

the pit floor; resultant pulp is scooped across floor with long-handled scoops to the foot of one of the banks, in the face of which a series of small basins or puddles is cut at vert intervals of about 4 ft. Coolies at each puddle dip the pulp, with long-handled dippers holding about 1 gal, from one puddle to the next above, and finally to the lanchute on the surface. Aver duty per coolie is about 16 dippers per min = 2.5 cu yd bank measure per hr on a 4-ft lift. With labor at 50¢ per day, stage working costs approx 0.7¢ per cu yd per ft lifted. As many as 12–14 stages may be used, but such heights are unusual. Stage working, the most effective hand-puddling method, can be used only where karang will form a sludge: mixtures of sand and clay give best sludges. (Note. Stages are used for elevating material in opening pits to bedrock for gravel pumps and in working small rich areas.) (*c*) By power-driven arrastras. A 25-ft diam machine, with 2 drags and 0.5-in discharge screen kept open with a water jet, requires 3 hp at 5 rpm. Capac, 5–15 cu yd per hr; water, 50–75 cu ft per min. At one mine arrastra puddling cost 15¢ per cu yd. (*d*) By box puddlers similar to log-washers but run at high speed; this is the usual method. A puddler 12 ft long has 5 sets of steel blades; speed 120 rpm; power, 20–35 hp; water, 10 cu ft per cu ft of dirt. These machines do imperfect work, but have large capacity. (*e*) Low-speed puddlers, consisting of horiz shafts about 20 ft long with blades extending about 2 ft, the blades tilted so that the clay is moved ahead slightly by each blade as it comes around, were introduced in 1927. They are effic puddlers and are used for final disintegration of clay on some dredges. (Art 132g.)

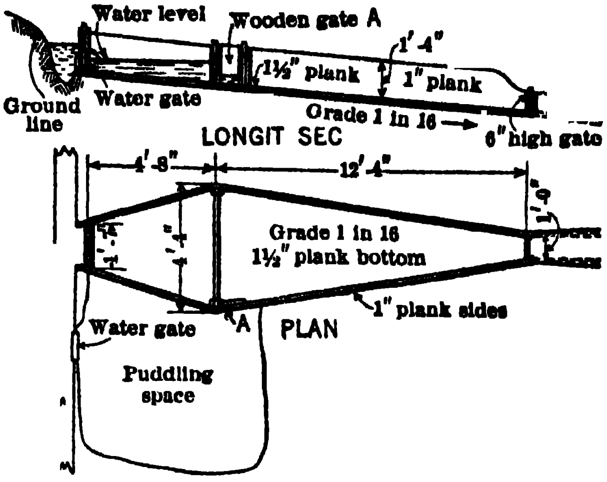

Fig 874. Lanchute

6½"

Fig 875. Changkol used in Lanchutes and Palongs

Ground sluices (Art 121) are extensively used in mountainous districts and in hydraulic mines. Capac, about 2 cu yd per hr per ft of width; slope, 4°–8°; water, 15–25 cu ft per cu ft of material washed. They are poor tin savers; recovery often less than 50%. They are cleaned up either by panning the material in the bottom, or by digging it out and concentrating in a lanchute. No blocks or stops are used; the sides are confined and the sand in sluice is allowed to form its own riffles and eddies.

Palong (Fig 876) is a wooden sluice box, in which most of the Malayan tin is recovered. Dimensions vary; typical palong is 120 ft long, 4 ft wide and slopes 3°. Bottom is smooth; transverse baffles *A*, 4 in high and held in grooves formed by vert cleats *B*, are usually 10–12 ft apart. Palongs are single or in sets of 2 or more side by side; they are roofed for protection from weather and supported on trestles to give headroom for tailing. Cost of single palong, in 1937, $1 400; cost of moving and re-erection, $1 000. Capac, about 1.5 cu yd per hr per ft of width; water, 8 cu ft per cu ft of material washed (see also under Dredging). Operation. Material flowing through is stirred by coolies with changkols (Fig 875) and rakes; 1 coolie per 40 ft of length. As heavy sands accumulate and become difficult to agitate, additional baffles are inserted on top of original 4-in baffles, with no further attempt to stir the bottom layer. In 24 hr, a well managed palong builds up about 1.5 ft of concentrates. Clean-ups, usually one per day, are made with a small stream of clear water. Concentrates are dragged up stream with changkols; each section between baffles is cleaned separately, starting at upper end of palong. Multiple-palongs permit continuous operation, as they are cleaned up one at a time. Final concentrates carry 15–30% cassiterite, depending on amount of amang present. Concentrates are shoveled into buckets

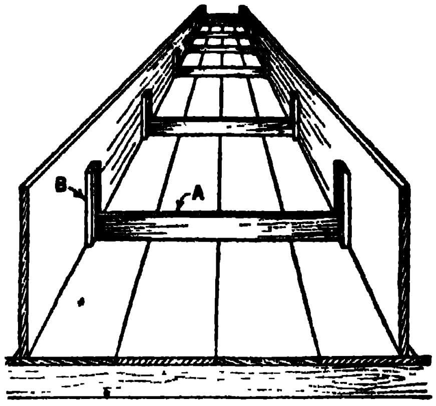

Fig 876. Typical Palong (supports omitted)

and carried to a clean-up house ("tin shed"), where they are brought to standard grade in lanchutes. Extraction: Chinese miners say that an aver palong saves about 80% of tin delivered to it and that 80% of this is caught in first 30 ft. With properly puddled feed, and proper stirring throughout a run, extractionmay reach 90% or more.

Principal factors affecting extraction: (1) Character of material. Water-worn cassiterite is easy, angular grains are hard, to save. It is generally thought that coarse (+ 10 mesh) and very fine (−80 mesh) grains are difficult to save. But, admitting this in saving minus 60 to 80-mesh grains, samples of dredge tailings indicate that the cassiterite lost comprises grains of all sizes in about same ratio as in the feed. Lumps of clay (sluice robbers) cause serious losses by picking up cassiterite; much fine sticky clay in the water causes losses, even though large lumps are removed. In working in clayey ground with little sand, the sands in bottom of the palong tend to scour out. (2) Stirring is important to loosen the sands and permit concentration; packing causes rapid losses. (3) Skill of workmen, their physical condition and amount of inspection. Continuous stirring is drudgery and coolies can not be depended upon at night. (4) Slightly overloading a palong causes heavy loss; transverse ridges of sand form on the bottom, causing swift currents which prevent settlement; the ridges themselves also move down the sluice. Extraction varies greatly under varying combinations of above conditions; fair estimates place losses in palongs at 5% min, 30% max, 15–20% aver. See also under Dredging, Art 132g.

Jigs are the most important washing devices on modern tin dredges. See dredging (Art 132g).

c. Disposal of Tailings

Problems resemble those in gold placers; often tailings must be impounded to prevent silting up streams or injuring adjacent property.

In small mines using lanchutes, sands are commonly carried in baskets from a sump at tail of lanchute and stacked, while slimes run into streams or old mine pits. Some coolies load and others carry sands; duty of labor is about the same as for carrying the original dirt (Table 152). Palongs produce large volumes of thoroughly disintegrated tailings, which build up an alluvial cone under the discharge; slope of cone is from 20% at apex, where coarse sands lodge, to 0 at edges, where slimes are deposited. Cassiterite lost in the palong concentrates near apex of cone; resultant deposit of clean sand and ore is in ideal condition for reworking, and such old tailing cones are worked by tributers on royalties up to 40% of tin recovered. If impossible to run tailings into old mine pits, they are impounded by dams. In hydraulic mines and where much water must be restrained and settled, ordinary earth dams are used.

In many smaller mines, impounding dams are made of alternate layers of long grass (lalong) and sand, built up around the tailings pond as the level rises. Slope of dam face, about 45°, it is soon covered by vegetation, which prevents washing by rain Such dams cost about 1¢ per sq ft of dam face, hence cost of tailing storage is very low. For substantial construction, a layer of grass is laid across the dam, the ends of stalks projecting beyond the face and covered with bundles of grass laid parallel to face. The projecting ends are then doubled back over upper layer and held in place by a layer of sand and dirt hoed up out of the tailings pond. These cost more than simple grass-sand dams, but can be built 15–20 ft high and will hold slimes as well as sand Drains, provided in tailings piles and dams in the areas where finer material is deposited, comprise long A-shaped frames of wood or bamboo, covered first with bamboo matting with 1/4-in openings and then with a 2-in layer of grass. Sand is piled on the grass to hold it in place until it is covered by tailings. These drains are built at any elev in the tailings pile and drain through the dam face.

d. Drainage

Large open-cut mines are drained by power pumps; small mines by hand bailers or China pumps worked by hand, foot or water power. Bailers, for lifting water short distances, are made from 5-gal oil-cans; sides braced with light wooden slats. Fig 877 shows operation; the coolies are 15–20 ft apart; each holds 2 light lines attached to can, by which the bailer is swung back and forth and tipped for loading and dumping. Aver lift, 5 ft; coolies aver 20 swings per min; max output, about 80 gal per min. Oil-can bailers are used in lifts to 15 ft; speed of swing varies little with lift, but less water is taken per swing. This is hard work and coolies in a gang spell each other. To bail more than 80 gal per min, 2 crews work in rhythm from the same stands

China pumps worked by coolies rarely lift more than 4–6 ft; pumps are set on about 30° slope; if power is available, higher lifts are obtained with pumps to 80 ft long. Chief use of China pump is in small workings requiring only intermittent drainage.

Wooden buckets, with a vert pole handle attached to a counterbalanced sweep, are used to bail water to heights of 8–15 ft; they are arranged in batteries of 2–6; men work in rhythm; duty per man,

30–45 gal per min on an 8-ft lift. For lifts over 12–15 ft, batteries of these bailers are arranged on different levels.

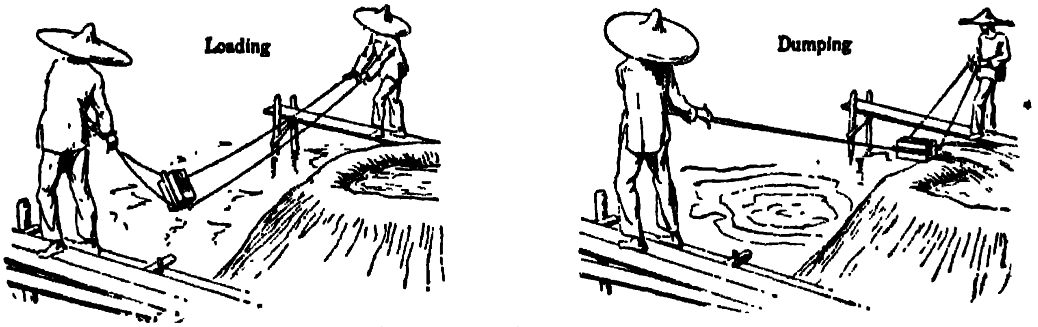

Fig 877. Oil-can Bailer

e. Miscellaneous Hand Operations in Open Cuts

Transport in hand-worked open-cuts is by baskets, wheelbarrows, and cars on tracks.

Carrying in baskets, suspended in pairs from a shoulder pole, is practiced in stripping and moving karang: (*a*) where yardage is too small to warrant cost of barrows and trestles; (*b*) where carry is less than 50 ft, so that relative cost of loading and dumping barrows is high; (*c*) where carry is uphill and conditions do not justify or permit mechanical haulage in trucks; (*d*) in cleaning irregular bedrock. Output is not a serious factor, as large yardage may be moved by increasing number of coolies employed.

Flat rattan baskets are used; capac, 50–60 lb; cost, 17¢; life about 2 weeks. Faces of pits are usually in steps 1–2 ft high; baskets are placed on ground at face and loaded with a changkol. Loading time, 17–80 sec, depending on whether dirt is clay or sand, packed or loose; aver time, 50 sec. A contract coolie carries 2 baskets (aver load, 100 lb); he goes at a trot, which, through the spring of the pole, takes the load off his leg muscles while walking and puts it on when his leg is straight. On up grades, pace is slower, advantage of the spring in the pole is lost, lighter loads are carried and output per hr decreases rapidly. Contract work is usual, with pay based on vol in place; where this is difficult to measure, as in cleaning bedrock, coolies are paid by the trip from the face, regardless of load carried, with resultant lower effic (see Table 152).

Wheelbarrows are used on level leads over 50 ft long, also on long leads where yardage does not justify cost of cars and tracks.

Chinese barrow (Fig 878) is entirely of wood; aver load, 350 lb; cost, $3.50; life, about 2 yr. The projection of the frame in front of the wheel cheapens cost of dumping, etc. Double barrow tracks of 6-in planks are laid at 10-ft intervals along faces. Barrows are loaded with changkols; aver loading time in aver ground, 2 min, 50 sec; dumping time, 3 sec. For duty of labor, see Table 152. Barrow work is usually done by gangs on contract paid by volume in place.

Cars or trucks are V-shaped, steel mine-cars holding 15 cu ft, or about 0.33 cu yd bank measure; they are used on level leads of 600 ft or more and at mines when material is elevated on inclines.

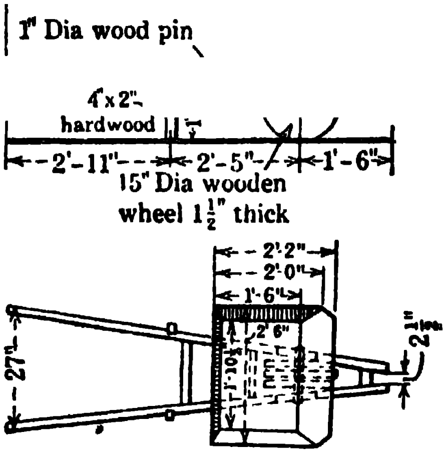

Fig 878. Chinese Wheelbarrow

Track is of 12-lb rails, usually poorly laid; life of cars, 1.5–2 yr. Cars are loaded by 2-handled rattan baskets or trays; area about 18 by 16 in; bottom of tray is curved, with max depth of 6 in. Basket, holding an aver of 63 lb, is loaded with changkols at the face in about 20 sec; it is then picked up and carried to car; hence loading effic depends on distance between car and face (Table 152). Miners do their own tramming; usually 3 coolies per car; with well laid track, 2 coolies per car. Miners paid by truck load.

Duty of labor in above methods of loading and transport is given in Table 152. These data were obtained from typical working places and are averages respectively of 60 time studies of carrying in baskets, 200 of barrow work, and 170 of truck loading.

f. Open-cut Mining

Principal methods: (*a*) by benches; (*b*) with inclines; (*c*) with gravel pumps; (*d*) by hydraulicking and hydraulic elevators.

Table 152. Cu Yd Bank Material in Place that One Coolie Loads and Moves per Hr

Method			Loading (c)	Distance moved, ft					
				100	200	300	400	500	600
Carrying in baskets	Pd by vol (a)	Sand	2.42	1.05	0.67	0.47	0.32	0.26	0.22
		Clay	0.85	0.5	0.32	0.24	0.18	0.14	0.1
	Pd by trip	Men	1.5	0.32	0.18	0.12	0.1	0.07	0.06
		Women	1 25	0.25	0.13	0.08	0.07	0.06	0.05
Wheelbarrow work (d)		Sand	2.5	1.75	1.38	1 1	0.94	0.84	0.75
		Clay	2 0	1.48	1.18	0 99	0.86	0.78	0.7
Loading cars by baskets		Ft carried in basket	0	10	20	30	40	50	.....
		Sand	4 6(b)	2.5	1.9	1.5	1.25	1.05	.....
		Clay	1 7(b)	1 25	0 9	0 7	0.6	0 53	.....

(*a*) Duty of male coolies. (*b*) Loading basket. (*c*) Loosening and loading. (*d*) Contract work.

Working by benches is used in mining large flat alluvial deposits (Fig 873) to 50–60 ft deep. Face is carried in benches (Fig 879); light trestles across the pit provide the shortest possible level distance to dump; max height of benches, limited by danger of caving, is usually about 20 ft.

Overburden is stripped and carried in baskets or moved in barrows over trestles to back of the pit; karang is carried up chicken ladders in baskets to a series of lanchutes set on top of the tailings. The stacked overburden is kept as close as possible to the working face; aver carry or tram from face to dump is approx 150 ft. Drainage of pits is by gravity where possible or by pumps. All digging is done with mining changkols (Fig 875), used as a combination pick, mattock and shovel. To about the year 1900, most large mines were worked by hand in this way; in places faces were 0 25–0 5 mile long, up to 3 500 coolies being employed on one face. Open-cut mines using only hand methods of moving earth generally advance the faces in a fairly straight line; overburden and tailings are dumped in the worked-out pit.

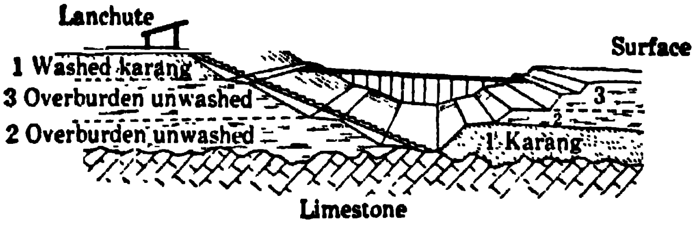

Fig 879. Open-cut worked by Benches. Diagrammatic Cross-sec (trestles to lower benches omitted)

Inclines are extensively used in the deeper mines (to 300 ft) along granite-limestone contacts and in other large open-cuts to depths of 50–60 ft, to hoist waste to dumps, and elevate karang to washing plants. Layouts vary widely with local conditions. Washing plants comprise power-driven arrastras or high-speed puddlers, which feed into elevated palongs or jigs. Pits are drained by centrif pumps, which furnish water for washing; water drained from tailings is often reused. Steam, costing about 2¢ per hp-hour, is the usual power for driving hoists and pumps.

Pits may be advanced in benches (Fig 879), in which case karang is loaded in cars on floor of pit and trammed by hand to foot of incline. At times stripping is handled by cars: (*a*) hoisted in cars on separate inclines serving each bench; (*b*) trammed along benches and dumped into the pit at points where it will not interfere with future work; (*c*) barred down slopes into cars on pit floor and hoisted to surface up main incline. Open pits on contact deposits are usually long and narrow, but in places are circular or elliptical, worked in benches, each served by an incline. In flat alluvials, pit faces are fairly straight, as in bench working (Fig 879). Basins or pockets of karang, occurring too low in bottom of pit for convenient loading into cars, are worked by carrying in baskets to lanchutes on the pit floor. Loading and tramming is done by contract; labor in hoisting, puddling and washing is usually paid by the day.

Gravel-pump mines (see Art 126) are, next to dredging properties, the most important source of tin in Malaya. In 1938, dredges produced 24 550 tons of tin in the Federated Malay States, gravel-pump mines, 20 875 tons, other methods, 9 128 tons.

Usual operation involves: (*a*) hand work to break material from the bank; (*b*) ground sluices to carry material to a sump; (*c*) a pump, usually steam-driven, to elevate materials; (*d*) palongs for washing. Impounding dams are built around the tailings storage areas, the water running back into the pit and through ground sluices along base of the working face. Clays and sand are broken down into ground sluices with hoes or bars, face slopes being kept steep so that material slides to sluice by gravity. This method, applicable under widely varying conditions in different types of deposit, requires delivery of the entire overburden and karang to the sump in the pit floor; hence, working faces are continuous from floor to surface and in plan are apt to take a roughly circular shape around the sump as a center. Entire bank is elevated by the pump and must be stored in tailings piles at ends of the palongs. Max lift of pump is about 75 ft; max depth of pit that can be worked is less than this by the elev required for palongs to provide room for tailing-storage. Pumps are usually high enough above pit floor to avoid drowning out during shut-downs. BREAKING GROUND. Some undercutting is done by water in ground sluices, but typical method of excavation is by "steps" (Fig 880). Pit faces slope about 45°; coolies begin at surface and cut a series of steps about 18 in high in face of slope, using bars for cutting and prying off the ground, which rolls down the face to the ground sluice. When the bottom is reached, men work back up the slope, barring off the steps as they go; duty of labor, in stiff clay, 7–8 cu yd per man-day. Work is on a tribute system; men on steps and those working ground sluices receive a percent of ore recovered in ground sluices; owner retains the ore from the palongs. Recovery of over 75% in ground sluices is rare.

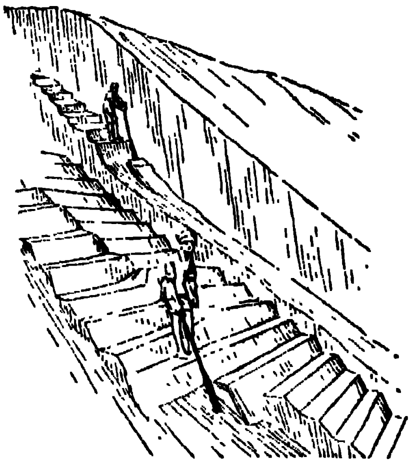

Fig 880. Breaking Ground in Steps

The method provides cheap breaking on contract, and delivers low-grade material to palong, thus reducing losses there. Other advantages of gravel pump: (*a*) elevates at fairly low cost; (*b*) delivers material to palong well puddled and with correct ratio of water for washing; (*c*) drains excess water from pit. The large percent of clay and sands and small percent of coarse gravel, combined with necessity of puddling the clay, makes Malayan tin deposits far more favorable for successful gravel-pump operation than most gold-placer deposits. But, liners and impellers are rapidly worn by the sharp sands, and must be cheaply and quickly replaceable; they are renewed about every 6 weeks. Pump intakes are 3–12 in diam; 4 and 6-in are commonest; larger units not usually successful, due to difficulty in keeping their feed steady. Steam costs about 2¢ per hp-hr; power costs are usually about 25% of total working cost. Capac of 6 in pump is approx 16 cu yd of bank material per hr. Pumps can handle up to 25% solids, but this pulp is too thick for palong feed. Under favorable conditions a gravel-pump mine with an 8-in pump can treat 25 000 yd per month.

Hydraulicking and hydraulic elevators are used under same general conditions as in gold placers (Art 123, 126), except that washing is done in ground sluices or palongs.

Monitors are used in a few places in the hills, followed by ground sluices or palongs; tailings go to dumps by gravity. The more important hydraulic mines, of which there are a few, work alluvial deposits that lie too low for gravity tailing disposal; hydraulic elevators or large gravel pumps then elevate the material to palongs built high enough to give tailing room.

In general, the large percent of fine materials in the banks, need for puddling and absence of coarse boulders, are much more favorable conditions for hydraulic-elevator work than are found in most gold placers and elevator efficiencies are higher. The elevator-monitor combination has the great advantages of completely puddling the material, lifting a high percent of solids, and using small labor force. Chief disadvantage: the usual large proportion of tough clays in the banks results in low duty and high water consumption by the monitors. There are few localities in Malaya (except the Gopeng district, Perak), having enough water under head for large hydraulic operations, and, where sandy karang permits undercutting, for caving of banks and large duty. Data on duties and costs are not available.

g. Dredging

General. First dredge started in 1912; it was successful and dredging is now the most important method, as it allows profitable exploitation of low-grade deposits unworkable by hand. All early dredges were sluice type, described below, and had washing capac of 75 000 to 90 000 yd a month. Installation of classifiers and jigs on a Malayan dredge in 1925 focussed attention on better ore-saving methods and led to an enormous increase in the capac of single dredges and the number of dredges in the field. In 1939 there were 126 dredges in Federated Malay States, 20 in Netherlands East Indies, and a few in Siam. Some can dig 130 ft below water level and treat 400 000 cu yd a month. Their high effic is shown by the facts that their ore-saving devices are contained in spaces 90 ft long.

70 ft wide, and 40 ft high, and that they treat 16 000 tons of gravel a day, with less than a value of 0.5¢ a ton left in the tailings.

Types of deposit worked by dredging are the same as in gold placers (see Requirements and limitations, Art 128). Depths now dredged are 20–130 ft. Schist and granite bedrocks are soft and ideal for dredging; limestone bedrocks are hard and always have pinnacles; in some areas most of the karang lies above the pinnacles, making high recovery by dredging feasible; at present, karang lying between pinnacles is left, though there are promising methods for recovering it. Sunken timber sometimes interferes with dredging.

Chain-bucket dredges are used; suction dredges have generally failed. First dredges had open-connected bucket lines, but with development of large-capac washing devices, close-connected buckets are favored. Steam is generally used, with power plant on the boat. Fuel is wood or poor-quality coal mined locally; power costs are high. Some companies operating several dredges have central turbo-electric power plants. Chinese labor is used almost entirely.

Principal factors affecting design and operation of Malayan tin dredges, in comparison with gold dredges, are: absence of boulders, small size of grains composing the deposits, large amount of clay present, and lower sp gr and value of cassiterite. These conditions affect details of dredge design as follows:

Hulls, mostly steel, resemble those of gold dredges; type of washing devices determines whether hull is long and narrow or short and wide. Digging machinery is same as on gold dredges; broad, shallow buckets are required to dump clayey ground. As digging is easy, head lines are used instead of spuds to hold dredge in position. Trommels always receive material from the dump hopper; they are the same mechanically as on gold dredges, but of smaller mesh. Stone-chutes at tail of dredge are generally used instead of stackers, as there is usually no coarse gravel to handle, hence no stern gantry; tailing piles behind the dredge are level and approx at same elev as original surface. More water is needed than on gold dredges of same capac. Washing devices differ greatly from those for gold (see below).

Types of dredge: (*a*) sluice dredge, developed from the sluice-type gold dredge, was the first used; (*b*) classifier-jig dredge, invented by J. F. Newsom, was first used on a commercial scale in 1925; (*c*) jig dredges without classification, introduced 1927, are an outgrowth of (*b*); (*d*) recent clay-working dredges have reached a high state of effic.

Sluice dredges. Trommel undersize is distributed to sluices running fore and aft, which operate like palongs. Many operators prefer wide sluices; 6-ft width is considered a max, due to difficulty of distributing water in wider ones. Capac: 15–20 cu yd bank measure per sq ft of sluice area per month. Grade: approx 2°, when hull is level; trim of dredge is affected by wt of loaded sluices, which operate on slopes of about 3.5°. Common practice uses 1 coolie per sluice for stirring; mechanical rakes working across the sluice are being tried and appear promising. Large dredges have double decks of sluices, and, where steam-operated, require about 100 men for 3-shift work.

Sluices are cleaned up in rotation, like palongs. Bucyrus Co reports that the sluice area of a tin dredge is usually 4–5 times the table area of a gold dredge of the same capac; water for hopper, trommel and sluices is about twice that for the usual gold dredge of same capac. Overcrowding is more apt to occur in dredge sluices than in palongs on shore; dredges take horiz cuts in descending order and adjacent beds in flat alluvials vary from pure sands to pure clays; these conditions tend to increase losses in sluices (see Palongs, Art 132b). Sampling of tailings by some companies indicates a sluice loss of 15–20%. Use of puddlers is rare; clay that is not disintegrated in the trommel goes through rock chute to dump. It is difficult to provide washing capac for more than 100 000 cu yd per month on sluice dredges, although larger digging capacities are easily obtained.

Classifier-jig dredges operate on basis of results of extensive screen tests of bank materials and sizes of ore grains. In general, free- and hindered-settling ratios of sand and ore grains are such that classification discards much of the slimes and finer sands, without serious loss of mineral. Products from classifier spigots are easily concentrated on jigs. A classifier of large capac and good performance has been developed, allowing the whole plant to be erected on a dredge. In 1927, there were 15 dredges of this type in Malaya.

Flow-sheet for handling about 150 000 cu yd per month is typically as follows: material from buckets passes through a trommel with $^3/_8$-in openings; oversize to tailing; undersize to 2 classifiers (Fig 881). Each classifier makes 4 products: Spigot 1, coarse sand, divided between 2 jigs (105 rpm, stroke 1–1 $^1/_4$ in); spigot 2, medium sand, to 1 jig (115 rpm, stroke $^5/_8$ in); spigots 3–4, fine sand, to 1 jig (160 rpm, stroke $^3/_8$ in); spigots 5–6 and overflow, very fine sand and slimes, to tailing. All jig tailing goes direct to waste. All hutch products go to a desliming sump and thence to 1 cleaner jig, having 6 compartments, each 2 ft wide by 3 ft long; speed 180 rpm, stroke $^1/_4$–$^3/_8$ in. Tailing from the cleaner jig goes to waste, 1st hutch to a final washing plant (lanchute) on shore, while hutch products from other compartments return to the desliming sump. Fig 882 shows jigs and classifiers on a dredge of Rantau Tin Dredging Co; flow-sheet differs slightly from the above; many variations in flow-sheet and arrangement of machines are possible.

Classifier. Fig 881 shows the Newsom double-current classifier; length, 12–16 ft; width, 6 ft; 3 rows of discharge hoppers, each 2 ft sq at top. It has large capac; 1 machine has successfully handled 300 cu yd of sand (without clay) per hr. Water required, 2 500–4 000 gal per min, depending on veloc of currents desired.

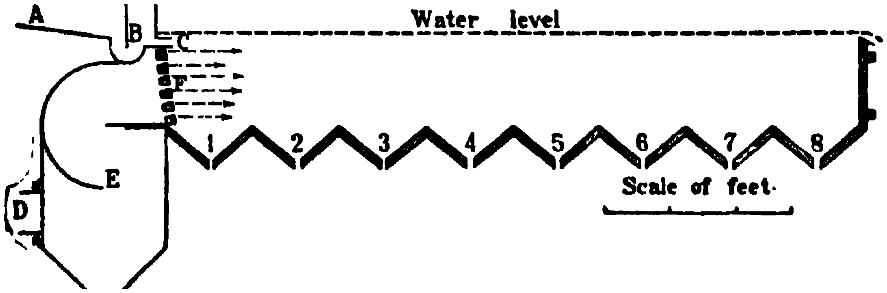

Fig 881. Classifier

Pulp current flows over apron *A*, passes under adjustable gate *B*, and enters classifier through feed slot *C*. Fresh water enters through pipe *D* into pressure-box *E*, thence through grid *F* into body of classifier.

Recovery by classifier-jig system, 90–95%; concentrates run 20–60% cassiterite, depending on kind of ground and skill of operators. The high recovery and large capac of this type of dredge is because the bulk of the cassiterite usually comes down in the classifier with the coarse sands, giving a product that can be jigged rapidly with low loss.

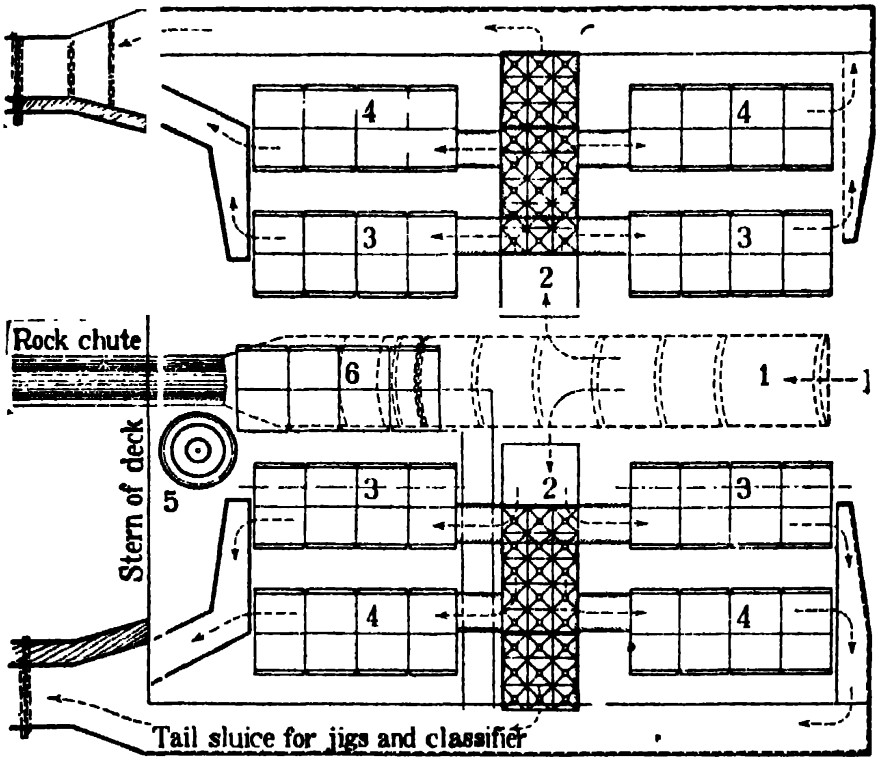

Fig 882. Rantau Classifier-jig Tin Dredge; Outline Deck Plan, showing Arrangement of Equipment. 1, trommel; 2, classifiers; 3, coarse jigs; 4, fine jigs; 5, settling cone to remove water from hutch products; 6, cleaner jig. Classifiers are high enough to feed jigs by gravity. Arrows show direction of flow.

As there is a relatively smaller vol of material discharged from the later spigots, fines can be treated slowly and carefully on a small number of jigs.

Jig dredges without classification have advantage of simpler operation, all jigs being adjusted alike, but yardage treated per jig is lower and tailings losses are higher than for properly operated classifier-jig dredges.

Flow-sheet is typically as follows: Material from buckets passes through a trommel with $^3/_8$-in openings; oversize to tailing; undersize divided equally among 12 jigs (115 rpm, stroke $^5/_8$ in). All jig tailings go direct to waste. All hutch products go to a desliming sump and thence to 1 cleaner jig having 6 compts, each 2 ft wide by 3 ft long; (180 rpm, stroke 1/4–3/8 in). Tailing from cleaner jig goes to waste; 1st hutch to a final washing plant (lanchute) on shore while hutch products from other compts return to desliming sump. Many variations in flow-sheet are used; for example Dorr classifiers to remove slimes, sand from classifiers going to jigs If ground contains clay, disintegrating knives running at high speed may be placed in trommel, or trommel oversize may pass through secondary puddlers (Art 132b, Clay puddling, type *e*) followed by desliming cone (see flow-sheet for clay-working dredge, below.)

Clay-working dredges are frequently necessary, because values are often in tough residual clays. The first attack on such ground was with standard dredges, which proved unable either to dig it rapidly or to extract the values efficiently. Recent dredges, built especially for such ground, are very effic.

Flow-sheet covers a dredge built in 1938 which has handled over 400 000 yd a month. Ground is spotty; barren clay, clay carrying substantial values, sand, and alternating thin layers of clay and sand. To make yardage, the dredge was designed to handle all of this ground at full bucket-line capacity. Because of barren spots and occurrence of pure sand in places, the flow-sheet is flexible, with provision to by-pass material when desired and to change the treatment routine in other ways. Buckets of 13.5-cu ft capac, turning 18 per min, deliver the material to primary trommel. When digging clay, an automatic 3-arm clay extractor is swung into place at the upper tumbler, where it scoops the clay out of each bucket as it comes over. The primary trommel is 9 ft diam by 36 ft long, with screen perforations 1/4 by 5/8 in. Undersize goes to settling tank, described below. Oversize may be by-passed to pond behind the dredge or put through the clay disintegrating screen, 9 ft diam by 28 ft long. The walls of this screen are manganese-steel grids with openings 4 by 5 in. Inside is a puddler shaft, 54 rpm, with blades 4 ft long. Oversize from the clay disintegrating screen goes to pond, undersize to two secondary puddlers (Art 132b, Clay puddling, type *e*). Discharge from the secondary puddlers passes through two secondary trommels 4 ft diam with 3/8-in screen openings. Trommel oversize is rejected, undersize drops into 2 Dorr classifiers 8 ft wide by 30 ft long. Slimes from the Dorr classifiers are rejected to the pond; sands are discharged onto conveyer belts which deliver them to the upper 3 primary jigs on each side of the dredge.

Sand from the main trommel (see above) goes to a settling and desliming box 22 ft long. Slimes are discarded, sands divided among 14 primary jigs, 7 on each side of dredge. Bendelari 4-cell diaphragm jigs, each cell 3 ft 6 in sq, are used throughout. Tailings from primary jigs are rejected. Concentrates are deslimed and then go to cleaner jigs, one for each bank of 7 primary jigs. Tailings from cleaner jigs are rejected. First-cell hutch product is taken ashore to tin shed (see Final concentration, below). Hutch products from the other cells of cleaner jigs return to heads of these jigs.

Jigs were originally 4-compt Cooley jigs (Harz type) of steel; plunger and sieve compts each 3 ft wide by 4 ft long. Lately, other types have been used, mainly low-head jigs with pulsation device in screen compt, thus saving floor space and wt. Screens are punched plates with slots $^1/_{16}$–$^1/_8$ in wide. Hutch water added, usually 50 gal per min per cell. Speed and stroke vary, 115 rpm and $^5/_8$ in being typical. Drops between jig beds are 2–4 in. Beds are usually 4 in thick, of hematite sized below 0.75 in. Iron punchings sometimes used for jig beds. Jig capac on classified product is about 1 cu yd per hr per in width of bed; considerably less for effic work on unclassified feed. Many operators in Malaya place jig screens on even slope from head to tail. The beds are then held in place by transverse 4-in baffles. ADVANTAGES: stops boiling on jig beds, speeds the travel of material, thus raising capac, but at the cost of effic. DISADVANTAGES: very loose bed at lower end of cell and packed bed at upper end, with resultant low-grade product. Stroke must be short, to hold bed on lower end of cell. This sometimes causes packing of whole jig and total loss of values from that jig.

Costs. Sluice dredges cost less than jig dredges, but their capac is much smaller; hence, both first and operating cost of dredges equipped with jigs is much less per cu yd. Sluice-box type, common in Malaya up to about 1925, treated a max of 100 000 cu yd per dredge-month at 10¢ (U S) per cu yd. The modern dredge, equipped with jigs, treats 250 000 to 450 000 cu yd per month at 5¢ (U S) or less per cu yd. This illustrates the great improvement in dredging since 1925, when the first classifier-jig dredge was installed by Yukon Gold Co. Tables 153 and 154 give details of 2 jig-type dredges, fairly representative of current practice in Malaya (G. W. Coffey).

Table 153. Malayan Tin-dredging Data (1937)

Dredge	Time operated		Cu yd mined	Cu yd per aver dredge-month
	Hours	% of total time		
A...........	7 495	85.6	2 871 100	239 000
B...........	7 512	85.8	3 470 400	289 000
Total or aver.	15 007	85 7	6 341 500	264 000

Table 154. Distribution of Working Costs during Operations in Table 153

Item	U S ¢ per cu yd	% of total	Item	U S ¢ per cu yd	% of total
European staff	0.64	12.63	General expense (*c*)	0.72	14.22
Native labor	0.90	17.95	Auto and truck expense	0.02	0.37
Power (*a*)	1.15	22.82	Transport (employes)	0.05	0.97
Material and supplies	0.84	16.79	Drilling (prospecting)	0.11	2.24
Replacements	0.33	6.57	Miscellaneous	0.08	1.51
Ore dressing (*b*)	0.12	2.44			
Land rental	0.01	0.28	Total	5.03	100.00
Insurance	0.06	1.21			

(*a*) Cost of power, approx. 1.0¢ per kw-hr. (*b*) Final concentration on shore. (*c*) Not including dredge depreciation nor home office expense.

Final concentration. Dredge concentrates are taken ashore and raised to standard grade in lanchutes (built of concrete) and by jigging with hand sieves. This is done by contract; usual pay, 50¢ per picul of clean concentrate. Capac of lanchute in final concentration, 700 lb cassiterite per 8 hr. Jigs are sometimes used to lighten the load on lanchutes. Tables, vanners, etc, often tried, have failed. Lanchute middlings containing pyrite are dried, roasted and rewashed. Magnetite, scheelite, monazite, etc, are sometimes extracted by magnetic separators, but only in small quantities from low-grade ore. Final concentrates are dried, sacked, and shipped to smelter or sold to buyers.

Marketing. Malayan tin smelting industry is concentrated in Singapore and Penang, because refined tin is cheaper to transport than the more bulky cassiterite; also because of heavy export duties on ores shipped outside of Malaya. Smelter contracts usually call for delivery at smelter, but ore is weighed and sampled at the mine. Smelter charges are about $19 per ton of ore, based on 74% tin, with deductions for lower assays. Payment is at market price on day of delivery to smelter agent at mine, or any subsequent day fixed in advance, but within 14 days of delivery. Penalties are charged for S, As, Pb, Cu, Bi, Sb, if in appreciable amounts. Other realization charges are freight, which is very low, and a gov't tax which varies (8–13% *ad val*) with the market price of tin. Total realization cost, including this tax, freight, smelter charges, and ocean transportation of finished product, averages about 15% of New York price.

Malayan weights and money. Many companies report values in "katis" per cu yd, ore production in "piculs," and costs in Straits cents per cu yd. Equivalents are as follows:

Weights	Money (at par of exchange)
1 kati = 1 1/3 lb	1 Straits dollar = 100 Straits cts
100 katis = 1 picul = 133 1/3 lb	1 Straits dollar = 2s 4d
16.8 piculs = 1 long ton = 2 240 lb	1 Straits dollar = 56.776 U S cts

For additional information on Malayan tin mining, see Bib (645, 684, 685, 686, 687).

GEOPHYSICAL PROSPECTING

Geophysical prospecting aims to establish the existence, position and boundaries of mineralized areas and geologic structures, or obtain other information of economic or scientific value. It utilizes the gravimetric, magnetic, electric, seismic, and thermic properties of rocks and minerals, natural to the ground in question, or produced artifically. Under either condition, properties of different materials relative to one another are significant. Two factors, applying to both country rock and mineral deposits, are most important: (*a*) kind and amount of material; (*b*) its geometrical form.

1. GRAVIMETRIC SURVEYS

General. Purpose of these surveys is to measure small local variations (ANOMALIES) in the force of gravity, as caused by salt domes, dikes, faults and anticlines. Differences in density of the formations, as well as their geometrical forms, control the size of these anomalies. Since the geol features are very small compared with the earth's volume, the anomalies are correspondingly small. The gravimetric field unit is the GAL (Galileo), the strength of a gravitational field that will act upon a mass of 1 gram with a force of 1 dyne. Thus the earth's field is equal to about 980 gal, whereas the anomalies are of the order of 1 milligal, or approx a millionth of the earth's field. The limit of accuracy is 0.1 milligal; constantly changing celestial and terrestrial disturbances mask smaller anomalies. Most surveys are made with pendulums and gravimeters. PENDULUMS are used at single locations in connection with crystal clocks for determining absolute values; for differences in gravity, they may be spaced several miles apart. GRAVIMETERS determine change of gravity directly from measured changes in their spring extensions. Observations take about 20 min per station. Measurements start at a base station, preceded by pendulum observations. Base stations are about 25 miles apart, and serve to tie in larger areas.

Gravity fields. Older methods called for use of the Eötvös torsion balance, measurement of gravity gradients being in terms of EÖTVÖS UNITS, one unit representing a change of one millionth of a milligal per centimeter, equivalent to 0.1 milligal in 1 km. In the equation of the gravity field, certain coefficients permit evaluation of the change in gravity field.

If v is the gravity potential, then $\frac{\delta v}{\delta z}$ is the gravity component in the z or vert direction. Also $\frac{\delta\left(\frac{\delta v}{\delta z}\right)}{\delta x} = \frac{\delta^2 v}{\delta z \delta x}$ is the change of the vert component horizontally in the x direction; and $\frac{\delta^2 v}{\delta z \delta y}$ is the change of the vert component horizontally in the y direction. The resultant value $\frac{\delta^2 v}{\delta s^2} = \sqrt{\left(\frac{\delta^2 v}{\delta z \delta x}\right)^2 + \left(\frac{\delta^2 v}{\delta z \delta y}\right)^2}$, the rate of change of the vert component horizontally in direction of the max rate of change. The function $\tan \theta = \frac{\delta^2 v}{\delta z \delta y} \div \frac{\delta^2 v}{\delta z \delta x}$ gives the direction of this horiz gradient. These values are determined from the torsion balance deflections in various azimuthal positions.

A second function, the CURVATURE FUNCTION, has the form $\frac{\delta^2 v}{\delta y^2} - \frac{\delta^2 v}{\delta x^2} = g\left(\frac{1}{\rho_1} - \frac{1}{\rho_2}\right)$, where g is the value of gravity and ρ_1 and ρ_2 are the max and min radii of curvature of the equipotential surface at point of observation. Dimensions of this unit are the same as for the potential gradient. It is sometimes referred to as the H D T ("horiz directing tendency"). The value of this function bears somewhat the same relation to the vert gradient as the horiz magnetic variation bears to vert magnetic variations; increase in its value shows the proximity of an anomaly. Fig 1 shows anomalies for simple configurations; the full line gives the gradient values, or vert variation of gravity per unit of horiz distance; the dotted line, the H D T, or curvature function.

The geol interpretation of gravity anomalies is made by comparing observed curves with theoretic curves for ideal bodies. Such anomalies may be defined by the rate of change of the vert component, horizontally and in direction of the max rate of change $\frac{\delta^2 v}{\delta s^2}$ (the full line in Fig 1); the dotted line shows the value of the curvature function $g\left(\frac{1}{\rho_1} - \frac{1}{\rho_2}\right)$ for the same anomaly indicated by the hatched cross-sec. These cross-sections resemble the geol formations and the observed gravimetric gradient and curvature functions in Fig 2.

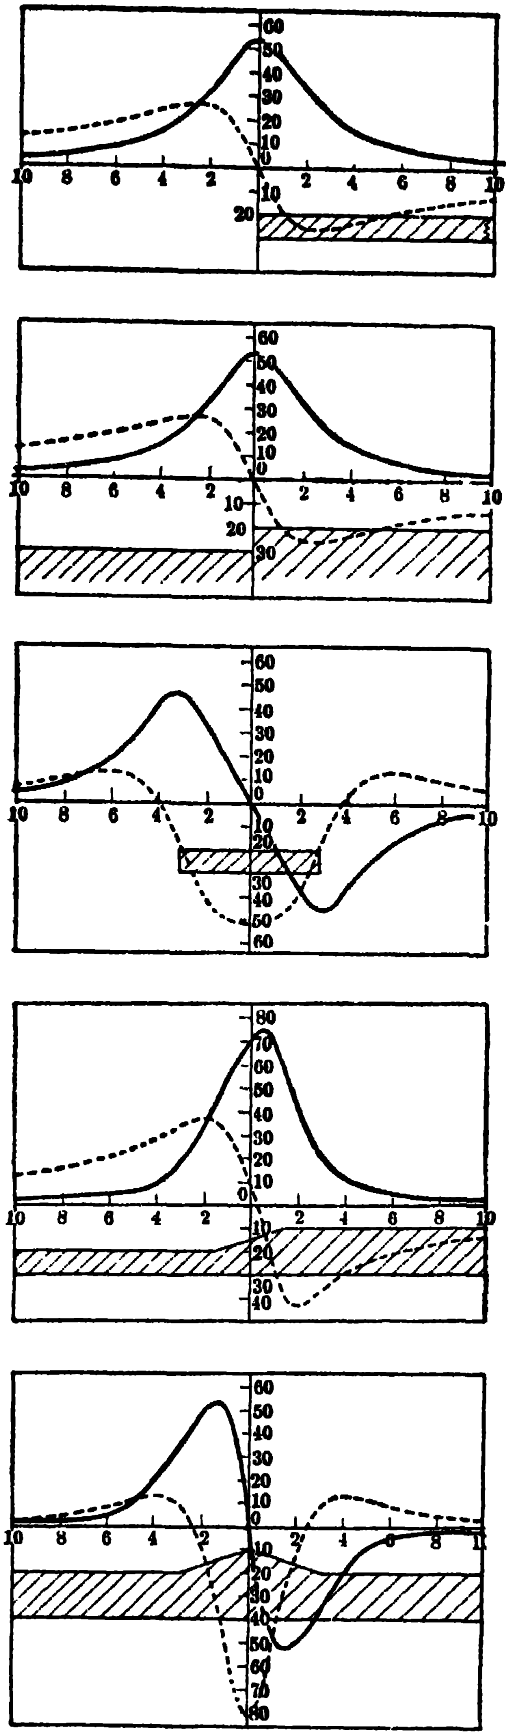

Fig 1. Theoretical Gradient and Curvature Anomalies caused by Geologic Conditions (1)

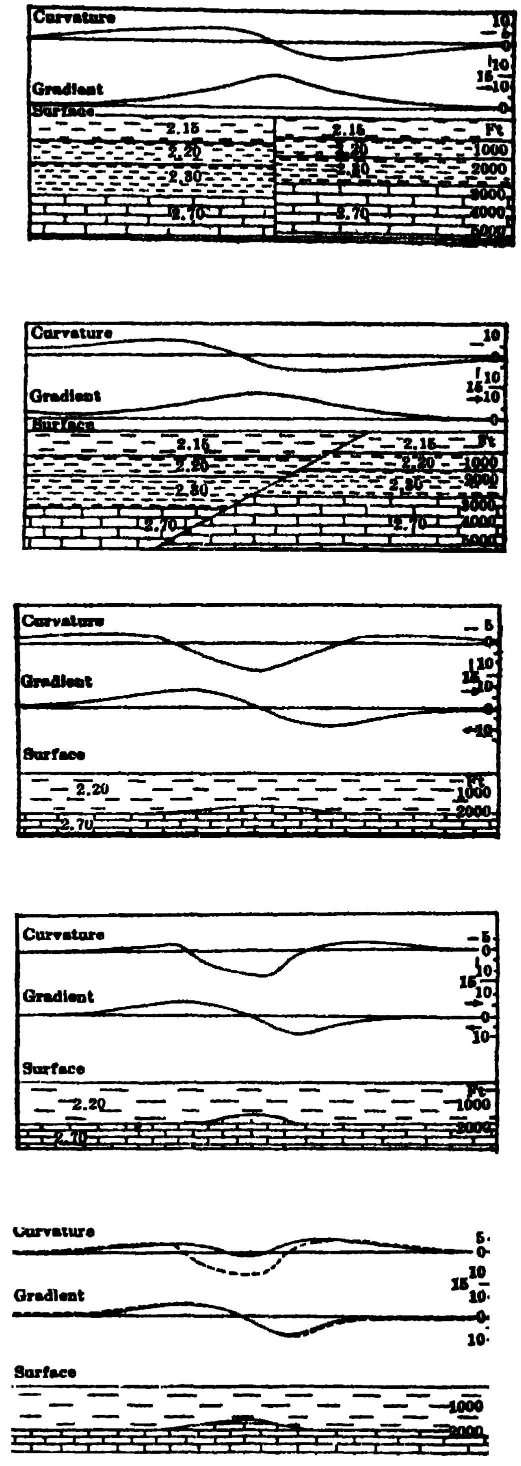

Fig 2. Common simple Types of Geologic Structure and Their Gradient and Differential Curvature Profiles (2)

Vector relations of gradient and curvature (Fig 3) are connected by the values of angles θ and ϕ_2. The value of θ is given above; that of ϕ_2 follows from the relation

$$\tan 2\phi_2 = -\frac{\dfrac{\delta^2 v}{\delta x \delta y}}{\dfrac{\delta^2 v}{\delta y^2} - \dfrac{\delta^2 v}{\delta x^2}}$$

Computation of anomalies is not always difficult. In Fig 4*A*, the gradient is $\frac{\delta^2 v}{\delta s^2} = G = 2\gamma\sigma \log_2 \frac{\rho_2}{\rho_1}$, where σ = density and γ is a factor depending on the units used. In Fig 4*B*,

$$G = 2\gamma\sigma \left[(\sin\theta\cos\theta)(\alpha_2 - \alpha_1) - (\sin^2\theta) \log_2 \frac{\rho_2}{\rho_1} \right]$$

the sense of the angle θ being from OA to P_1P_2.

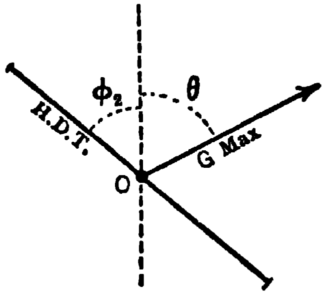

Fig 3. Conventional Representation of Curvature and Max Gradient (1)

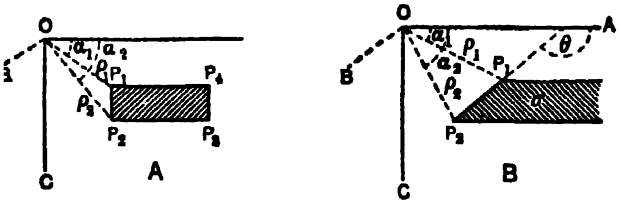

Fig 4. Gravity Effects of Infinite Horiz Slabs (1)

To interpret the anomalies, charts are used (Fig 5), by which the anomaly at a given station due to a geol body may be computed graphically. Each dot represents a unit effect at the instrument *O*, for material of unit density. A scale drawing is made, showing a vert sec through the ground along a plane passing through the station center and perpendicular to the long axis of the body. A transparent-dot chart is placed over the drawing, its center coincident with the instrument location on the drawing. The unit value of each dot is then multiplied by the density of the material over which it lies; their sum is the gravity anomaly at *O*. Observed anomalies are compared with graphically computed anomalies for geol bodies of various kinds, shapes, sizes, density distributions, and distances, until the correct combination giving the curve type is found, each type having its own chart.

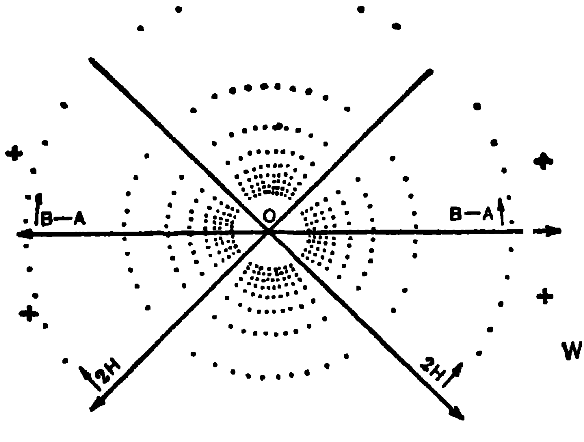

Fig 5. Example of Network for Eötvös Calculations (1)

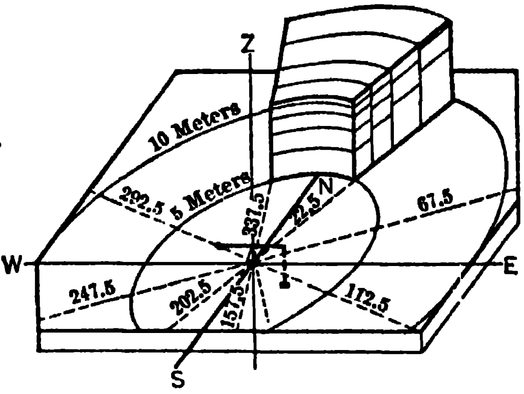

Fig 6. Block Diagram of Terrane around a Torsion Balance Station (3)

Separate charts are used to determine gradients and curvature functions for different axial extents of the geol body. Fig 5 shows a chart for graphic computation of the curvature function for bodies having an infinite extent perpendicular to plane of the chart; $B - A = \frac{\delta^2 v}{\delta y^2} - \frac{\delta^2 v}{\delta x^2}$ and $2H = \frac{\delta^2 v}{\delta x \delta y}$.

To determine the value of deep-seated anomalies, the local mass distribution of the ground must be corrected. Correction factors for sectors immediately around the torsion balance (Fig 6) must be computed, by a chart like that in Fig 7. The ground is surveyed as in Fig 8, and the chart applied to each sector. The corrected results are charted as in Fig 9, which shows a gravity anomaly over a salt dome capped with anhydrite. The gradient arrows around the margins of the dome point towards the center; farther away, the direction is reversed, since the density of salt is less, and that of the cap rock greater, than that of the surrounding material. The lines without arrows represent direction and magnitude of the curvature.

Apparatus for gravity measurements. The torsion balance was first used to measure gravity anomalies. The observations require a long time, since 5 azimuthal positions must be observed at each station; shortened to 3 by using a double balance; 2 stations per day for 2 men are usually the max. With gravimeters, readings can be taken every 20 min, measuring the change of the vert component of gravity $S = \frac{\delta v}{\delta z}$; level data are needed for each station, accurate to less than 0.5 ft to preserve the limiting accuracy of 0.1 milligal, since a 1-ft difference of elev corresponds to 0.2 milligal in the vert component of gravity.

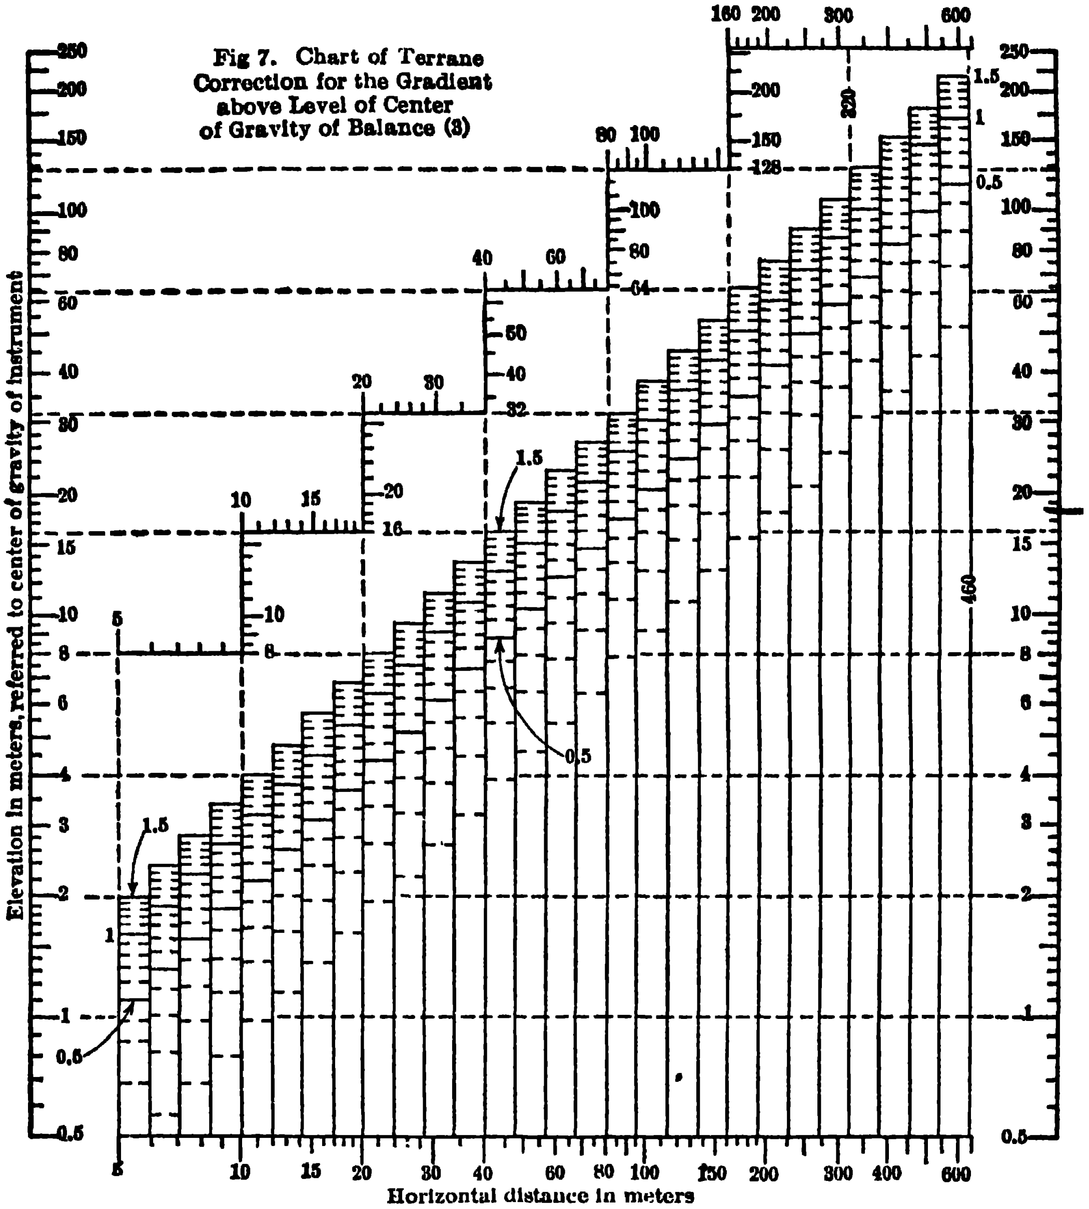

Fig 7. Chart of Terrane Correction for the Gradient above Level of Center of Gravity of Balance (3)

. Pendulum stations at intervals of 25 miles are probably most accurate for measuring differences in the vert component. By using photoelectric cells and wireless to transmit the pendulum's position to a common station for oscillographic recording, with a timing interval on the record of 1 cm per 1/500 sec, differences of 0.1 milligal can be measured, each measurement requiring about 50 min. Charts of equal gravity differences, plotted in iso-gals, give a clear picture of salt domes and other geol formations

2. MAGNETIC SURVEYS

General. **Magnetic exploration is the oldest geophysical method, dating to the 17th century; it is based almost exclusively on measurements of the earth's natural magnetism. Origin of the earth's magnetism is unknown, although its lack of constancy, which bears no relation to geologic bodies, has been explained. Magnetic surveys employ the ordinary compass, together with more precise magnetic instruments. The 2 factors measured are:** change in direction and intensity of the magnetic field. Change of direction in a horiz plane is a change in DECLINATION; that in the vert plane is a change in INCLINATION. Declination measurements can be made with an ordinary compass, to which sights are attached for maintaining a constant direction. Inclination can be measured with a balanced needle swinging vertically in the plane of the magnetic meridian, as determined by compass. This instrument may be called a dipping needle. The balance is tested by turning it at right angles to the magnetic field; the needle then assuming a vert position and deviating equal amounts from the vert for equal displacements in opposite directions from this right-angle position. The results are charted as profiles, or as iso-declination, or iso-inclination lines, connecting points having same deviations.

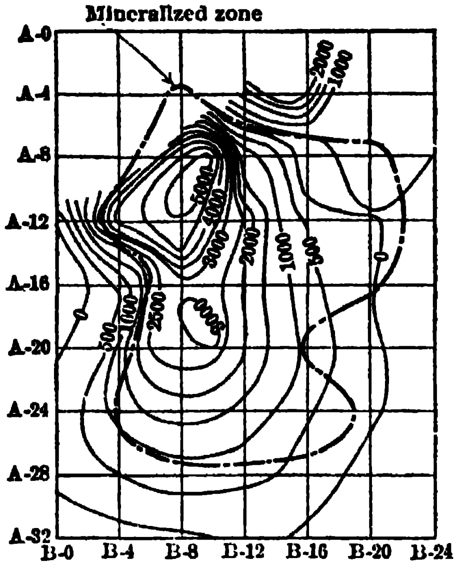

Fig 10. Correlation of Vert Isograms with Zone of Mineralization (5)

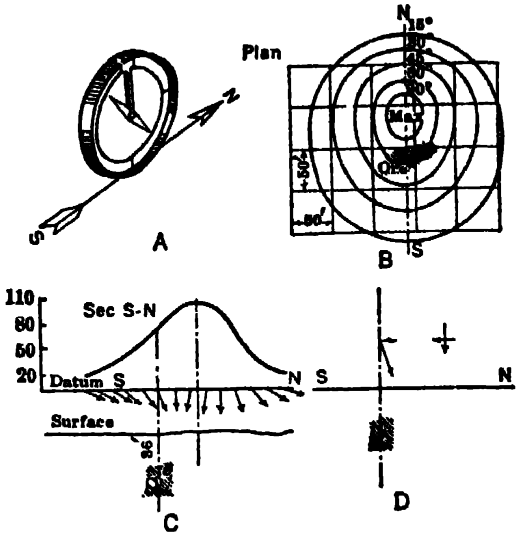

Fig 11. Dip Needle parallel with Magnetic Meridian (6)

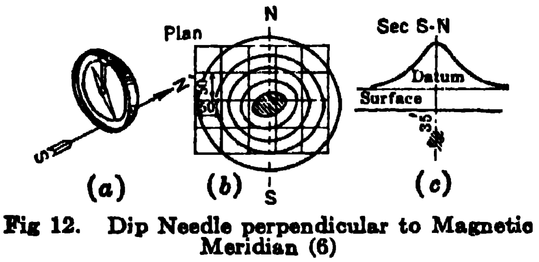

Fig 12. Dip Needle perpendicular to Magnetic Meridian (6)

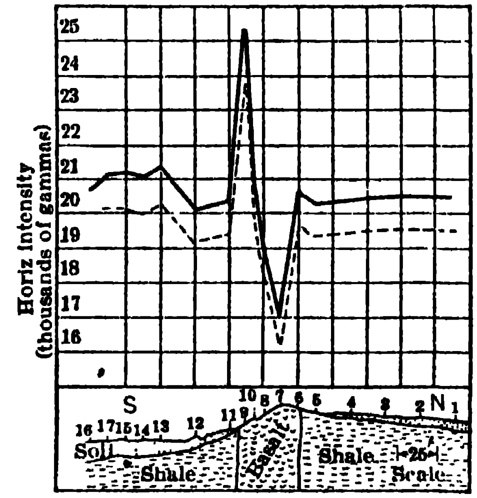

Fig 13. Survey of Horiz Magnetic Intensity, Valmont Dike Extension (7)

To measure changes in intensity of magnetism, the unit is the GAMMA, or 10^{-5} cgs units. The old-type dipping needle is sensitive to about 2 000 gammas per degree; improved instruments to about 200 gammas per degree. The dip needle outlines satisfactorily a magnetite deposit, as that in Fig 10, where the anomalies are large.

Dip needle. Two methods are followed. (*a*) That shown in Fig 11 places the plane of swing of the needle in direction of the magnetic field. The vert component of the field, governed by a single pole, has a max directly over the magnetic pole, whereas the max of the horiz component, having a value less than that of the vert max, lies to one side of the pole. Hence, the needle's deflection is not always directly over the poles, but is offset so that the ore lies under the more gently sloping side of the magnetic profile, Fig 11. (*b*) If observations are made with the needle swinging in a plane at right-angles to the magnetic meridian, only the vert component is effective, and the max deflection will coincide with the position of the magnetic anomaly (Fig 12). A non-magnetic tripod, which permits proper orientation of the needle, is best.

Magnetometer, for measuring variations in vert magnetic intensity, uses an ordinary compass to determine the horiz direction of the magnetic field, and then places the measuring system, similar to a dip needle, at right-angles to this position. This is done by the Hotchkiss Superdip and the Schmidt variometer. The Thalen-Tiberg magnetometer and its simplification by Brunton permit measurement of variations in horiz magnetic intensity exceeding 200–300 gammas. The anomaly of a basaltic dike in shale, as measured by a horiz Thalen variometer, is shown in Fig 13. The dotted line indicates the anomaly after correction for length of the deflecting magnet. Modifications by the Askania Corp have made the movement sensitive to 20 gammas by a design resembling a chemical balance. Further refinements eliminate the temp coefficients, and permit observations to the order of 3–5 gammas. Practically, little added information can be expected from further increasing the sensitivity of magnetic instruments.

Analyses of magnetic measurements are probably approached most simply by adding geometrically the effect of the space distribution of magnetic poles. Variations in vert intensity and those of the horiz component both require consideration. Fig 14 shows the anomaly caused by induced *N* and *S* poles. Fig 15 shows that the inclination of the poles changes the character of the anomaly for both vert and horiz intensities; in such case the max vert component is nearest the source of the anomaly, whereas the max horiz component is not directly over the pole.

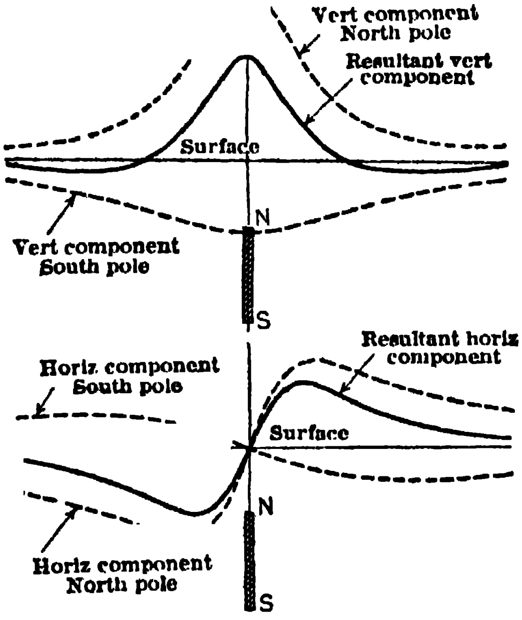

Fig 14. Theoretical Anomalies for Vert Dike of Finite Length (5)

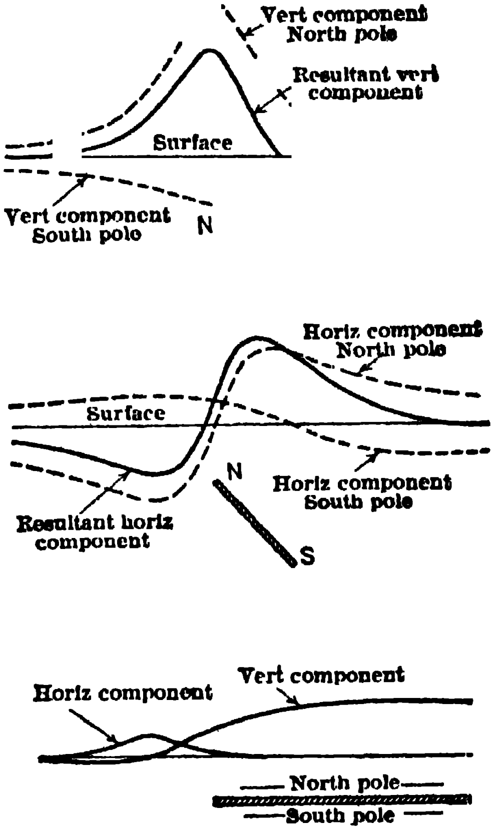

Fig 15. Theoretical Anomalies for Dikes of Finite Length (5)

The character of the function representing magnetic intensity depends on polarities and strength of the induced poles, and their distribution over the body producing the anomaly. If the body parallels the earth's field and has infinite vert extent, as a narrow dike in the magnetic meridian or a volcanic pipe paralleling the magnetic resultant, only the magnetic poles induced on top of the body need be considered, since the poles on the bottom are so distant as to be negligible. Magnetic intensity of a narrow dike is represented by an inverse first-power function. In case of the volcanic pipe, the poles on top are regarded as a point source, the magnetic intensity being represented by an inverse-square function. If the body is a sheet of finite thickness, so that poles of opposite polarity induced on upper and lower surfaces of the body are both at finite distances from the surface and hence both effective in determining the intensity, the function is an inverse-cube. Generally, the intensity function is complicated by geometrical and intensity factors having no common relation.

Fig 16 shows that the elements causing the 3 functions do not produce different types of anomalies, but only different intensities. Unless the form of the body is known, correct interpretation is difficult. Fig 17 shows the magnetic profile across a nickel orebody, striking E–W. The theoretical vert anomaly indicates the function to be less than $1 \div d$, because the poles are distributed over the sides separated by the dike's width. If the strike of the dike were N–S, the top only would enter the computation, which would be for a simple inverse function. The horiz component, measured by a variometer, shows the general anomaly at about 100 ft N of the pole. The incongruent portion of the horiz magnetic curve south of the dike indicates another of smaller size, which could not have been found by the vert magnetometer alone.

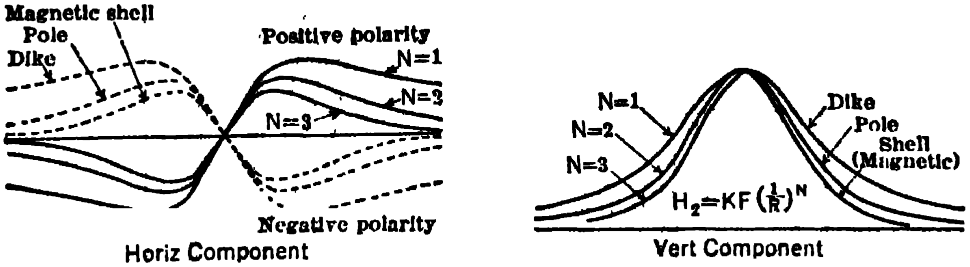

Fig 16. Variation in Magnetic Components for Dikes, Poles, and Shells (8)

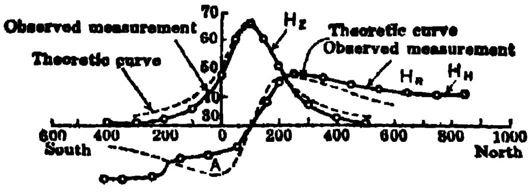

Fig 17. Comparison of Observed and Computed Curves of Vert and Horiz Magnetic Intensity Variations (8)

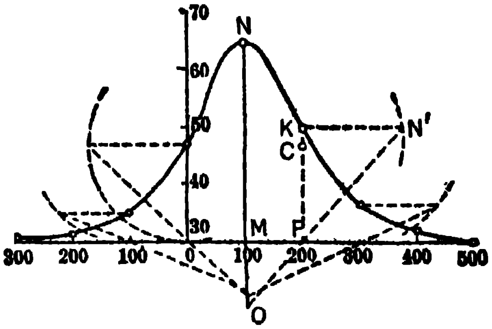

Fig 18. Approximation of Depth of Dike from Vert Magnetic Profile (8)

To ascertain the shape and depth of the source of magnetic anomalies requires knowledge of magnetic field theory. In case of a dike, relatively simple relations can be used (Fig 18). At any point *P* of the traverse, erect *PK*, passing through the anomaly curve. About a center *C* on *PK* pass circle *PN'*, with radius *CP* equal to 0.5 *MN*, through point *P* and tangent to the base line. Through *K* pass line *KN'* perpendicular to *PK* and *MN*, intersecting circle *PN'* at *N'*. Extend *N'P* through *P* to line *NM* extended; intercept *MO* gives the depth. Similar construction starting at other points on the magnetic profile should check at same depth. An understanding of magnetic theory is necessary to determine the mode of analysis best suited to any particular case.

If the country rock is magnetic and the orebody is not, the body is defined by a reverse anomaly. Fig 19 shows a hematite body bordered by magnetite in slate. The magnetite causes the vert components to show a max on each side of the body and a magnetic low over it. In some places, faulting has caused the loss of a vein (Fig 20). Here, surveys of the vert magnetic variations indicate the displaced position of the orebody, and the amount of shift along the fault; a magnetic high on the edge of the vein characterizes the formation. Local measurements often show features of an area definitely outlining magnetically different rocks related to the vein.

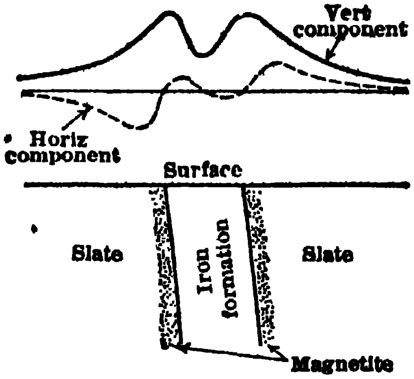

Fig 19. Typical Magnetic Anomalies for Conditions as shown (5)

Magnetic variations sometimes reflect changes of elev of the crystalline basement. In such surveys, very small but important anomalies exist; great care is needed to avoid false observations, since the measurement involves differences of only a few gammas. As diurnal variations are often far greater than the anomaly, a base station is used with a second instrument to give the proper correction for the time of each observation. Magnetic storms often prevent such work. Horiz sedimentary formations free from folding may contain considerable magnetite without greatly altering the picture of the underlying basement rock, if the magnetite is uniformly distributed over the area.

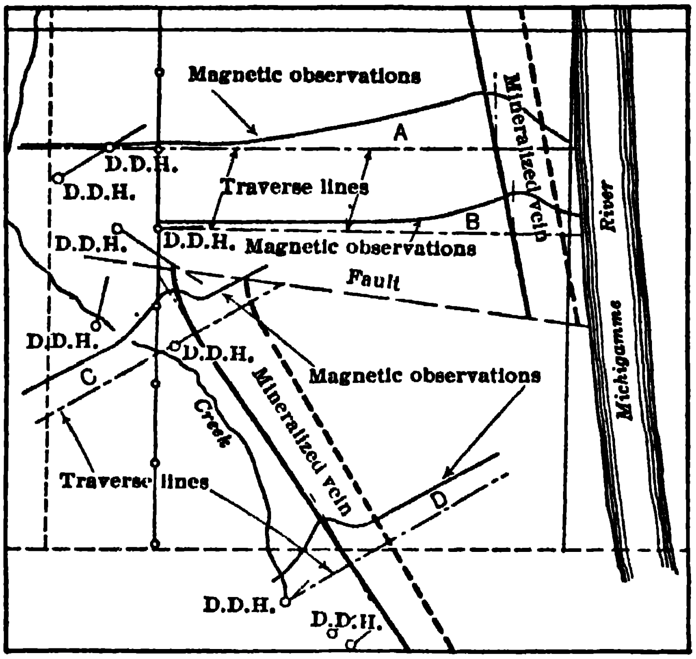

Fig 20. Detection of Horiz Faulting by Magnetic Anomalies (5)

Field operation. Traverses are run with stations at intervals less than width of the anomaly sought. Cost of the work depends largely on the spacing of stations. In oil surveys, where stations are 1 mile apart and the section corners difficult to find, 13 stations may constitute a day's work; on open profile lines, more than 100 observations can be made per day by an observer and assistant. When using a horiz magnetometer, corrections are necessary for the effect of vert intensity. Fig 21 is a chart for this purpose, prepared by U S Coast and Geodetic Survey.

3. ELECTRICAL METHODS

These methods are in 2 main groups: (*a*) Self-potential methods measure the natural potentials of the ground; (*b*) induction methods measure artificially-applied currents and potentials.

Self-potential methods have been widely used. The elec field is of chemical origin and the methods are especially adapted to oxidizing sulphide deposits, the manner in which oxidation occurs determining the polarity. Oxidation at the top produces solutions that are positive with respect to the ore. Ore at depth may be positive or negative, depending on location and quantity of oxidized substances in the material at the point of reference. Oxidation is controlled by seepage of meteoric waters containing O. Where deposits are active and near the surface, differences of 500 millivolts may occur over an interval of 100 ft. Potential differences at the surface are common and often due to differences of concentration of solutions acting as concentration cells. These are of the order of 20 millivolts in 100 ft. The poles produced by deposits at increasing depths eventually become indistinguishable from those present from other sources.

Care must be taken in making natural-potential surveys to avoid variable ground potentials, which may originate in auroral discharges, artificial sources, or magnetic storms. Fig 22 shows a section across a sulphide deposit undergoing oxidation from the top. Ground contacts are made at *e* and *e'* by non-polarizing electrodes, and the potential difference is measured by potentiometer *P*; conductor *L* completes the circuit.

Field surveys. There are 2 methods: (*a*) using a comparatively short distance between *e* and *e'* (Fig 22), most useful where the terrain is difficult; (*b*) keeping 1 electrode

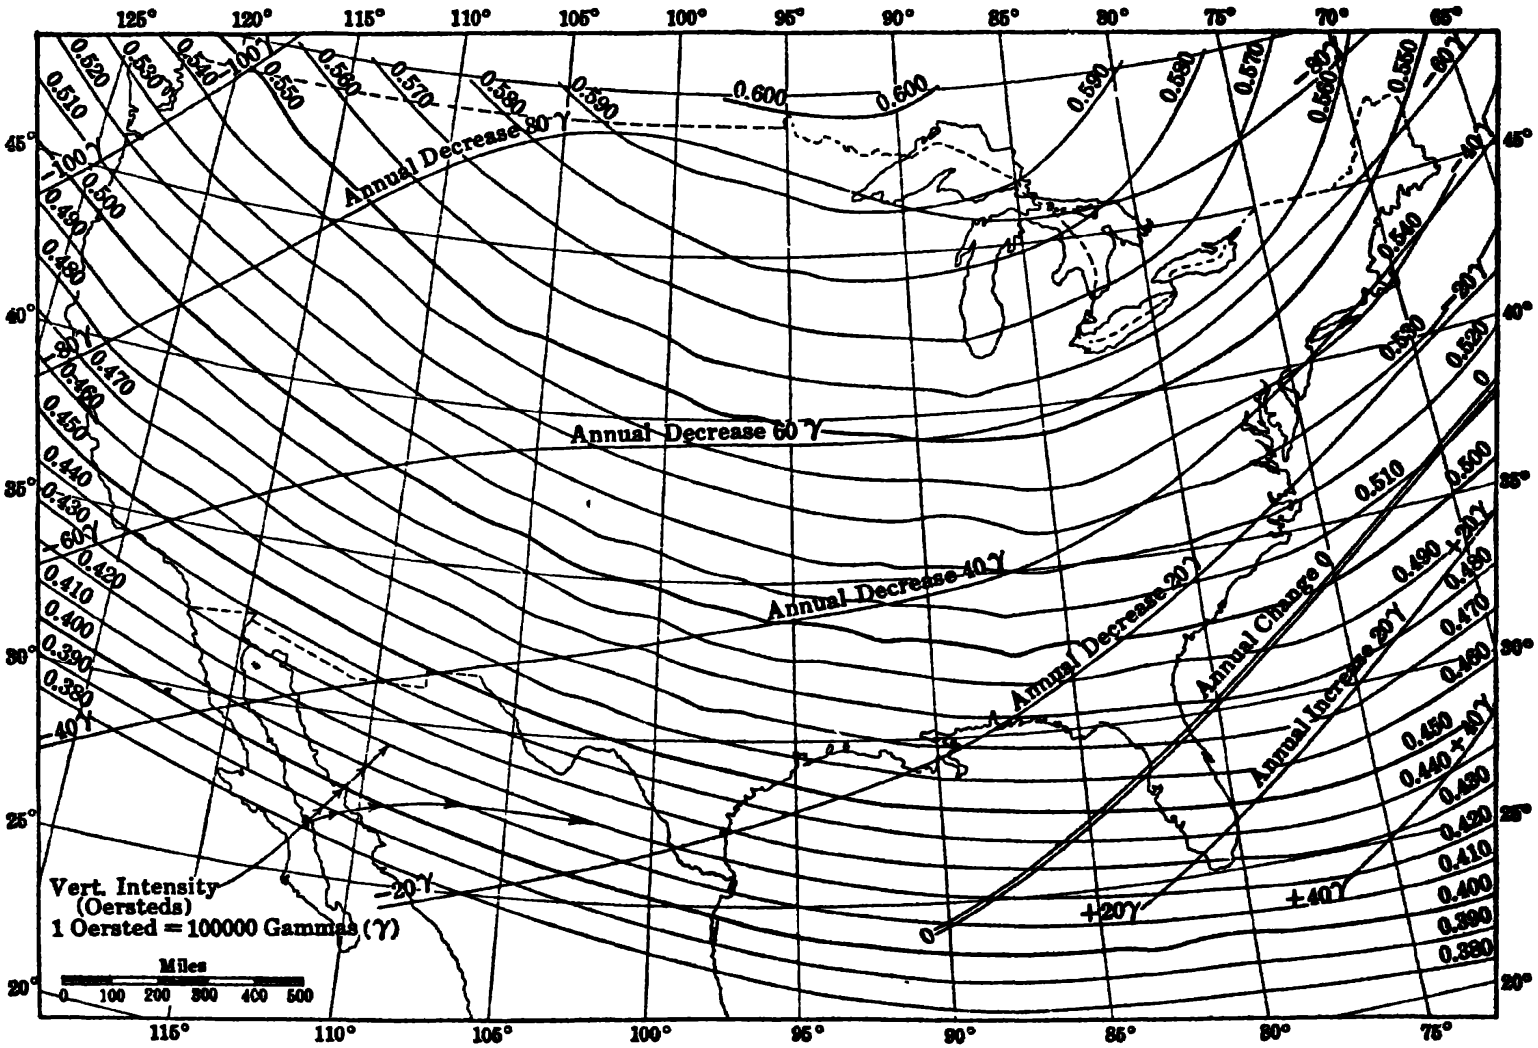

Fig 21. Lines of Equal Magnetic Vertical Intensity, and of Equal Annual Change in the United States, 1935. (U S Coast and Geod Surv)

e′ fixed and gradually increasing interval *L*. In Fig 22 *L* is short, and the leading ground contact *e* advances the same distance for each observation, the trailing electrode being placed on the point previously occupied by the leading electrode; hence, there is a reversal of potential over the deposit, not a max value.

The field is best laid off in parallel traverses, on which the potentials are plotted as in Fig 23. Differences in potential between some specific point and points on the separate traverses are also observed. From these data, iso-potential lines are drawn as in Fig 24. The position of the orebody is generally directly under the greatest anomaly. Standard elec instruments are used: potentiometer with a range from 1 millivolt to 1 volt, 2 porous-pot ground contacts, wire connectors, tape, and compass. The method applies to deposits of electrically-conducting sulphides and oxides, as pyrite, galena, chalcopyrite, pentlandite, and associated minerals; less applicable to magnetic oxides. It can not be used to prospect for non-conductors, as sphalerite, cinnabar, and stibnite.

Electrical ground resistivity. Correlation of this to geology is well recognized; investigations have provided solutions of problems relating to geol formations and structures, even where few surface indications were available.

In this method, the earth is regarded as a medium having ohmic resistance, and much work has been done regarding the distribution of currents and potentials. Practical results often give enough information for the purpose. It has been found that certain factors so complicate the laws of ohmic conductivity as to put theoretic conclusions at variance with physical observations. Such factors are the non-uniformity of resistivity with current density, anisotropy, the combination of electrolytic activity associated with ohmic conductivity, and the channeling of the current instead of a uniform distribution through the medium. Hence, a simple number, neither exact nor aver, called APPARENT GROUND RESISTIVITY, is taken as an index and computed on the assumption of a simple distribution of currents and voltages in a uniform isotropic medium.

Two methods for measuring the apparent ground resistivity are: (*a*) Schlumberger places the current electrodes in the ground very far apart and measures the earth resistivity near one of the contacts, neglecting the effects of the distant electrode; (*b*) a method first used by Wenner makes equal spaces between current and potential electrodes (Fig 25). This has been modified by Lee, who introduces a third potential electrode P_0, midway between P_1 and P_2, permitting ground comparisons, determination of geol continuity, and elimination of surface resistivity anomalies not related to deeper formations. Fig 26 shows the general principle of the modified Wenner method. The effective field penetrates deeper into the ground when the battery contacts are moved farther apart. The ground around the electrodes is excluded from measurement and the mid-section divided into 2 parts *m* and *n* for comparison. Deeper observations are made by gradually separating the electrodes, keeping point *A* fixed (Fig 27*B*). As new material is encountered (Fig 28, *a*, *b*, *c*) the apparent resistivity varies with the elec resistivity of the deeper material. It may often be preferable to maintain a fixed spacing and move the whole elec configuration along a line, as in Fig 27*C*, for discovering lateral changes of ground material.

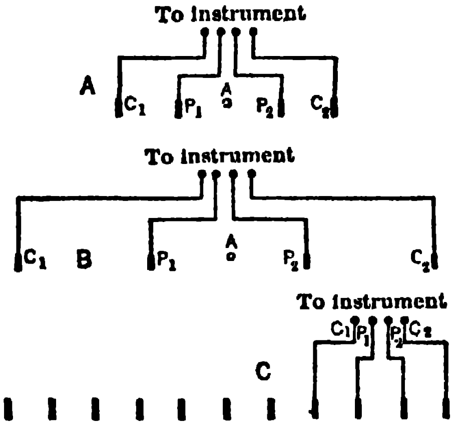

Fig 27. Stake Layout for Measuring Resistivity. A and B, for increasing depths at one point. C, for constant depth along a line (11)

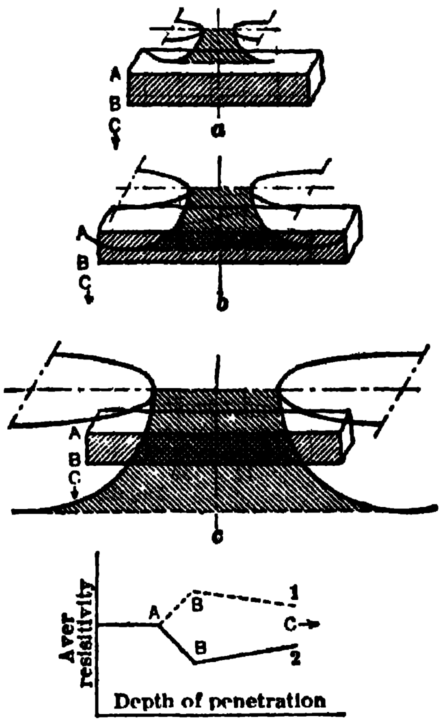

Fig 28. Effect of Increasing Depths on Resistivity Curves (11)

Fig 29 shows application of this method for determining gravel beds, illustrating the changes in apparent ground resistivity with depth. The gravel has high resistivity, causing the curve (Fig 29*A*) to rise rapidly after it is encountered at a depth of 18 ft on the N side of the instrument. Similar conditions exist on the S side, except that the resistivity is lower, indicating more silt. The bed extends to depth of 36 ft before meeting clay. The second pair of curves (Fig 29*B*) indicate uniform ground, containing no gravel to depth of 48 ft. In the method of ground measurements shown in Fig 30, the current contacts can be made regardless of polarization, whereas the potential contacts are best made with non-polarizable electrodes. Reversing switches in both the current and potential circuits are needed to eliminate natural ground potential. If variable ground currents are present, commutating devices operating simultaneously on both current and potential circuits, as used by Gish, are preferable; but commutated current is disadvantageous, owing to the small amount of current used on high-resistance ground, compared to the charging current. Also, for great depths, the skin effect, or lack of current penetrations, is a limiting and disturbing factor.

Simple mathematical relations. For a simple isotropic medium the relation between potential and current is (see Fig 25):

$$V = \frac{I\rho}{2\pi}\left[\frac{1}{r_1} - \frac{1}{r_2} - \frac{1}{r_3} + \frac{1}{r_4}\right],$$

where V = voltage between the potential electrodes, P_1 and P_2; I = current in amperes applied to the ground; r_1 = distance P_1 to C_1, cm; r_2 = distance P_1 to C_2, cm; r_3 = distance P_2 to C_1, cm; r_4 = distance P_2 to C_2, cm; π = 3.1416; ρ = resistivity in ohm-centimeters (ohms per cubic cm).

In the Wenner configuration, $C_1P_1 = P_1P_2 = P_2C_2 = a$, and the above formula reduces to $\rho = 2\pi a \frac{V}{I}$ ohm-centimeters.

In the Lee configuration, $C_1P_1 = 2\,P_1P_0 = 2\,P_0P_2 = P_2C_2 = a$, and the above formula reduces to $\rho = 4\pi a \frac{V}{I}$.

If a is measured in ft, $\rho = 191.5\,a\frac{V}{I}$ ohm-centimeters for the Wenner configuration; $\rho = 383\,a\frac{V}{I}$ ohm-centimeters for the Lee configuration.

Measurement of depth of overburden by the elec superposition method of Roman. It is often desirable to measure this depth, which can be done if overburden has uniform elec resistivity, if bedrock is at least as thick as overburden, and if the resistivity of bedrock differs from that of the overburden.

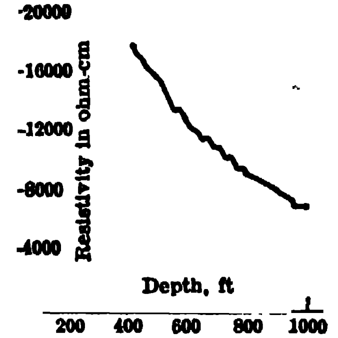

Fig 31. Resistivity Curve as Measured (13)

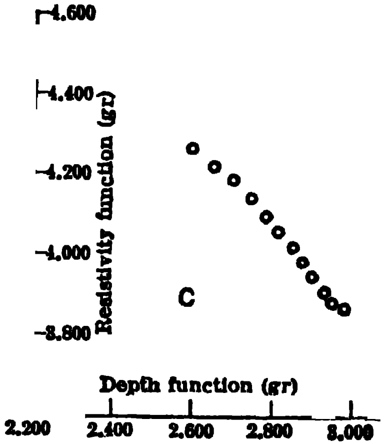

Fig 32. Resistivity Curve Plotted from Conversion Table (13)

Details for an example of sand and gravel on clay are as follows:

(*A*) Using the Wenner or other suitable electrodes, obtain a resistivity-depth curve (Fig 31) by changing the spacing.

(*B*) Replot this curve logarithmically (Fig 32) from Table 1 for both axes; *GR* is mantissa of the log of the number *NO*. In Fig 31, depth 400 ft and resistivity 18 000 are coordinates of first point; corresponding logs, from Table 1, are 2.602 and 4.255, where .602 and .255 are the mantissas in the table; 2 and 4, the characteristics for 3 and 5 digit numbers respectively. If the curve rises to the right, the underlying bed is an insulator; if the curve falls, a conductor.

(*C*) Template curves, Fig 33, 34, best plotted on transparent sheet, are provided. Two groups of master curves are given, one for high-resistance or insulator beds and one for low-resistance or conducting beds. Table 2 gives values from which the master curves of Fig 33, 34 are plotted, and serves for plotting the templates on a larger scale. Care must be taken in plotting the observational curve (Fig 32), to see that the scale for a logarithmic cycle is the same as that on the template master curves.

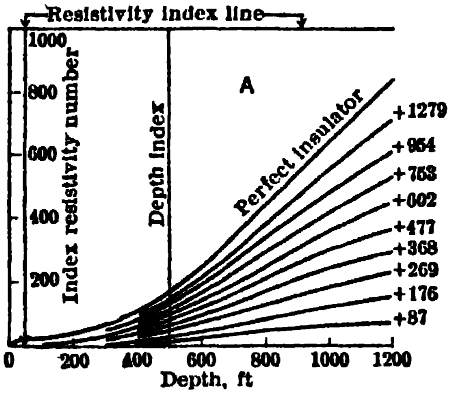

Fig 33. High-resistance Bed (13)

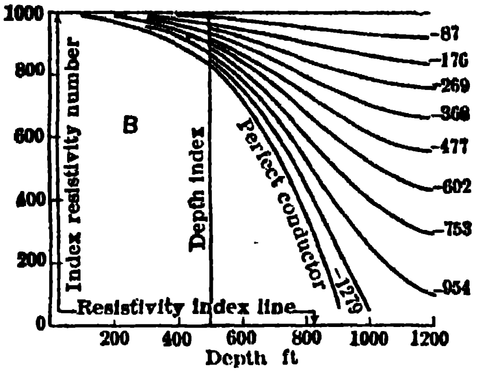

Fig 34. Low-resistance Bed (13)

(*D*) Slide the template over the curve of Fig 32, as in Fig 35, until the observational curve coincides approx with a master curve. In Fig 35, the curve falls along the conducting-bed master curve, having curve index number −753.

(*E*) Depth index line of the template shows a value of 2.500 in observational curve sheet *C* (Fig 35). Using Table 3 for *GR* = 500, the corresponding number is 316 and, as the characteristic is 2, the depth is 316 ft.

(*F*) Overburden resistivity is obtained from the resistivity-index line intercept on curve sheet *C*, (Fig 35), in this case 4.440. The anti-log of this number being 27 500, the overburden resistivity is 27 500 ohm-cm.

(*G*) Logarithm of resistivity of the bedrock equals the resistivity-index intercept, plus curve-index number, or 4.440 − 0.753 = 3.687, the antilog of which is 4 860 and the resistivity of bedrock is 4 860 ohm-cm.

Alternating-current and inductive methods, formerly confined exclusively to mineral prospecting, are now used also for oil. They aim to measure the reaction of a geol body to the change of a magnetic field passing through it. Usually they employ alternating magnetic fields with frequencies of 500 cycles per sec. The measured distortion of the original field, in phase and amplitude, is related to the body causing the anomaly. Since the resultant magnetic field is always plane and elliptically polarized, the position of the plane in space and the axes of the ellipse must be determined; hence the measurements of the complete field distribution are slow, and restricted to certain components directly related to the anomaly, but are not contained in the main exciting field, thereby simplifying interpretation.

An inductive method, of Nunier, permits measurement of resistivity to increasing depth, without losing geol continuity, by placing on the ground a coil the diameter of which is proportional to depth desired. The coil is excited with an alternating current. A small exploring coil in the center is adjusted to measure the magnetic field from the induced current in the ground. Various frequencies are used to avoid errors from skin effect. A curve, plotted between depth of penetration and the resistivities observed, is the inductive counterpart of the Wenner system. Potential ratio method applies a c to the ground, and measures the ratio between 2 pairs of points in the field by a bridge circuit in which the potential differences of the earth circuits are 2 arms in the bridge, while the other 2 arms are in the measuring set and adjustable for making a balance. Measurements are made along profiles with a definite spacing. Changes of impedance and impedance ratios are correlated with the geology. In the Bieler-Watson method, a large coil of about 600 by 1 200 ft is placed on the ground and excited by a 500-cycle a c. Induced voltages are measured in a 2-coil system, adjusted in the resultant plane of vibration, and balanced against each other through circuit

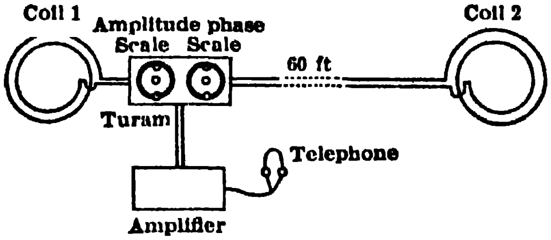

Fig 36. Apparatus used in Turam Method (14)

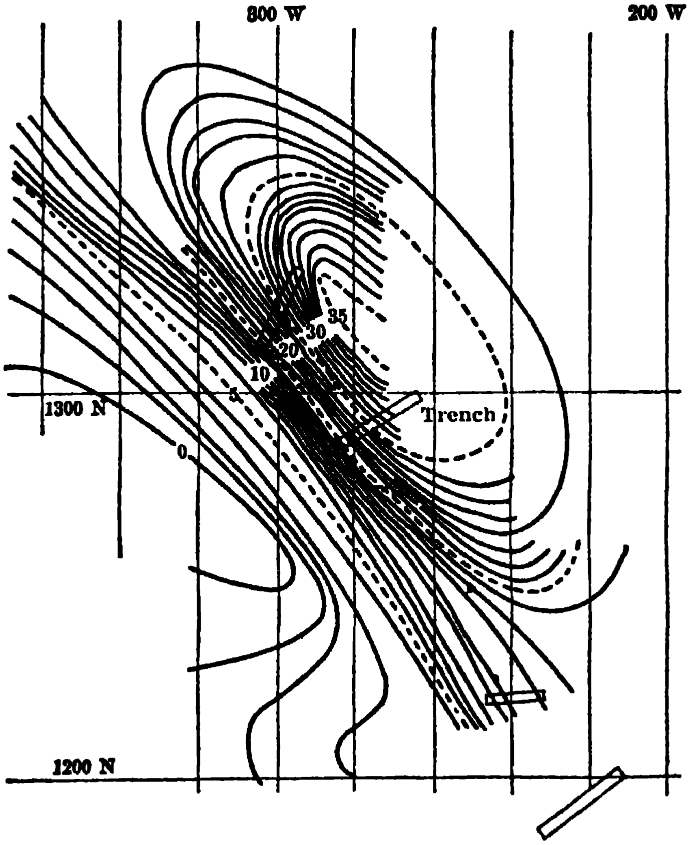

Fig 37. Equiphase Curves in Electromagnetic Field over Orebody discovered Electrically (14)

arrangements; the ratio of minor to major axis of the polarisation ellipse is entered on the charts, and iso-anomaly lines are drawn. The Turam method employs a long, straight conductor, laid on the ground, grounded at each end, and supplied with a c. Two coils (Fig 36), a fixed distance apart, are used to run traverses at right angles to this wire, and changes of phase and amplitude are measured between the induced voltages in each coil. Iso-phase curves are then charted as in Fig 37;

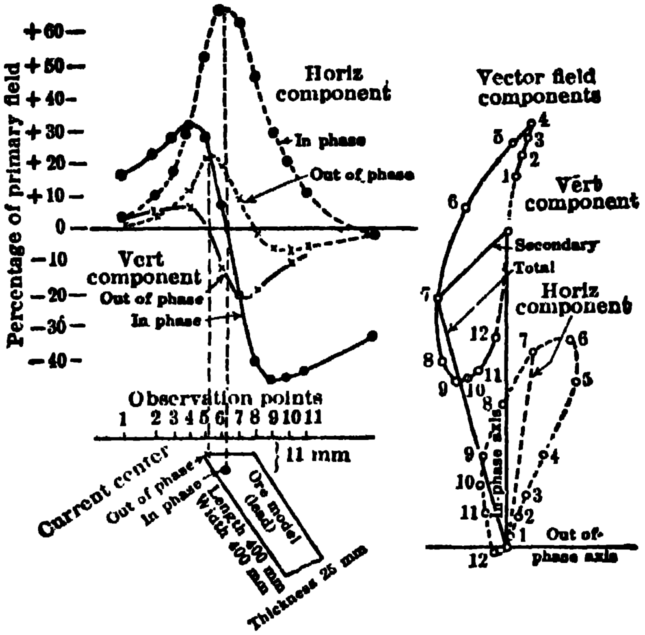

Fig 38. Electromagnetic Secondary Field Components over Ore Model (14)

iso-phase-difference charts are also plotted; the places where steepest gradients occur on the charts are the areas sought. Tests on models (Fig 38) show position of an artificial orebody and the change of the various associated a-c magnetic components.

Electromagnetic methods are generally advantageous in needing no ground contacts (especially helpful in frozen districts), but they often fail to give detailed geol definition, and often do not permit restriction of vert or lateral boundaries to certain limits. The theoretic values of current and potential distribution, even under simple assumptions, are difficult to calculate, especially if the orebody is imbedded in an electrically conducting medium. These methods now rest on a quasi-scientific basis. Changes in amplitude of

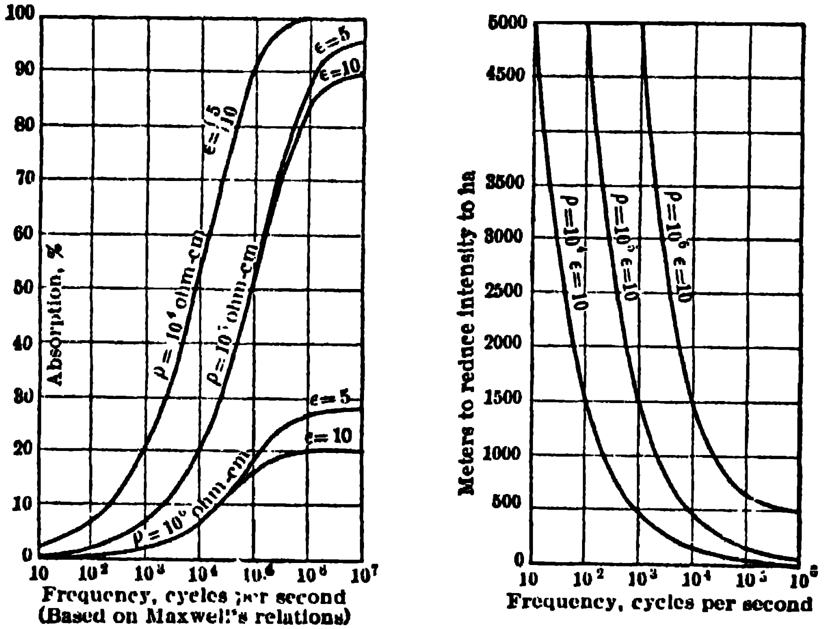

Fig 39. Absorption of Plane-polarized Electromagnetic Waves in Homogeneous Media (15)

electromagnetic waves when passing over dikes and faults are noticeable for certain frequencies and can be used for mapping them.

High-frequency radio waves are not well adapted to geophysical work. There is a lack of penetration, due both to skin effect and to absorption of the waves by the rocks. Since the dielectric constant of water is 80, and that of rocks much less, geol anomalies are difficult to identify by using high frequencies, as they are often concealed by effects due to water in the rocks. The percentage absorption of a plane-polarised magnetic wave, and the depth in meters required to halve the intensity, are shown in Fig 39.

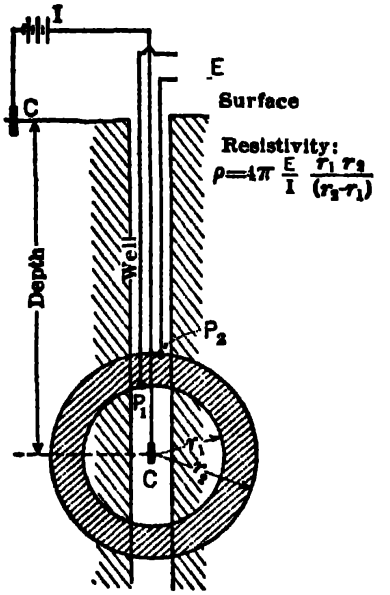

Fig 40. Resistivity about a Single Electrode. Adapted from E. R. Shepard (12)

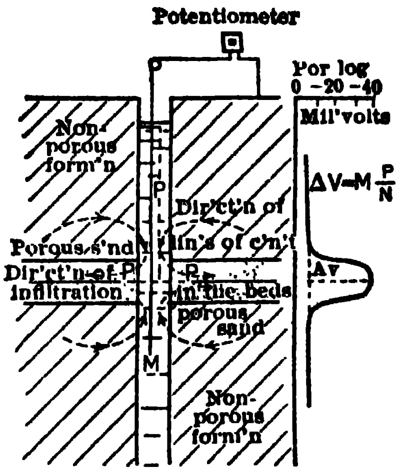

Fig 41. Recognition of Porous Beds by Resistivity Measurements (16)

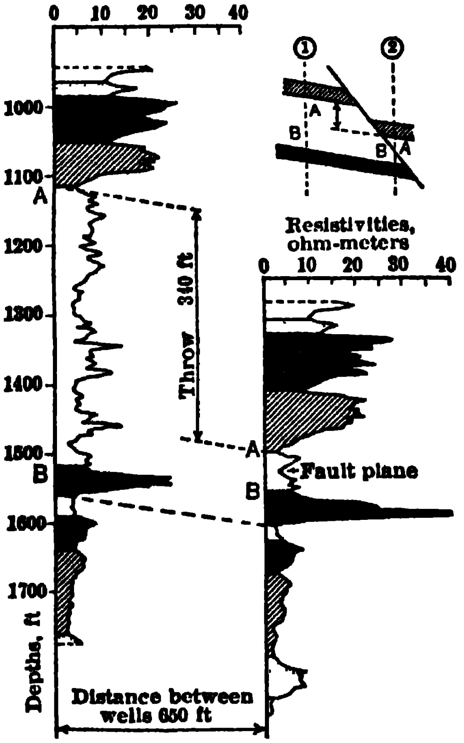

Fig 42. Solution of a Fault by Resistivity Measurements in Boreholes (17)

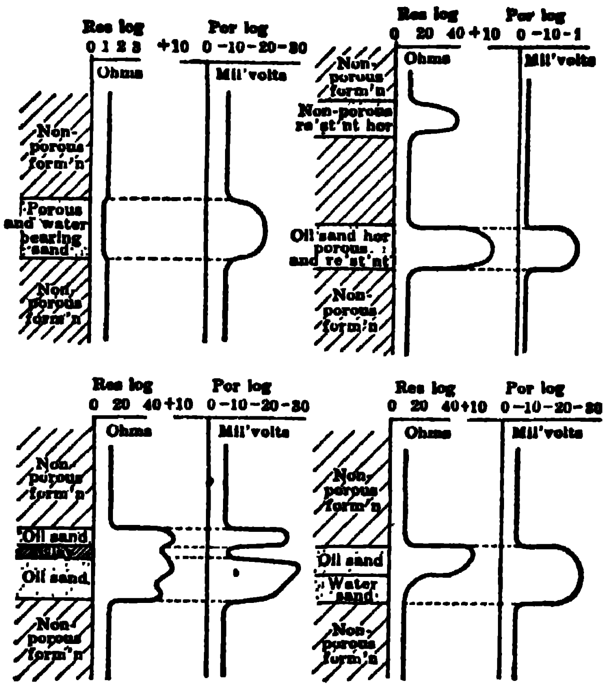

Fig 43. Interpretation of Resistivity Measurements in Boreholes (16)

Electrical well logging, according to Schlumberger, comprises measurement of elec resistivities of the formations penetrated by drill hole or well, and charting the values at successive depths, and includes elec observations related to porosity of the formations. To measure RESISTIVITY, a set of electrodes, (P_2, P_1, C, Fig 40) is gradually lowered into the well; current I is held constant and the potential E is registered on a recording chart. The resistivity is proportional to the measured potential, since $\rho = 4\pi \frac{E}{I} \frac{r_1 r_2}{r_2 - r_1}$ in which all factors except E are constant. To measure POROSITY, a potentiometer is connected from one electrode at top of the well and a second in the well (Fig 41). An increase in potential indicates a wider spreading of the drilling mud into the formations.

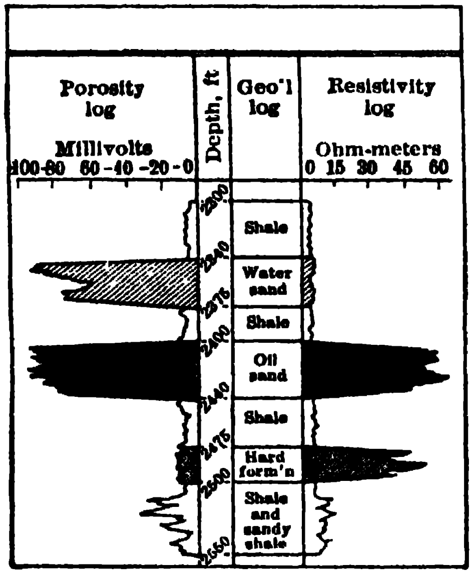

Fig 44. Typical Interpretation of Theoretical Porosity and Resistivity Measurements in Same Hole (18)

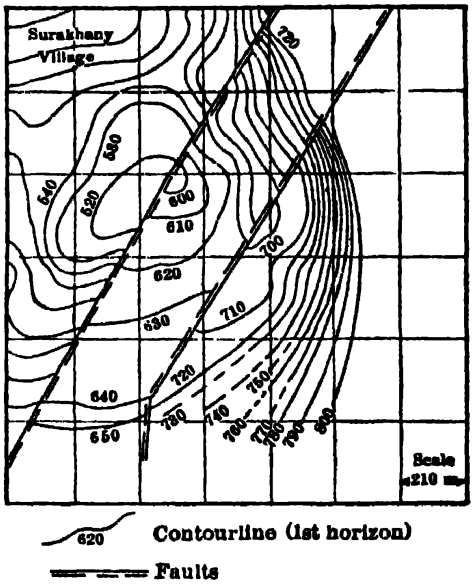

Fig 45. Example of Stratigraphic Contouring by Resistivity Logs (19)

Fig 42 shows a theoretic log. Water and oil sands show considerable penetration of mud; shale and limestone do not. The log of an oil well shows low resistivity for sands containing saline water and high resistivity for sands impregnated with oil, but the porosity log shows high porosity for both. Hard formations have high resistivity, but low porosity. Thus, oil sands are distinguished from water-bearing sands, and non-porous, hard formations from oil-bearing sands (Fig 43). Usually, other compact formations show small porosity and high resistivity. In water wells the work is less simple, since clay deposits and mud in porous gravel are much alike, and potential differences are often too small to distinguish between them as to porosity. Gravel beds impregnated with fresh water have very high resistivity compared with clay beds, the reverse of the saline situation in oil wells.

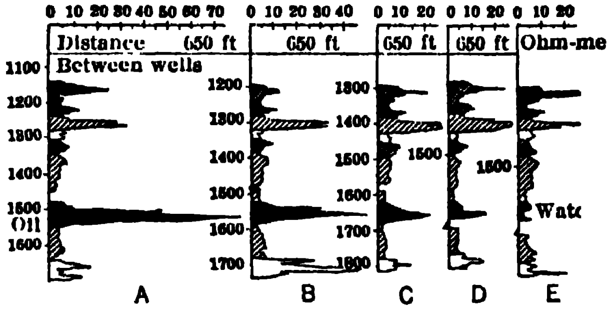

Fig 46. Transition from Oil- into Water-sand, Venezuela (20)

Stratigraphy and structure. The elec resistivity in well logs when plotted against depth forms well defined profiles. By comparing these (Fig 44), and identifying corresponding sequences, faults may be located and their throws measured. To contour the elev of certain identifiable beds, resistivity logs from dry wells are valuable for both stratigraphic and structural information (Fig 45). Resistivity logs of wells are also useful for determining the salt-water boundary of oil pools (Fig 46). Resistivities of oil beds are high, gradually tapering towards the water-impregnated boundaries. Fig 47 shows 3 producing horizons; also an anticlinal structure continuing up into comparatively shallow beds.

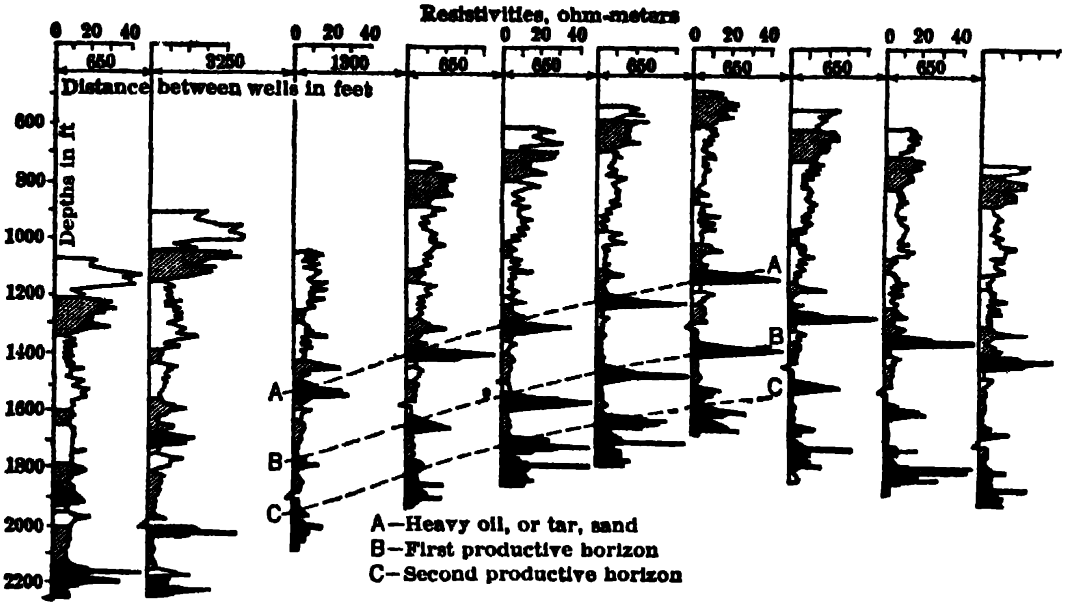

Fig 47. Example of Oil Structure disclosed by Resistivity Logs (17)

4. SEISMIC PROSPECTING (20-22)

General. Seismic prospecting utilizes waves artificially generated in the ground, and examines their path, veloc, time, and character from their origin to their destination. Waves in a homogeneous medium are: (*a*) dilatational or compressional, similar to sound waves; (*b*) transverse or shear waves, like light or electromagnetic waves.

Certain combinations of physical constants of the medium determine the veloc of elastic waves. With simplifications due to Macalwain, the factors are:

1. Young's modulus, $E = \frac{Fl_0}{A_0 \delta l}$, where F is the stress; l_0, the original length before stress was applied; A_0, the original area before stress was applied; δl, the change in length in direction of the stress.

2. Poisson's ratio, $\sigma = \frac{\delta d/d_0}{\delta l/l_0} = \frac{l_0 \delta d}{d_0 \delta l}$, where l_0 and d_0 are the original length and diam of the material before stress; δl and δd are the changes of length and diam after stress.

3. Sum of the principle stresses, $X + Y + Z = \frac{E\theta}{1 - 2\sigma}$, where X, Y, and Z are the components of the stress F in the x, y, and z directions, and θ is the cubic or volume dilatation; the latter has the value $\theta = \frac{\partial V' - \partial V}{\partial V}$, where ∂V and $\partial V'$ are volumes of an element of constant mass δm before and after application of stress F.

4. Lame's constant, $\lambda = \frac{\sigma E}{(1 + \sigma)(1 - 2\sigma)}$. 5. Coefficient of rigidity, $\mu = \frac{E}{2(1 + \sigma)}$.

6. Bulk modulus, $K = \frac{E}{3(1 - 2\sigma)}$. 7. Coefficient of incompressibility, $1 + k$.

8. Longitudinal veloc, $P = \sqrt{\frac{2\mu + \lambda}{\rho}} = \sqrt{\frac{K + 4/3\,\mu}{\rho}} = \sqrt{\frac{E(1 - \sigma)}{\rho(1 + \sigma)(1 - 2\sigma)}}$, where ρ is the density;

9. Shear-wave veloc, $S = \sqrt{\frac{\mu}{\rho}} = \sqrt{\frac{E}{2\rho(1 + \sigma)}}$; also: $\sigma = \frac{\frac{1}{2}\left(\frac{P}{S}\right)^2 - 1}{\left(\frac{P}{S}\right)^2 - 1}$.

If an impulse is applied to homogeneous ground, the first arrival is a longit or P wave; followed by a shear or S wave, and then by surface (Rayleigh) waves, the origin of which is controlled by surface boundary conditions.

Seismic prospecting methods, now current, utilize the first arrival of the P or compression waves, which are similar to sound waves and reflected and refracted at surfaces of discontinuity. For reflection, angle of incidence = angle of reflection. For refraction,

$\frac{\sin\alpha}{V_1} = \frac{\sin\beta}{V_2}$, where α is angle of incidence and β the angle of refraction, V_1 is the veloc in medium 1; V_2, the veloc in medium 2. The same relations apply to shear waves. There is a difference in seismic waves, as they can carry both compressional and shear stresses at boundaries of mediums, because a compressional wave will generate not only the usual reflected and refracted ray, but also a reflected and refracted shear wave. This difference is analysed best by considering the differential coefficients for both dilatation and shear on boundary conditions. The relations at such a contact surface of an impinging compression wave are (Macalwain):

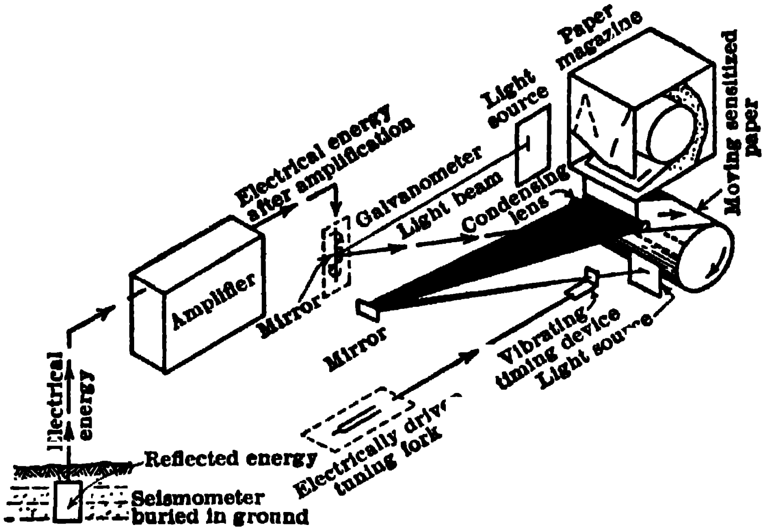

Fig 48. Diagram showing Reflection Seismograph System (21)

$$\frac{\sin\alpha}{P'_1} = \frac{\sin\gamma}{P'_1} = \frac{\sin\delta}{S'_1} = \frac{\sin\eta}{P'_2} = \frac{\sin\zeta}{S'_2},$$

where P'_1 and P'_2 are velocities of compressional waves P_1 and P_2 in medium 1 and medium 2 respectively, and S'_1 and S'_2, are the velocities of shear waves S_1 and S_2 in mediums 1 and 2; α = angle of incidence of P_1, γ = angle of reflection of P_1; η = angle of refraction of P_1, *i e*, the direction of P_2 in medium 2; δ = angle of the shear wave generated in medium 1, and ζ that of the generated shear wave in medium 2. Similar analysis can be made of an impinging shear wave. The veloc of the waves in mediums 1 and 2, and the sine of the angle of incidence of the original wave, control the directions of generated waves. The equation shows that under certain conditions the sine is greater than 1, indicating that no such wave is possible. In seismic reflections, a series of waves are generated at such surfaces of discontinuity and internally reflected.

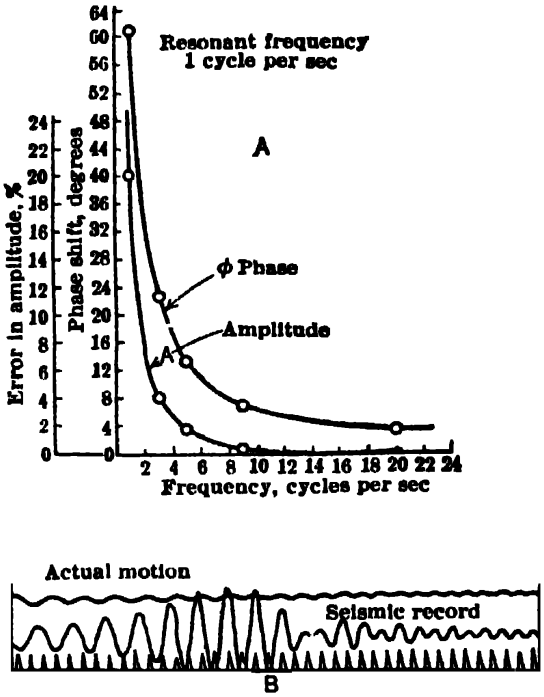

Fig 49. A. Error in Amplitude and Phase. B. Phase Reversal below Critical Frequency; Frequency increasing (22)

Apparatus for refraction and reflection prospecting is similar, except that the seismic "pick ups" need higher sensitivity for recording reflected vibrations (Fig 48). The wave impinges on the seismometer, usually buried in the ground to avoid wind and other disturbance. The seismometer transforms the mechanical into an elec impulse. The latter is amplified by automatic volume control for weak waves near the end of the record, and the output of the amplifier passes through an oscillographic element, the light beam from the latter passing through a condensing lens, to focus the image on sensitized paper. A second light beam is flashed across the paper every 0.01–0.05 sec by a tuning-fork to show elapsed time. The instant of the explosion furnishing the impulse is recorded by interruption of current in a wire wrapped around the explosive. Accuracy of vibration measurement is modified by the motion of the seismometer, when it begins to vibrate. Fig 49*A* shows the error which may occur in phase and amplitude, especially when nearing the resonant frequence, an operational condition to be avoided. Fig 49*B* shows a complete reversal of phase in recording on opposite sides of the instrument resonance point.

Shallow refraction is the simplest application of seismic prospecting as used to determine the bedrock depth for dam sites and depth of glacial drift. Fig 50 shows such a survey. The shot point is at *S*, from which seismic waves travel as indicated. The paths to the first detectors remain in topsoil; those to the second group pass through the soil twice and through the clay; those to the third group pass twice through both topsoil and clay, and through the rock. Charting a travel-time curve shows that the curve consists of nearly straight lines, with a slope in each section inversely proportional to the wave speed in the lowest medium involved. If the angle of entrance is taken as 90°, an assump-

tion usually introducing only a small error, the depths of the respective layers of topsoil, clay, and rock are as in Fig 50. When the contrast in speed between the beds is great, this method is very effective where alluvium rests on hard rock, but if water-soaked gravel rests on a comparatively slow-speed bed, as shale, the contrast is small and its recognition difficult. Where the bedrock is decomposed, seamed or chemically altered, or has an indistinct boundary, causing a gradual increase in speed through considerable depth or thickness, the method is not applicable. Faults are recognized by the offset of lines parallel to *DW*, owing to change of depth H_1 or H_2.

Deep seismic refraction. Seismic refraction waves have been used for exploration to depths as great as 3 000 ft; beyond that, the proportion of time spent in passing through the anomaly becomes small compared to the total time, and renders results doubtful. Fig 51*A* shows path of the longit wave in a medium where speed increases uniformly with depth; this path is the arc of a circle. Fig 51*B* shows effect upon the time-distance curve caused by salt-domes; similar anomalies may be caused by other lenticular high-speed beds like slate. Phase and amplitude control often furnish enough information for proper interpretations.

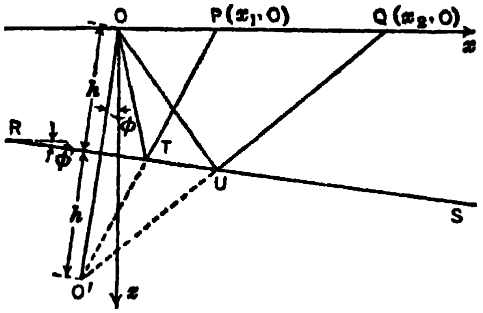

Fig 52. Determining Dip by McCollum-McGhee Method (24)

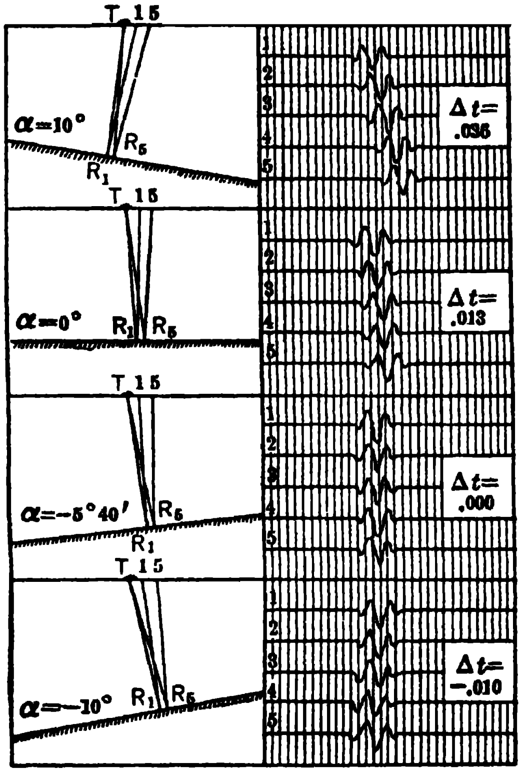

Fig 54. Theoretical Seismograms for varying Dips. Aver veloc, 6 000 ft per sec. Depth, 7 000 ft. Space between geophones 1 and 5, 1 000 ft (21)

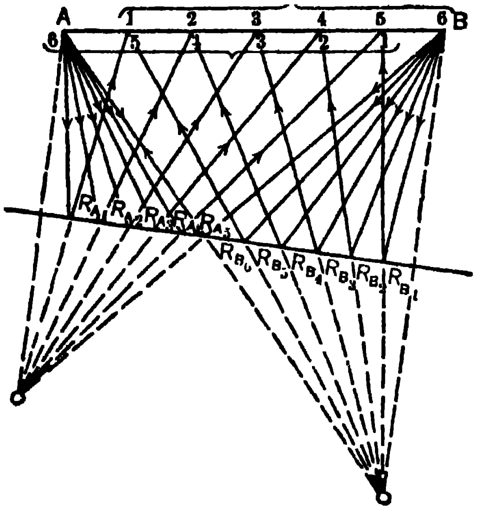

Fig 53. Seismic Paths in Continuous Profiling (25)

Reflection surveys are chiefly used in seismic prospecting for contouring deep-seated formations. Beds greatly differing in elasticity, as the " big lime " in northern La, cause excellent reflections. The origin of seismic impulse in the ground is the detonation of a charge of dynamite, but the reflected wave from the various beds bears only slight resemblance to the form of this impulse. Impingement sets the echoing bed into vibration with its own characteristic frequencies; hence, a permanent, reliable record is important, such as a sound track that can be produced for analysis. The analysis is interpreted by selecting from the record certain frequencies having direct correlation with the echoes and depths in question. Fig 52 shows the reflection paths of a wave at the border of 2 media; *O* is the shot point; *RS*, the reflecting surface; *OT* and *OU* are 2 wave paths impinging on the reflection surface at *T* and *U* and returning to surface at *P* (x_1, *O*) and *Q* (x_2, *O*). Draw a line from *O* perpendicular to the surface *RS* and extend below to the image point *O′*.

Let OZ be a vert line and ϕ the angle it makes with OO' (same as dip of bed RS). Knowing the speeds of the beds in the region, h and ϕ are computed. To determine bed RS, a number of receptors (Fig 53) are kept in position while the shot point is changed from A to B. Fig 54 shows effect of changes in angle α (dip of bed) upon the reflection records. Fig 55 shows reflections from 2 limestone beds as received at 1, 2, 3, 4, and 5, the source being at H. The echoes C and D refer to the 2 beds. Record B is the time of first arrival of the waves and bears no relation to the reflecting beds. To make a reflection survey, the ground is laid off as in Fig 56 for the shot points. The important factor is the closure of the contour of a reflecting bed.

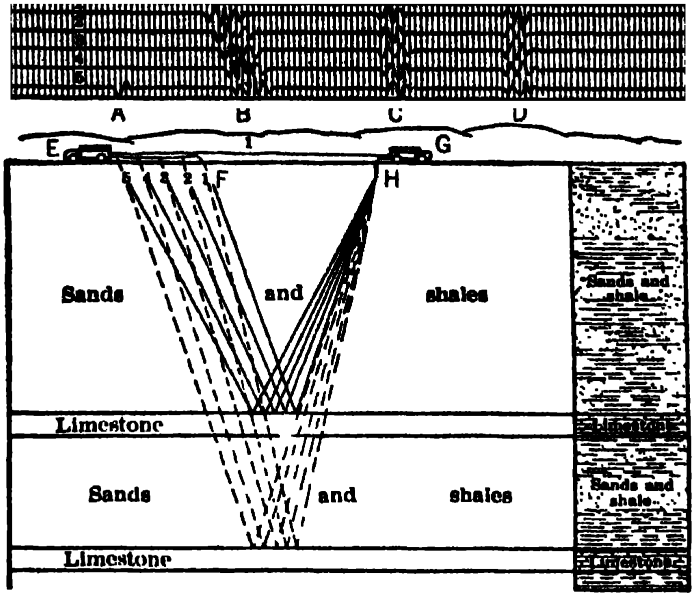

Fig 55. Observation Points, and Theoretical Seismograms for Two Limestone Horizons (21)

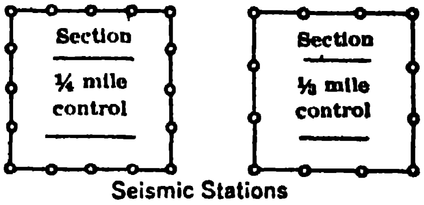

Fig 56. Individual Spreads of Seismograph Stations (25)

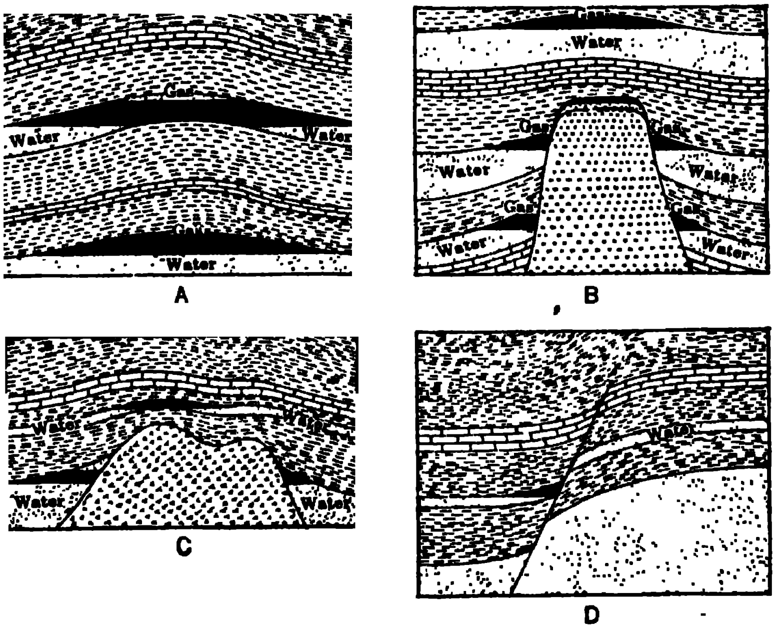

Fig 57. Four Typical Occurrences of Oil (21)

Fig 57 shows a few of the formations and geologic structures to which reflection seismic surveys have been applied. A is a simple anticline with 2 productive oil horizons. B is a salt dome with

shallow oil and gas, and an impervious cap rock, oil and gas being entrapped on the flanks of the dome. *C* shows possible reservoirs on a granite ridge; *D*, the oil trapped on a fault.

The limit of reflection surveying has not been reached, but depths of about 20 000 ft have been recorded. Since variations in thickness of the low-speed weathered zone near the surface lead to false interpretations, the explosive is put in a drill hole below this weathered zone; this procedure takes time and increases the cost of reflection surveying. Changes of thickness, as caused by lensing, interfingering, erosion, and overlap, modify the interpretations, and are obstacles in the application of these methods; uniformity and continuity of formations are desirable for good results.

5. TEMPERATURE SURVEYS

General. Temperature phenomena give certain information not obtainable in any other manner. There are 2 kinds of surveys: one in which a well has reached thermal equilibrium, the other where a temp transient (see below) is important. A temperature-depth curve shows temp gradually increasing with depth; that near the surface of the ground should be a little above the mean annual temp of the area. The well should be surveyed some time after drilling has stopped, to permit dissipation of local heat generated by drilling. If the temp log as measured is abnormal, owing principally to escape of gas from the hole, such conditions must be remedied before a final log is made. Actual temperatures and temp gradients are both important, and must be simultaneously examined in a given region. In general, over salt domes and other geol bodies with high thermal conductivity, the temp and temp gradient are above normal. It is customary to use the number of ft per deg instead of the temp gradient or the degrees per ft.

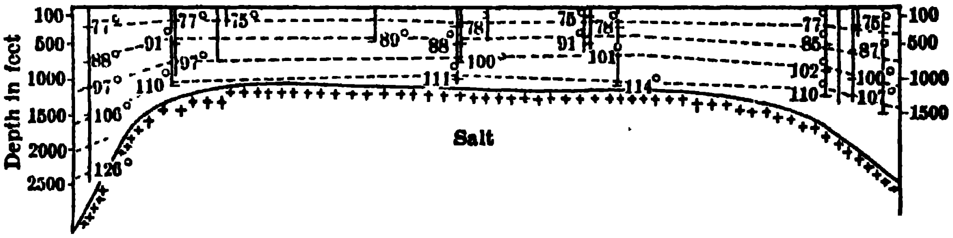

Fig 58. Isogeothermal Profile W–E across Humble Salt Dome, Texas (26)

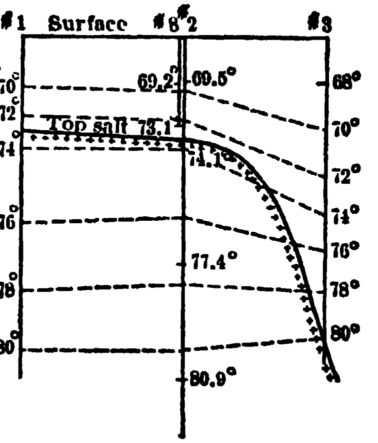

Fig 59. Isogeothermal Profile across South Edge of Grand Saline Salt Dome, Texas (26)

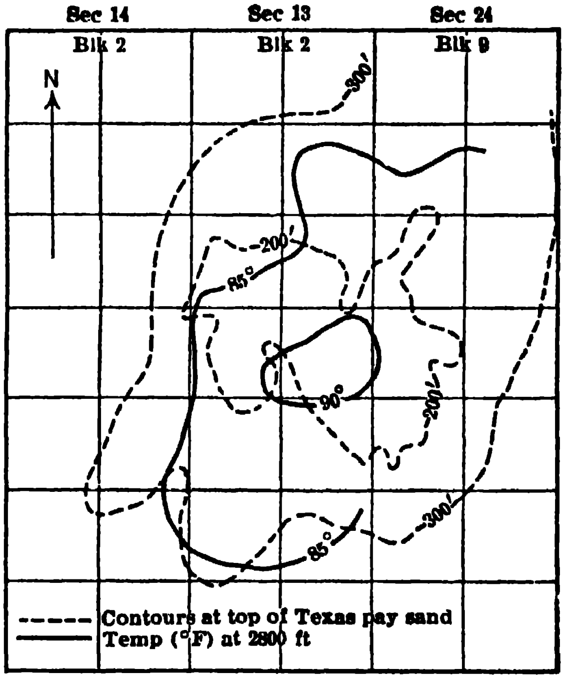

Fig 60. Stratigraphic and Isogeothermal Contours of Part of Big Lake Oil Field, Texas. Adapted from E. M. Hawtof (26)

Fig 58 shows the temp profile over the Humble salt dome; Fig 59, that at edge of the Grand Saline salt dome. Owing to the better heat-conductivity of salt domes, the temp at top of the

Humble dome is higher than along the margins, whence the number of ft per deg over the dome is less. According to Van Orstrand, the number of ft per deg F over salt domes is 20–50. Using well-temp measurements as a guide, the direction showing least number of ft per deg generally points towards the top of a dome or anticline. Fig 60 shows the constant-temp contours over the Big Lake field, Texas, at depth of 2 800 ft. Another way of showing temp distribution is to contour the elevations at which a given temp is encountered. Regional temp charts are valuable for large structural features (Fig 61).

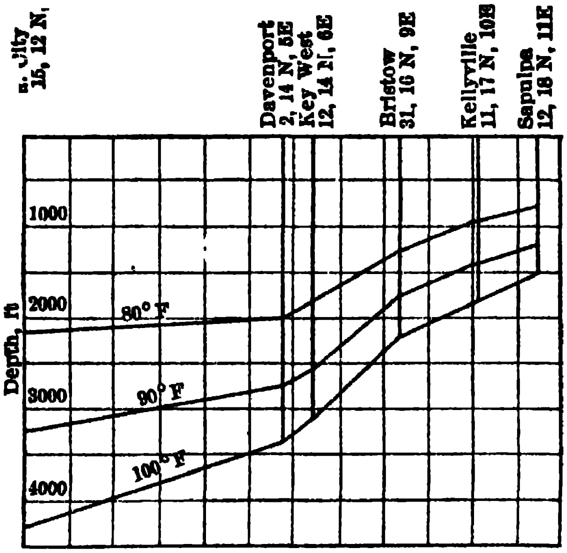

Fig 61. Temperature Profile, Oklahoma City to Sapulpa (27)

Temp measurements in wells are made by maximum thermometers, lowered into the well. For more detailed temp data, other apparatus, as elec resistance thermometers, is necessary.

Ground-temperature transients. The measurement of these, especially in wells, has value for obtaining information upon formations differing greatly in their ability to transfer heat. Such measurements also serve to locate cemented zones in wells, even when cased. Another advantage of these observations is that they furnish information on changes in distribution of fluids around wells in operation. Measurements can be made

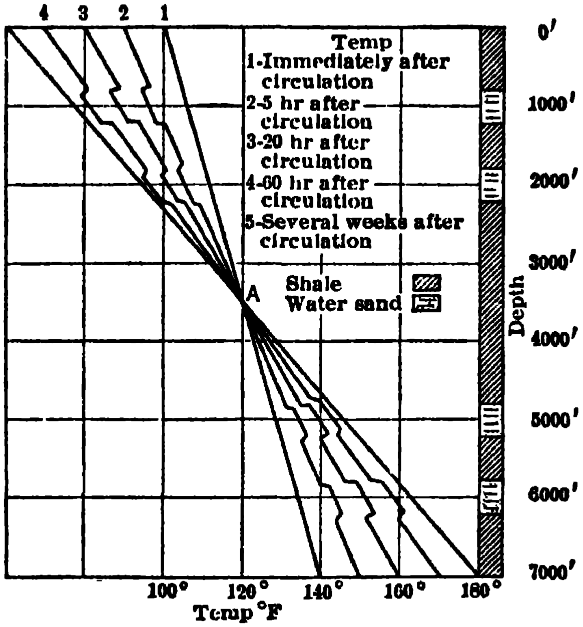

Fig 62. Probable Variation of Temp with Time Elapsed from Moment Circulation Ceased. Deep Wells (28)

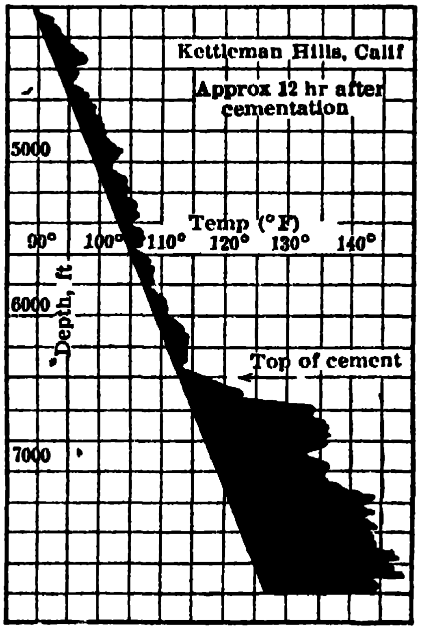

Fig 63. Temperature Survey 12 Hr after finishing Cementation around Casing in a Calif Well (29)

by observing changes in elec resistivity of a resistance element inserted in the well. As the instrument is lowered, the leads also introduce a temp effect. The use of 2 resistance elements (one having a zero temp coef), connected to form 2 arms in a Wheatstone bridge, is therefore recommended. The effect of the leads can then be compensated by a variable resistance in one of the 2 bridge arms containing the resistances. Variation in resistance is a simple function of the temp.

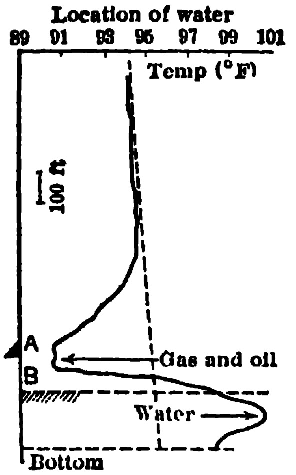

Fig 64. Location of Sands having produced water (30)

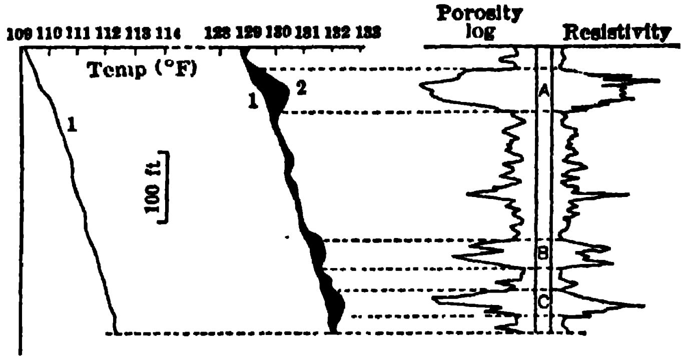

Fig 65. Study of Formations through Casing and "Old" Cement (30)

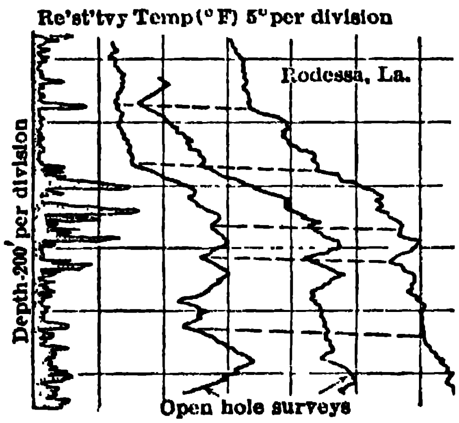

Fig 66. Correlation of 1 Cased and Cemented Well (right) with 2 Open Holes (29)

The temp of drilling mud is usually intermediate between the surface and bottom temperatures. When the mud circulation is stopped, the mud temp will drop at top of the well and rise at bottom. Fig 63 shows an idealized temp graph made after different time intervals. The important feature is that the changes of mud temp occur faster opposite water sands than opposite shale or limestone. Such beds therefore introduce temp fluctuations in the well indicating both the thickness and position of the horizon. The temp rise caused by the setting of cement within a few hours after placing it outside the casing clearly indicates the position of the cemented zone (Fig 63). The top of the temp rise is shown at 6 400 ft, from which depth the high temp persists downward, and indicates the portion of the well that has been cemented.

The method of locating water and gas horizons is shown in Fig 64. Rapid expansion of the gas reduces the temp, while the water below it has a much higher temperature and heat capac; hence the temp transient is reversed below point *B*, and indicates the position of the water horizon. Fig 65 shows a temp transient curve, obtained in a cased well, compared with a resistivity log in the same well before being cased. The porous formations give similar elec and temp anomalies. Fig 66 shows the correlation between a resistivity log, the open-hole temp survey of 2 wells, and a temp survey in a cased well. The formations can be identified and compared, permitting determination of variations in elev. At present, the transient temp method is the only one by which the positions of various formations can be measured in a cased well.

6. RADIOACTIVITY SURVEYS

Rocks containing minute amounts of radioactive elements can be prospected by measuring the ionization caused by radon in the air absorbed by the ground. At certain stages of decomposition, radioactive elements emit α particles which are positively charged helium atoms, β particles, negatively charged units or electrons, and γ rays, which are hard X-rays. Each of these ionize a gas, making it electrically conducting. By using an elec-charged condenser, and recording the rate of decay, the variation of radioactivity can be measured. Unit of measurement is the Mache unit, the amount of radioactive emanation in 1 liter of gas which will produce a saturation current of 0.001 electrostatic unit. In an electroscope, let V_1 = voltage (electromagnetic units) before discharge; V_e = voltage at end of discharge; t = time in sec; C = electrostatic capac, centimeters, of condenser system being discharged, I = amperes (electrostatic units) of saturation current. Hence,

$I = (V_1 - V_o)C + 300\,t$; and since the number of Mache units (M U) = 1 000 I, the formula per liter of gas is: M U = $^{10}/_3\,(V_1 - V_o)C$, where $V_1 - V_o$ is the change of voltage per sec.

The ground is laid off on traverse lines, and the number of M U are plotted at measured points. If the traverses are sufficiently close, iso-radioactive lines are contoured. This method, useful in locating faults through which radioactive gases are flowing, can be used for prospecting for radioactive ores, as carnotite and pitchblende. Due to small amounts of zirconium and other weakly radioactive elements in the soil, a certain amount of radioactivity is always present, bearing only an indirect relation to the geologic structure.

7. MICRO-GAS SURVEYS

Analysis of soil and of its gas content, for the presence of hydrocarbons, as an indication of gas seepage, has had much attention. According to Rosaire, this seepage is greatest at edges of a pool. By charting the hydrocarbon and gas content along a profile, the presence of oil deposits is indicated. No details are yet available as to methods for differentiating between methane and ethane in small amounts. Methane is often generated by vegetable decomposition and then bears no relation to oil or gas deposits, whereas ethane, propane, and butane generally occur in natural gas.

8. CHOICE OF GEOPHYSICAL METHOD

In planning the surveys several methods should be applied to the same problem, especially if these methods are not related, and depend upon different properties of the same geol anomaly. Thus, oil prospecting in unknown territory would combine gravimetric methods with seismic reflection; or, when drilling on known structures for the boundary of discovered fields, elec well logging and well-temp methods are preferable. Mining problems combine magnetic with elec methods. Water investigations use elec, magnetic, and shallow seismic methods. On dam sites and excavations use the shallow seismic, together with the elec resistivity methods. Gravimetric methods are relatively more expensive, because the instruments are large and costly, and because subsidiary parties are necessary to measure elevations. Seismic reflection entails considerable auxiliary expense for drilling through weathered zones. Elec resistivity methods require many helpers to "run wire" and brush out lines. Less expensive are shallow refraction and magnetometer surveys, which usually require 2 men (operator and assistant). While well-logging and temp surveys do not require much field personnel, the technical equipment is costly and suffers rapid depreciation. Table 4 summarizes the principal applications of the several methods.

Table 4. Summary of Geophysical Prospecting Methods

Class	Method	Principal Application	Geologic Units
Gravity	Torsion balance Pendulum Gravimeter	Oil	Intrusive bodies, salt domes, faults Anticlines, synclines Buried ridges
Magnetic	Dip needle	Mining	Magnetic rocks and minerals
	Horiz magnetometer	Mining	Contouring crystalline basement, dikes, faults, intrusive bodies
	Vert magnetometer	Mining, oil, water	
Electrical	Self potential	Mining	Sulphide and oxide orebodies
	Earth resistivity	Mining, oil, ground water	Stratigraphy, formations and structures. Depth of overburden Faults, dikes, salt water, gravels, channels
	Induction	Mining	Electrically conducting veins
Seismic	Shallow refraction	Road excavations, dam sites, ground water	Bedrock surface, buried channels
	Deep refraction	Oil	Salt domes
	Reflection	Oil	Salt domes, faults, anticlines, synclines
Thermic or temperature	Steady condition Transient condition	Mining Oil Oil	Igneous and sedimentary formations, salt domes, anticlines, synclines, faults
Radioactive	Gamma radiation Gas ionization	Mining	Faults, radioactive material

9. TABLES OF PHYSICAL PROPERTIES

For determining physical properties of rocks or geol bodies there are 2 methods: laboratory measurements on specimens or samples, and field measurements of material in place. In general, measurements on formations in place are preferable to those on samples. The measurements often involve modifying factors, as the averaging of samples, effect of moisture, and solution factors, which can not be retained in the laboratory samples. As a rule, some information is better than none, and all geophysical tables should be viewed from this standpoint.

Density. Since rocks are usually a complex of minerals, some of which may not be identical in properties from one locality to another, and rocks from different areas may have different degrees of weathering or alteration, many different values may be assigned to the density of the same rock type. Differences in porosity may also appreciably affect densities of similar rocks. Following tables therefore show different densities for like rocks, depending upon their origin and the kinds and degrees of alteration to which they have been subjected. Densities are calculated in c g s units; hence the values for density and spec grav are identical. Spec grav is a numeric and has no dimensions, whereas density is defined as mass per unit volume ($M \div L^3$). Table II, III show effects of certain modifying factors, which may materially alter the density or spec grav. For spec grav of minerals, see Descriptive and Determinative Tables, Sec 1; also Table 3, Sec 25.

Magnetic properties. While much work has been done on the magnetic properties of rocks and solutions, as to their diamagnetic, non-magnetic, and para-magnetic properties, their susceptibilities remain probably their most important characteristics (Table IV–VI).

The ability to measure very differences of magnetic intensity by variometers has enhanced the value of magnetic prospecting and the importance of magnetic properties of earth materials. Since susceptibility of rocks is not constant, but varies with the magnetic field strength at which observations are made, the intensity of the earth's field is the most desirable intensity at which to determine the susceptibility of rocks.

In rare cases, the magnetic field around certain iron deposits may exceed the normal earth's magnetic field. About 90% of all magnetic prospecting concerns areas where there are only slight differences in magnetic susceptibility of the materials involved. The magnetite content of rocks appears to be the chief source of higher susceptibilities. Table IX shows percentages of magnetite and ilmenite in some igneous rocks, and Table X gives corresponding data for other rocks.

Table X. Magnetite and Ilmenite Content of Average Rock Types.
According to N. H. Stearn (32)

Rock	Magnetite, %	Ilmenite, %	Combined, %
Aver granite	1.72	0.31	2.03
Aver basalt	5.80	0.73	6.53
Aver igneous rock (65% granite; 35% basalt)	3.15	1.45	4.60
Aver sandstone	0.58	0.25	0.83
Aver sedimentary rock (82% shale; 12% sandstone; 6% limestone)	0.07	0.02	0.09
Aver rock (95% igneous; 5% sedimentary)	2 95	0.001	2.951

Resistivity of rocks forms the basis for almost all elec prospecting methods. The degree of resistivity measured in the field differs materially from that measured on laboratory specimens, due to changes in moisture content or salinities of solutions impregnating the rocks, and to variations in constitution of rocks from different areas or geol formations. Differences in resistivity of rocks or members of formations in a specific locality are much more important than the resistivities *per se*. The mode of occurrence of rocks is of great importance; for example, magnetite has a very low elec resistivity, but if each crystal is imbedded separately in quartz, the resistivity will be controlled entirely by the quartz, which has a very high resistivity. In other districts, rocks containing magnetite may be undergoing alteration, and therefore should have extremely low resistivity. Very small amounts of solutions carrying salts will often noticeably modify the resistivity of rocks. In general, non-porous igneous rocks have higher resistivity than sedimentaries; of the latter, especially limestones, older beds have higher resistivities than the younger.

Table XIV. Resistivities of Sodium Chloride Solutions. According to H. Reich (31)

NaCl content, %	Resistivities, ohm-centimeters
1	57.0
5	14.9
10	8.25
15	6.08
20	5.11
25	4.68
26	4.65

Seismic properties. The application of seismic waves for determining geological horizons and structures utilizes primarily the longit wave, the speed of which varies in different rocks. In general, the heaviest, most crystalline rocks give the highest speeds. Cemented sedimentary rocks are next in order, followed by broken or shattered sedimentaries, talus and landslide material, and unconsolidated sedimentary deposits. Speed of propagation is measured: (*a*) in the laboratory, by determining the density and moduli of elasticity on rock samples; (*b*) in the field, from the formations in place; the second is preferable. Tables XV–XIX give the longit wave speeds and the elastic moduli.

Table XV. Modulus of Elasticity and Speed of Transmission of Longitudinal Waves in Rocks. After H. Reich (31)

Clymenia limestone	..	8.15	6 000	Bauschinger	*L*

(*a*) Aver value for a number of observations.

(*b*) *E* determined as follows: *L*, *H*, or *V* = by press experiments, in which: *L* = at low pres (about 1 000 megabars); *H* = at high press (about 2 000 megabars); *V* = at very high press (about 10 000 megabars); *HV* = press varying between 2 000 and 10 000 megabars. *C* = by compressibility tests. *K* = kinetically.

Table XVI. Speed of Propagation, V, of Longitudinal Waves in Rocks
After H. Reich (31)

Type of rock	*V*, meters per sec	Authority
I. Consolidated rocks		
Igneous rocks; metamorphic rocks; massive unstratified rocks; limestone; dolomite; gypsum; anhydrite; rocksalt	5 000–5 600	H. Salfeld
Cambrian (Villanueva de las Minas)	4 800	J. G. Sineris
Salt dome cap rocks	4 500 to 5 500	Fr. Rieber M. Hannemann
Texas salt dome rocks (anhydrite, gypsum, limestone, rock salt)		
Shell limestone (Rudersdorf)	4 300	W. Schweydar and H. Reich
Gypsum beds (Sperenberg)	3 500?	W. Schweydar and H. Reich
Zechstein beds (salt, anhydrite) Juterbog	4 500	G. Angenheister
Carboniferous coal measures (Dobrilugk)	3 800	H. Reich
Carboniferous coal measures (Villanueva de las Minas)	3 400	J. G. Sineris
Calcareous marl, calcareous sandstone, slates	3 200–3 800	H. Salfeld
Siliceous sandstone, slightly calcareous sandstone	2 200–2 400	H. Salfeld
Middle Bunter sandstone (Jena)	2 000–2 800 aver 2 500	O. Meisser and H. Martin
Chalk (Germany)	2 380	H. Reich
Chalk (France)	2 140	Ch. Maurin and L. Elbe
II. Unconsolidated rocks		
Coastal plain formations (Texas)	1 800–2 100	Fr. Rieber
Septaria clay and middle Bunter sandstone (?) (Juterbog)	1 900	G. Angenheister
Miocene (Villanueva de las Minas)	1 950	J. G. Sineriz
Clay, clay sandstone, slightly calcereous marl	about 1 800	H. Salfeld
Tertiary and clayey Quaternary (Germany)	1 630–1 800	H. Reich
Damp Quaternary sand (Sperenberg)	855–1 011	H. Reich and W. Schweydar
Broken rock, gravel, sand, loess	600–800	H. Salfeld
Same materials, very wet	1 200	H. Salfeld
Alluvium (Villanueva de las Minas)	600	J. G. Sineris

Table XVII. Longitudinal Wave Speeds in Other Media. After H. Reich (31)

Material	*V*, met per sec	Authority	Material	*V*, met per sec	Authority

Table XVIII. Compressibility and Longitudinal Wave Speeds in Minerals. After H. Reich (31)

Mineral	Compressibility, cgs × 10^{12}	Speed of longit waves, meters per sec
Sylvite	5.62	3 900
Rock salt	4.13	4 400
Gypsum	2.49	5 450
Anhydrite	1.83	5 650

Table XIX. Poisson's Ratios. After H. Reich (31)

Type of rock	Limiting values, σ
Various marbles	0.25–0.28
Various granites	0.20–0.26
Other igneous rocks	0.22–0.28
Ohio sandstone	0.26

Porosity depends on the origin of the rock, and its subsequent modification by tectonic, chemical, and physical processes; it is a factor often modifying other physical properties of rocks. Bureau of Standards has compiled porosity data on building stones, notably marble, sandstone, and slate (see publications by D. W. Kessler).

Table XX. Porosity of Rocks. *After* H. Reich (31)

Other physical properties *of* **rocks, which have not yet been carefully measured and tabulated, include their heat capac and thermal conductivity. Thermal conductivities of certain rocks and minerals are given in Table XXI. These values represent heat transferred (calories) through an area of 1 square cm and thickness of 1 cm in 1 sec, for a temp difference of 1° C. Dielectric properties of rocks have been proposed as a basis for prospecting by the use of radio waves. The constants usually range from about 1 to 7, when measured with d c or low-frequency a c; according to Dostovalow, the dielectric constant is much greater when measured at radio frequencies of 300 000 cycles (Table XXII); also the resistivities at high frequencies differ from those at low. Since the constant of quartz is usually greater than that of country rock, the possibility of employing these**

methods on quartz veins is obvious; but, since the constant of water is 80, presence of moisture would overshadow such observations, rendering interpretation difficult. Since electromagnetic waves involve 3 systems of constants (electrostatic, electromagnetic, and Heaviside-Lorentz values), conversions for these factors are given in Table XXIII.

Radioactive rocks contain radium and thorium, and emit radon, a gas which diffuses in the ground but can be detected, even when extremely diluted, owing to its radioactive power. According to Petraschak and Krusch, the amounts of radioactive elements per gram of rock for various rock types are as in Table XXIV.

BIBLIOGRAPHY

There is no complete index of publications on geophysics. Prior to 1926, the bibliography in Ambronn, "Elements of Geophysics" (McGraw-Hill), is most complete. Later publications, to July 1, 1936, are in *Geophysical Abstracts*, issued by U S Bur of Mines and U S Geol Surv. Abstracts in Annotated Bibliography of Economic Geology emphasize the geol phases. Patent abstracts by U S Bur of Mines, *Inf Circ* 6883 (1936), cover legal aspects, continued in the *Geophysical Abstracts*. Other important publications: Principles and Practice of Geophysical Prospecting, by A. B. Broughton Edge, and T. H. Laby, Cambridge Univ Press. Geophysical Prospecting, volumes 81, 97, 110, 1929, 1932 and 1934 by Am Inst of Min and Met Engs. Applied Geophysics in the Search for Minerals, by A. S. Eve and D. A. Keys, Cambridge Univ Press.

UNDERGROUND TRANSPORT

1. GENERAL CONSIDERATIONS

Underground transport of mineral, waste and supplies is a vital function in mine operation. Reports from 41 metal mines using various standard mining methods (1) show that underground transport costs averaged 37.44¢, or 17.22% of total underground cost, varying from 11.35¢ to 59.9¢ per ton hoisted, or 12.77% to 26.30% of total, depending on mining methods (Art 20 and correspondence). In many mines, if first cost and maintenance of workings used primarily for transport were so charged, the total cost of transport would be shown to exceed all other mining costs.

Centralization. If the output can be brought to one level or gangway, transport may sometimes be so concentrated that hand tramming can profitably be replaced by animal haulage, or the latter by mechanical haulage. Even in shaft mines, where, due to shape of deposit or distribution of workings, the output of several levels is lowered to one main haulageway, the increased cost of hoisting may be more than offset by the saving from a centralized haulage system.

Transport method is decided by comparing the total capital and operating costs of systems considered. If these involve changes in mine development, it is necessary to determine what saving in development and maintenance costs may result from adopting a centralized system, which reduces the number, length or size of sub-levels, crosscuts, shaft stations and trackage otherwise required. Such saving must be balanced against cost of installing and maintaining the proposed haulage system.

General formulas. Let D = useful duty per shift, mineral-ton-miles; G = gross duty per shift, ton-miles; d = distance mineral is to be moved, ft; s = aver speed when moving, ft per min; t = time loading and discharging per trip, min; T = mineral handled per trip, tons; T' = tare per trip, tons; C = time of 1 complete cycle, min; m = actual working time per shift, min.

$$D = \frac{m}{\frac{2\,d}{s} + t} \times \frac{dT}{5\,280} = \frac{mdT}{5\,280\,C}, \quad \text{and} \quad G = D + \frac{m\,2\,dT'}{5\,280\,C} = \frac{md\,(T + 2\,T')}{5\,280\,C}$$

Useful duty D varies directly with distance, speed and wt of mineral per trip, and inversely as the time required at terminals. If the gross duty limit has been reached, the useful duty will vary inversely as ($T' \times 2$). These principles apply to all kinds of transport, from shoveling to locomotive haulage. Despite the rule that cost per ton-mile, other things being equal, varies inversely as the unit load, underground conditions usually require small-scale equipment. But many large-tonnage installations exist in coal, iron and copper mines, varying from the most primitive to standard R R equipment.

2. PRIMITIVE TRANSPORT METHODS (30)

Packing. Mineral is carried in sacks, skins or baskets on backs or heads of men and women, in primitive countries, or occasionally in narrow, tortuous workings, or in emergency work. Unit load is usually 60 to 150 lb, but, in Latin America and the Orient, peones and coolies carry more. Duty varies widely, but approximates 12 to 14 man-hr per ton-mile. Boxes or hand-barrows, holding 200 to 700 lb, and carried by 2 or more men, are slightly more economic, but if there is room for such practice better methods are usually feasible.

Shoveling (Sec 3). Transport by carrying or casting with shovels is proper only as a last resort. One man can move 1 ton 100 ft in about 2.5 hr, equivalent to 125 to 160 man-hr per ton-mile. Long-handle, round-point No 2 shovels are standard for underground mucking; 1938 price, $12-$14 per doz. MUCKING is a common term for underground shoveling. In stopes, with chutes 40 ft apart, the standard duty is commonly 20 cars (17 to 20 tons) per shift, including sledging or blockholing lumps, and stowing filling. If chutes are advantageously placed, shovelers have time to assist miners, but if much sorting is done, their output may be greatly reduced. The stoping method greatly affects cost of shoveling; good shoveling floors and slides are as important as chute spacing. (For mucking in connection with tramming, see Art 10.)

Wheelbarrow transport (Sec 3), exclusive of loading, costs at least 1 man-shift per ton-mile, and is justified only in temporary work, or where first cost of track and equipment is not warranted. Short exploratory workings and small, irregular stopes, where the only alternative is shoveling, are the only proper fields for the barrow in mining work.

Best mining barrow has 3 cu ft capacity, No 14 to 16 B & S gage pressed steel tray, handles, frame, and wheel-guard of steel pipe; max height 21 in, wt 70 to 80 lb, price $70–$100 per doz, fob factory. For surface work in very hot or cold climates, wood handles are preferable. For thin seams a flat barrow without legs is used.

Examples. BUTTE, Mont. For periods of 4 years in the larger mines, comparative costs of shoveling for different stoping methods were: square-set, 100; rill, 75; timbered rill, 85; back-fill stoping, 120 (40). UNITED VERDE, Ariz. All mucking in drifts is now done by mechanical loaders (Sec 27). In stopes, broken ore and waste are handled by scrapers. Except for minor track cleaning, no shovels are used (H. M. Lavender, 1938). NORTH BUTTE, Mont (Linton). Classification of underground labor showed: shovelers 26.8% and trammers 18.9%, as against 15.7% miners, indicating importance of shovel and transport labor. MASCOT, Tenn (42, p 67). 1923 contract shoveling, 23¢ per car of 1.7 ton; aver duty over 6 mo, 16.8 ton per man. NATION No 2 MINE, Mo. 2 yr aver shoveling, company account, 15.46 ton per man-shift; contract, 22.23 ton. SOUTHEAST Mo. Aver for lead district, 1922: company account, 14–18 ton; contract, 19–22 ton. See Sec 10, for comparison with mechanical loading.

3. MINE CARS (1 to 11)

Standard design. The importance of the underground car justifies great care in design or selection. If possible, a single design suited to local conditions should be adopted. This cannot be done where hand-trammed, stope-filling or sub-level cars and larger mechanically hauled main-level or adit cars are all used, and in large mines several designs and sizes are employed. But, if a compromise design is feasible, standardization is advantageous in simplifying repairs and the stock of repair parts.

Car body is of wood, steel or composite construction. Wooden cars are bulky, become very heavy in wet mines, are less durable, but more easily repaired than steel. They are obsolescent in metal mining, and in collieries the number of composite and steel cars is rapidly increasing. Composite cars usually have wood stringers for the truck, and wood lining. The body is rigid, or is hinged on its truck for dumping in one direction, or has a king-pin or turn-table connection to truck to dump in any direction. When conditions permit, the body should be centered over the wheelbase, to equalize wheel loads and avoid accidental head-on dumping. Steel bodies are now generally used.

Rigid-body, flat-bottom cars are simpler and usually lower than others of equal capacity. Advantages: ease of loading because of the low sides, simplicity, cheapness, and high ratio of capacity to wt. Disadvantage: they can be dumped only at tipples or on track dumps at fixed places. Most colliery cars are of this type. Fig 1 shows an all-steel, " low-vein " car (3) of 100-cu ft level capacity, with bottom below the axles and

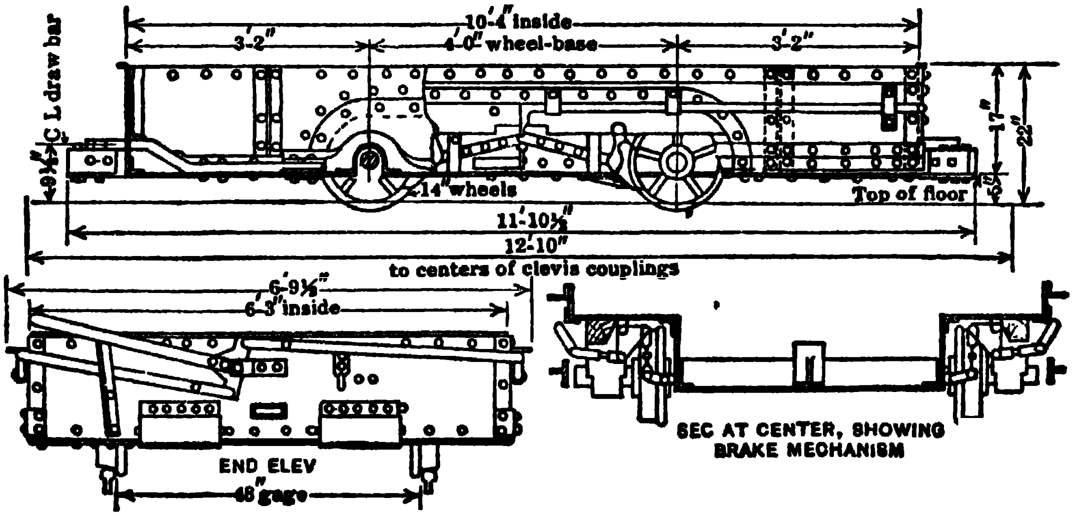

Fig 1. All-steel, "Low-vein" Car

no door; used with rotary dump at Lynch colliery; approx wt, 4 000 lb. Fig 2 is a standard car of Connellsville, Pa, district; wt, 2 200 lb, capacity 40 cu ft. Fig 3 is a wooden car used in sub-levels in the Mesabi iron range; simple, cheap and easily repaired. This sub-level car has been discontinued by Oliver Iron Mining Co in all but 2 underground mines; scrapers now used in handling ore from working faces to winzes, where it is dropped to a main-haulage level and trammed to shaft. There is very little sub-level haulage, due to use of slusher hoists and scrapers (Sec 27). Fig 4 is a car 9 ft long, open at both ends. It has wooden or steel stringers, 2-in wood bottom with 0.5 in plate liner, outside journals, wt, 2 600 lb, capacity, 5 100 lb. At stations of inclined shafts it is dumped by a cradle directly into skip. Fig 5 is an all-steel, 16-cu ft, rigid-body, sub-level car of a design largely supplanting Fig 4. It resembles the revolving car in outline, but is about 6 in lower.

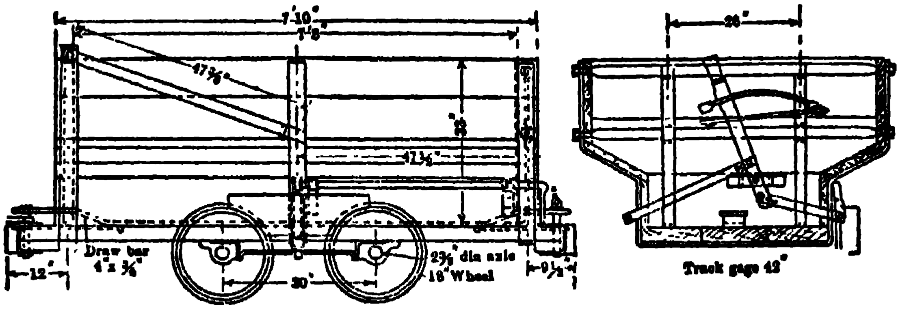

Fig 2. Hockensmith Standard Wooden Car

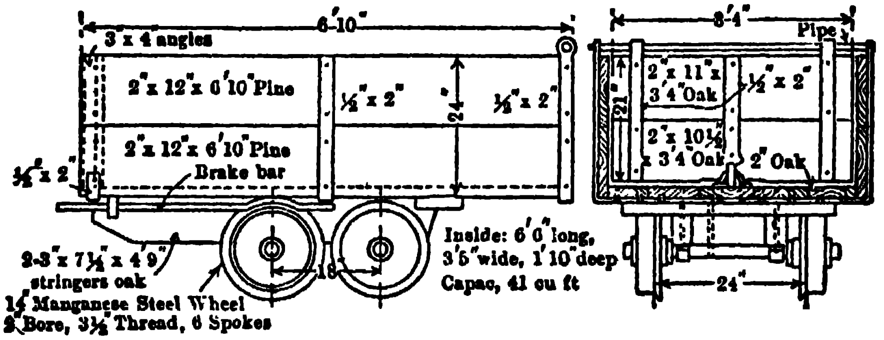

Fig 3. Sub-level Car, Mesabi Iron Range

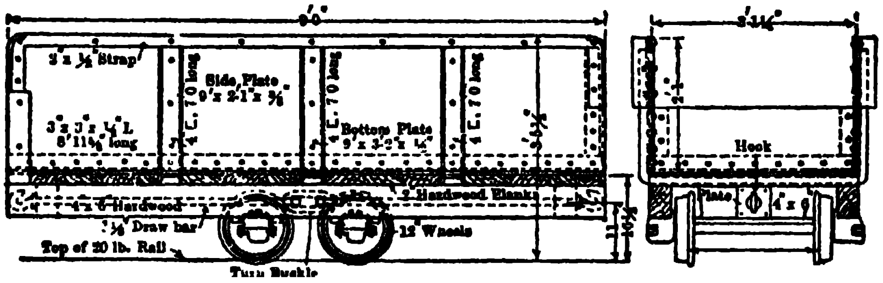

Fig 4. Trimountain Copper-mine Car

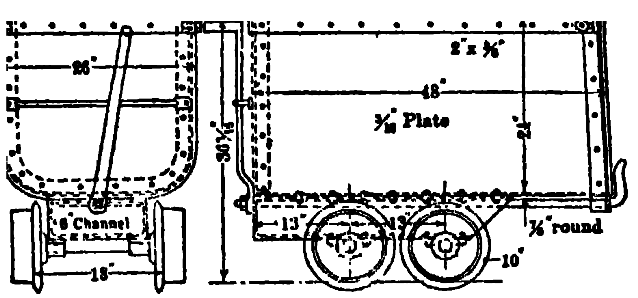

Fig 5. All-steel, Sub-level Car (Lake Shore Engine Works)

Hinged-body car (Fig 6) dumps in one direction only. For easy handling by 1 man, its body should be hinged not over 2.5 in forward of load center line.

Fig 7 (Mich copper mine) is open at both ends; capac, 40 cu ft. Side-dump car, Fig 8, is heavily reinforced, for taking 2-ft lump ore from chutes, at Anyox and Alaska Gastineau. V-BODY, supported on trunnions, may be single or double side-dumping (Fig 9). It is little used under-

ground, but for soft, fine ore, discharged at the side, it may be better than the revolving type. The V can be made high and narrow, or low and wide as required by gangway and chute clearances. It has no doors and can readily be made water tight. Fig 9*a* is a V-bottom, rolling side-dump car of 45 cu ft, used together with gable-bottom cars of 47 cu ft capac for main-level haulage by Oliver Iron Mining Co (1938).

Revolving dump-car can dump in any direction, and hence is useful for metal mines. Body must be high enough for the bottom to clear the wheels when side dumping. To avoid danger of overturning, the car body should not exceed 4 ft long when handled by 1 man. The car is therefore rather high and short. Wheels are seldom over 12 in. Fig 10 is a typical Butte car; wt, 965 lb; capac, 1 700 to 1 900 lb. Fig 11 is a 30 cu-ft car for both hand tramming and train haulage. Scoop car (Fig 12) is usually of the revolving dump type. Like the V-body car, it is simplified by omitting the door, and can then be made water-tight. It is good for discharging into a chute, but may require a clearance below track level, and it is more liable to upset when side dumping.

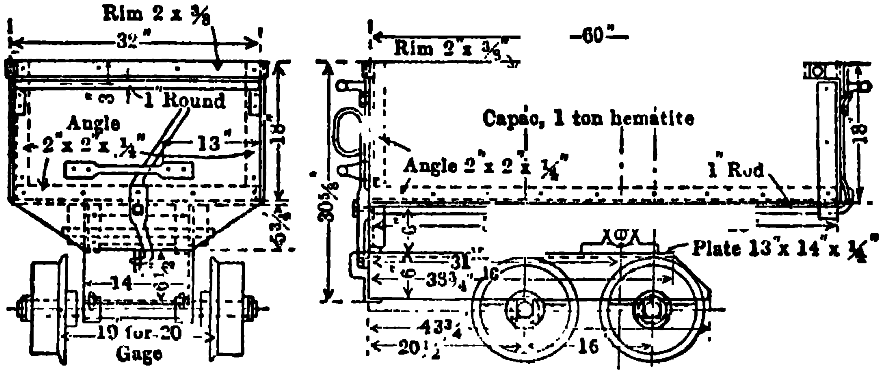

Fig 6. Standard Hinged-body Car

Hopper-bottom cars are unusual underground, but are good for transfer service, large unit loads and motor haulage. In the Sanford-Day car, bottom doors are automatically successively released as they reach the storage bin, and are closed and latched by passing over a knuckle on the exit side, the train dumping without stop.

Saddle-back cars, holding 1.5 to 5 tons, are common on main levels in motor-haulage mines. Discharging from both sides they keep tracks clean and fill pockets evenly. Fig 13 is a 6-ft car of 2.75-ton capac, with 16-in wheels and pocket couplers, used by Oliver Iron Mining Co with the V-body car of same capac (Fig 9*a*). Fig 14 shows end of a similar 45-cu ft car, at Miami, Ariz; it has an improved door latch. This is now (1938) replaced by a car of similar design, of 86 cu ft capac.

Fig 7. Open-end Dumping Car (Mich Copper District)

Special bodies are required for drinking water, toilet and man cars. Standard trucks with removable frames are best for drill steel, wedges and powder, and with side stakes for timber, drills and large supplies.

Steel cars continue to displace wooden and composite cars (Fig 2, 16), which, however, will long be used, especially when they have anti-friction bearings. When new, rigidity of steel cars often causes derailments, if the bearings are not self-alining and are without springs. Sizes of colliery cars: up to 120-cu ft level capacity and 14 ft long. Fig 15*a* is a Pittsburgh Coal Co all-steel car, for 40-in track, of 176 cu ft capac, 14-in wheels with Tyson roller-bearings and inside spring journals (L. E. Young, 1938).

Car trucks. Wheels, axles, bearings and frame make over 0.5 the wt and $^2/_3$ the cost of most mine cars. The frame may be the car bottom itself (Fig 1, 2), a pair of wooden stringers (Fig 3, 4), a built-up steel truck (Fig 5, 6, 9, 10, 12), or single rolled shape, usually a channel, forged into a U (Fig 11). The design in Fig 2 insures perfect alinement of axles, when a wooden car bottom carries journal boxes. On the other hand, cars at a Mich iron mine have the axle boxes carried flexibly by light diagonal straps, and it is claimed that one wheel will climb over a 3-in obstacle on the track without derailment. **Double-truck**, 8-wheel car may be used for large loads; it reduces the load per wheel for light rails, and can run on sharper curves than a car of same capac with rigid wheel base.

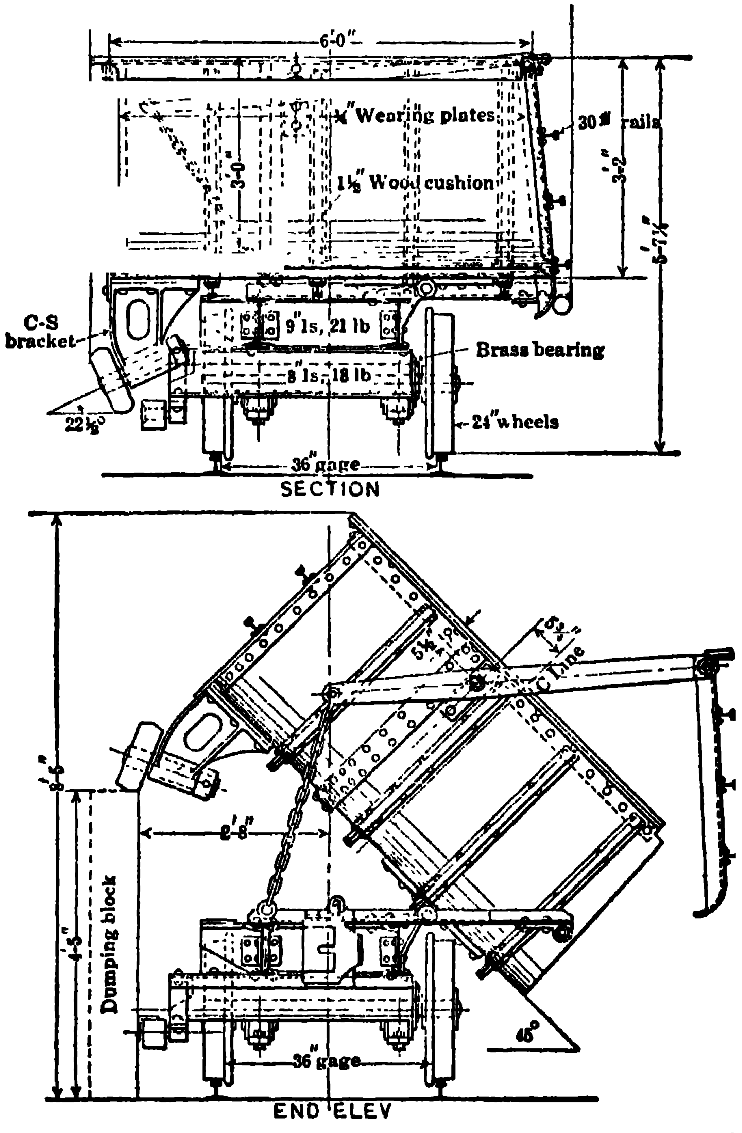

Fig 8. Side-dump Car, 130 cu ft, Granby Mining Co, Anyox, B C

Fig 17 is a 12-ton car. Large unit loads are economic, and the use of double-truck cars will increase (see *E & M J*, Vol 95, p 276; 96, p 1170). **Wheel base.** For the sharp curves of mine track the wheel base must be short; rarely more than the track gage. Exceptions: locomotives, because their drivers are of large diam, and cars for overhead rope haulage, since long wheel base tends to prevent derailments. For relation of wheel base to radius of outer rail on curves, see Track gage, Art 5.

Fig 17*a* is an all-steel, 6-cu yd double-truck coal car; wt 5 300 lb, using dumping cylinder (Fig 17*b*) which returns to at-rest position by gravity. Each pair of wheels (running on same rail) swivels about a king post for taking curves. Wheels have vert play on king post for uneven track. Fig 17*c* has gable-bottom for sticky lead-silver ore; wt 4 500 lb, 57 cu ft, with double truck, allowing minimum-radius track curve of 20 ft.

4. MINE CAR DETAILS (2, 5, 6, 7, 10, 11)

Draw-bar, coupling, and bumper. When cars are to run in trains, the frame or body must transmit and withstand both tractive and impact stresses. For light cars, separate draw-bars should be protected by bumpers, and be designed for 10 times the nominal locomotive draw-bar pull, to allow for jerks, braking and abuse. Cars dumped on a rotary dumper should have swivel couplings, as the car can then be rotated in the dump without uncoupling from train (Art 9). Automatic couplings, due to their cost and difficulty of uncoupling, or bumping without coupling, are justified only for cars of over 6-ton capac, and should be of spring-bumper type. Fig 17*d* shows Allen and Garcia Co's semi-automatic spring coupling, for 4-ton steel cars; Fig 8 is also a semi-automatic type.

Fig 12. Scoop Car

Small metal-mine cars are sometimes coupled by chains and rings at the vertical edges of body (Fig 11). This requires 2 connections, but on curves the outer chains only are in tension, curve friction is supposedly reduced, and couplings are more accessible. Cars of 2-ton capacity or over should have combined spring couplings and heavy C-I bumpers (Fig 9). 1 spring and 1 rigid coupling make a good combination for light cars. Bumpers should be rounded to avoid interlocking on curves. Fig 9*a* and 15 show devices for safely uncoupling cars.

Car wheels. MATERIALS: C I, cast, pressed or manganese steel. Standard C-I wheels are of definite composition, annealed to give toughness, and with deep chill on flange and tread. The treads are too hard to be trued on a lathe. Hubs are soft, easily worn, but readily machined and bushed. When scrapped they are salable to local foun-

dries. Cast-steel wheels are at least 30% lighter than C I; are tougher, not breaking under

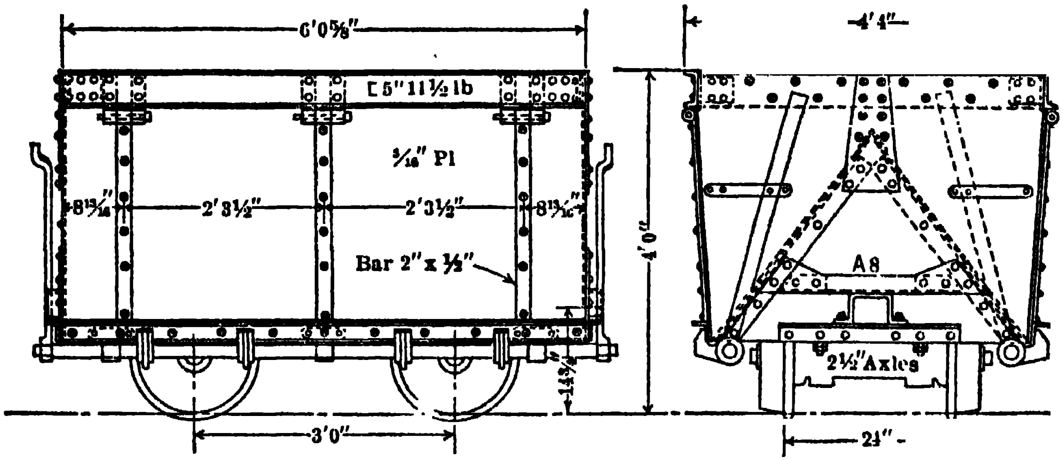

Fig 13. Gable-bottom Car, 47 cu ft Capac (Oliver Iron Mining Co)

impact (as iron wheels may), wear more rapidly on the tread, but are easily machined. In remote regions they are worth less per lb as scrap. Wheels of pressed-steel plate are tougher and lighter than cast steel, easily machined, but can not be made in one piece with self-oiling recesses. Some mines give satisfactory reports of them. Manganese-steel wheels are hard and tough, and outwear any others of the same design. They cost more, can not be machined with tool steel, and in many mining districts make unsalable scrap. Hard, smooth wheel tread gives lowest track friction. DESIGN. Diam, 8 to 20 in; tread, 2.5 to 3.75 in, coned $^1/_{16}$ to $^3/_{16}$ in (M C B standard coning is 1 in 20). When treads become grooved, wheels should be trued on a lathe or discarded; grooving causes derailment on frogs and increases tractive resistance, especially on curves. Flanges are from $^7/_8$ to 1 $^5/_8$ in deep. WHEEL BEARINGS. LOOSE WHEELS are held on axle by cotters or linch-pins (Fig 18*a*, 19*c*), by bolts or key blocks engaging annular grooves in axle (Fig 18), or have outside pedestal boxes and inner axle collars (Fig 4). With finished

collars, hubs should be counter-sunk to fit. Hub bore may be machined, or left rough for babbitting, or reamed out for a soft steel, brass or bronze bushing (Fig 19). TIGHT WHEELS

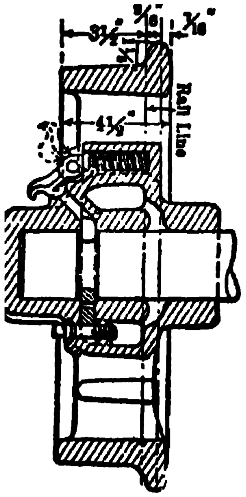

Fig 18. Faught Self-oiling Wheel

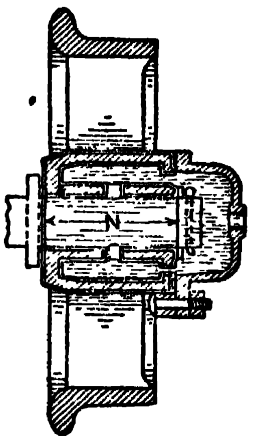

Fig 18*a*. Whitney Self-oiling Wheel

may be keyed or bolted through grooves in the axle; but a close fit is better, wheel being forced on axle by hydraulic press. Self-oiling wheels, of numerous designs, have hub caps, thus making an oil reservoir (Fig 18), or are cast with reservoirs in the hub; they have spokes or wheel disks with oil-feed holes to the journal and screw plugged or spring capped supply hole (Fig 10 and 18*a*). For large mines, plain and bushed wheel bearings are becoming obsolete, because of the higher effic of roller and ball bearings. Roller-bearing wheels are heavier and cost more, but so greatly reduce tractive resistance that they are rapidly replacing the cruder types in both coal and metal mines. Flexible and solid cylindrical rollers, tapered rollers and ball bearings are all in use. Fig 19*a*, *b* and *c* show 5 types of these bearings. For performance of different bearings, see Art 8. Axles may be fixed or rolling. Simplest and cheapest is a square axle bolted to truck frame or car bottom with outside loose wheels (Fig 10). Having no protection against dust or oil leakage, the hub bore wears rapidly, increasing friction and liability to derailment. A hub cap keeps out most dust and saves oil; bushing takes up wear and reduces friction. Roller-bearing wheels, with long bearings, are excellent on fixed axles, but they are often used in pairs on rolling axles, which is not a logical design; rolling axle should have one tight wheel to make rotation positive. Axle boxes often have no caps, and even worn axles may run smoothly. Open pedestal boxes with axle held by a U-bolt are much used abroad. They are cheap, but the axle wears rapidly. Plain solid or babbitted boxes are better. Many dust-proof bearings are on the market, varying from simple shrouds, multiple felt or metal-gasketted boxes, to the continuous sleeve enclosing the whole axle, with self-oiling boxes, as the Anaconda (Fig 9) or McCaskell (Fig 19) types. WHEEL GAGE. Axle collars or wheel bearings are spaced to make wheel gage 0.5–0.75 in less than that of straight track. M C B standard gage is measured at $^5/_8$ in above base of flanges, and is $^{13}/_{16}$ in less than the straight track gage. AXLE BEARINGS. Fixed axles require no anti-friction bearing, except at wheel hubs. Where axle loads exceed 2.5 tons, spring pedestal boxes, preferably outside the wheel, should be used, relieving shock on both car and track and minimizing derailments. Rolling axles have the same variety of bearings as for wheels. Fig 19c is a Gurney outside journal ball-bearing, with spring box; Fig 19*a*, part of a Sanford-Day anthracite truck, where both wheel and axle are loose, with outside spring box. Axle bearings are structurally better than wheel bearings, because on curves or poor track the wheels are eccentrically loaded. TIGHT AND LOOSE WHEELS. In standard R R practice, the tread coning practically compensates the increased length of the outer rail on curves, the outer wheel flanges crowding against the rail, while the inner travel on their small diam. With the short-radius curves of mines, wheel treads can not be sufficiently coned to make up this difference. Thus, on 24-in gage, a 20-ft radius curve of 90° requires the outer wheel to travel 3 ft or 10.5% farther than the inside wheel. Fixed wheels must therefore either skid or churn on curves. This is avoided by loose wheels. Or, as in the

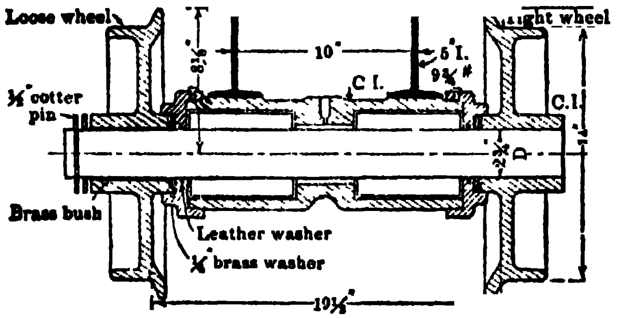

Fig 19. McCaskell Wheel and Axle

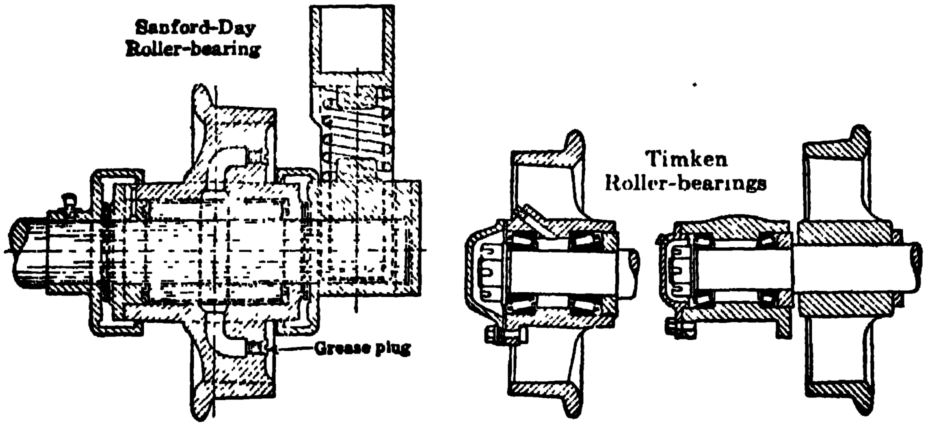

Fig 19*a*. Sanford-Day and Timken Roller-bearings

Anaconda truck (Fig 9), both wheels are tight, but are on separate short axles, in a continuous sleeve journal. Each axle is held in its bearing by a bolt or saddle key, riding in a slot cut around the axle weakness of this design is the 2-piece axle and poor provision to meet end thrusts. McCaskell truck (Fig 19) has a similar continuous oil reservoir shroud between bearings, and a solid axle, with 1 tight and 1 loose wheel. The loose wheel gives differential travel on curves, so that hub wear is negligible, or is provided for by bushing. Cased roller bearings for the axle (3), and a self-oiling loose wheel, would give an ideal combination to minimize tractive resistance.

Lubrication of wheels (25, 27). Thorough lubrication is essential for low tractive resistance. An oil bath on a standard R R axle reduces friction from 10 to 15% of what it is with oiled waste on one side of the journal. Open, unprotected pedestal boxes may require lubrication every trip, and, when used, there should be oil reservoirs beside or between rails, with revolving brushes or cams to oil or grease the axles automatically as they pass. Plain covered bearings should be oiled once or twice each shift. Self-oiling, dust-proof bearings (see above) may not require attention once a week. Best roller bearings run 3 to 12 months with one charge of grease, and makers claim a saving of 80% in cost of lubricant over plain bearings (27). Bearings are lubricated by a grease gun, attached to the grease-plug hole; grease is forced in by a screw piston displacing the old grease. Hand guns are customary, but for large mines a grease tank with 100-lb air pressure, and pressure hose lines to both sides of track is better. Mode of lubrication can be advantageously varied with size of wheel, as indicated by Fig 51*b* from the Pittsburgh tests (4, 6). Non-hardening cup grease should be used, and roller bearings should also be oiled sparingly at intervals with a good car oil. In winter use zero-test oil. For effect of lubrication on traction, see Art 8.

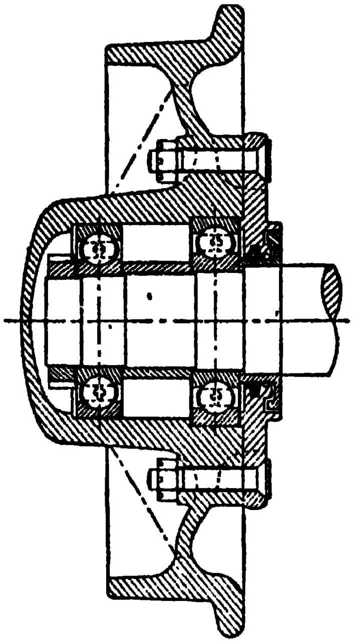

Fig 19*b*. S K F Ball-bearing

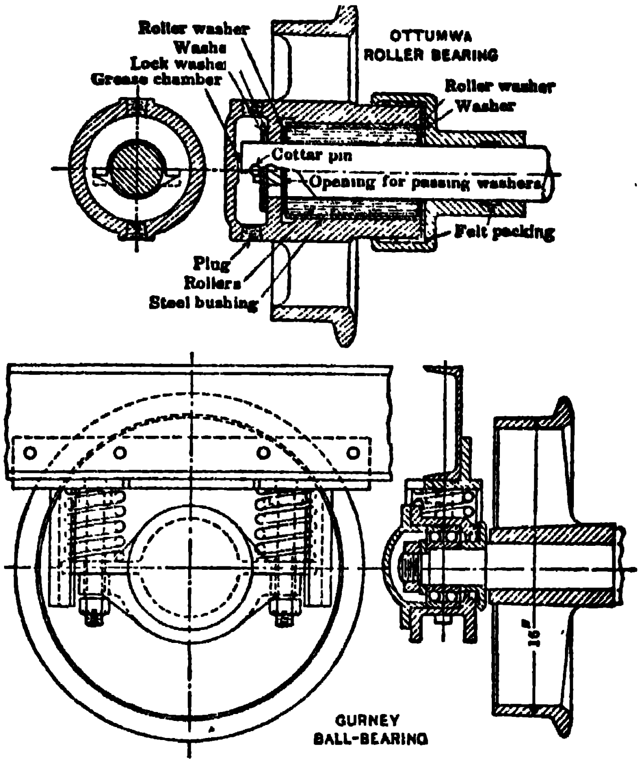

Fig 19*c*. Types of Roller- and Ball-bearings

Brakes. The simplest brake is a hardwood sprag, thrust between spokes and forcing the wheel to slide. It causes flat wheels and is usually applied to but 1 wheel at a time. A lever with wood block between wheels brakes 2 wheels on one side. A simpler steel-bar brake is shown in Fig 3. Brake shoes of wood or steel, in chairs, with toggle gear cross-connected under body to engage all 4 wheels, are best (Fig 1, 2). Brakes should have a ratchet, latch or counterweight, to set or hold them. Fig 20 shows brake system on a Gen Electric Co's trolley locomotive. For locomotives on steep tracks a special rail brake is sometimes provided to grip both sides of a third brake-rail to control train (Fig 21). It is said this brake will stop within 100 ft a 100-ton train and locomotive running 8 miles per hr down 8% grade.

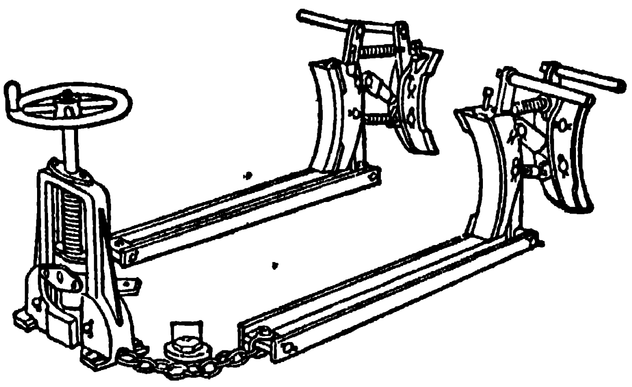

Fig 20. Vertical Screw Brake

Making vs buying cars. Special cars, as for drill-steel, timber, water, toilet or men, can advantageously be made in the mine shops during dull periods, at nominal labor cost;

but, for standard cars, only large mines with good shops can compete with mine car makers, either in cost or quality of product. Freight rates on manufactured cars are usually higher than on lumber or knocked-down car parts.

Present tendencies. Well-managed mines are standardizing car designs. The various roller and ball bearings are properly replacing plain and bushed bearings, though it does not pay to install expensive anti-friction bearings for bad grades and poor track. Mine mgrs report cast-steel, rolled-steel and manganese-steel wheels are more satisfactory for motor haulage than chilled-iron wheels.

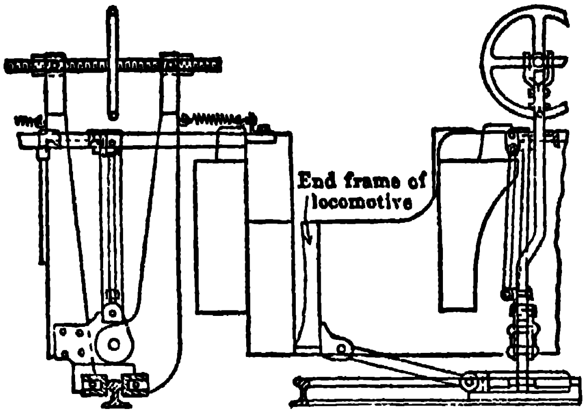

Fig 21. Locomotive Third-rail Brake

Welding is now so readily done, compared with riveting or bolting, that many mines are replacing wooden bodies and underbodies by all-steel construction. Cars for main haulage are becoming larger; thus, the gable-bottom car (Fig 14) of 45-cu ft is now replaced by 75-cu ft cars at Miami, and in Clifton-Morenci district, and, at Alaska-Juneau, 5.5-ton gable-bottom cars have been superseded by 10-ton cars. Doorless rigid-body cars, operated with rotary dumps, avoid the weakness and spilling nuisance of door cars and grow in favor. Colliery cars holding 4-6 tons are now common, where 1.5-3 ton cars were the rule. If sticky ores tend to build up in bottom of cars, rounded or steep gable bottoms are preferable.

5. MINE TRACK (12 to 24)

Wooden rails, 2 by 3 in or larger, are sometimes used in metal mines, for small-scale or temporary work, and in collieries for branch track in rooms or breasts. Frictional resistance to sliding of braked wheels on heavy grades is greater on wooden rails and less injurious to wheels. In its simplest form, the rail is spiked to the ties by 4-in or larger wire nails. A better form, for convenience in relaying, holds the rail by wedges in daps in the ties (Fig 22). Facing wooden rails with strap iron increases their life, but reduces sliding friction practically to that of the T-rail. Straps are 3/8 or 1/2 by 2 in, fastened by countersunk spikes or screws.

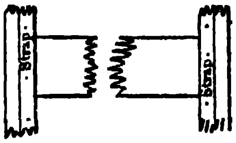

Fig 22. Wooden Rails

Steel rails are made in 3 standard series of sections, the Amer Soc C E, and A and B series of Amer Ry Assoc; also in many special shapes. For mine track thick web and broad base are best, because of use of light ties, and frequency of corrosive water. Amer Soc C E sections most nearly meet these requirements. R R rails are sold by the long ton, specifications usually calling for 30

Letters refer to Fig. 23. * Few mills roll this size. † Heavier rails, up to 150 lb, are rolled.

or 33-ft lengths, with not over 10% of shorts down to 24 ft. Shorter lengths (18 to 27 ft) are often necessary for mine track, especially at shaft stations. Relaying-rails, 56-lb and heavier, are usually on the market at reduced prices.

Spacing of holes in rails and splice bars varies with different makers for rails below 40 lb, and should be specified when ordering; *b*, *c*, *d*, *G*, *H* and *t*, refer to Fig 23. $G = 2F$; $H = 2F + 1/8$ in; *L'* for 4-bolt joints, up to 65-lb rail; *L* for 6-bolt joints, for 70 lb and heavier.

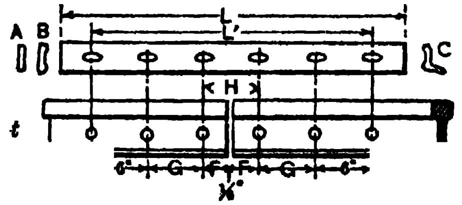

Fig 23. Rail Section and Splice Bars

Weight of rail. For strength: Fig 24 shows minimum wt of rail and max single-wheel load recommended for 1 1/2 and 3-ft tie spacings, to give reasonably low stresses. Heavier rails than indicated for given loads will reduce track resistance and maintenance costs, while lighter rails should be used only for temporary work. For locomotives, rails lighter than 25 lb will not keep alinement, and should not be used on main lines. For conductivity: rails for heavy traffic are usually amply large for return circuit for electric haulage, but with light equipment the size of rail for economic conductivity, rather than the wheel loads, may be the limiting factor in determining wt of rail. Rails carrying 0.25% Cu are reported by J. O. Greenan (15) as being ten times more resistant to acid mine water than non-cuprous rails.

Bonding. The contact resistance of ordinary rail joints is so great as to be equivalent to an open circuit. The best of bonds should be used under splice bars, and rails should be cross-bonded at about every third length, the rail circuit being connected to the negative pole to minimize corrosion. (For rail bonds, see Sec 16.)

Rail joints should have as nearly as possible the same strength and stiffness as the solid rail. Expansion is allowed for by leaving spaces between rail ends, using splice-bars with slotted bolt holes, and drilling the rail holes 1/8 to 1/4 in larger than the bolts. Flat fish-plates (Table 2, and Fig 23, *A* and *B*) are made for rails up to 40-lb, but for rails over 25-lb the angle-bar splice (Fig 23, *C*) is better. Electric welding is the best modern method of bonding, and is becoming standard practice for main-line track, for both bonds and joints.

Track spikes, to have the greatest holding power, should be straight, smooth, of uniform cross-sec, and with a sharp cutting edge beveled back 2 diams. Spikes of different makers vary over 10% in wt; number per keg should be verified when ordering and allowance made for extras. Spikes are staggered on opposite sides of the rail, and the stagger reversed for the other rail, the inside spikes being near the same side of tie. If ties are first bored with holes 1/8 in smaller than the spike, the holding power is greater, but to follow the hole, spikes must be pointed instead of beveled.

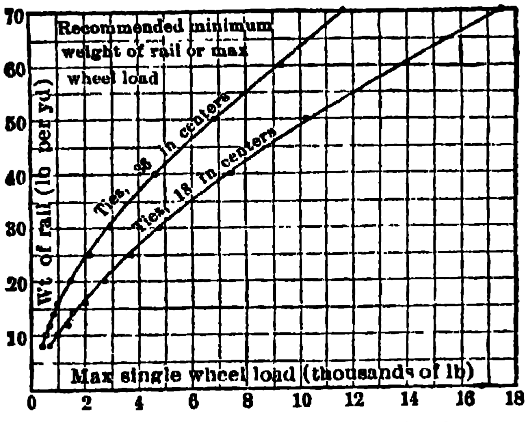

Fig 24. Weight of Rail for 1 1/2 and 3 ft Tie Spacing

Screw spikes increase life of ties, are more effective, but cost more. Though much used abroad, and almost indispensable for tropical hardwood, they are not yet common in U S, but are replacing driven spikes on some R R lines. Holes must be bored for them.

Wood ties for standard-gage track are 8 to 9 ft long, not less than 6 in thick, flattened to at least 6 in face, or, if sawed, minimum cross-sec is 6 by 8 in. For narrow-gage track, length of ties should be twice the gage, at least 1/4 in thicker than spike length, and 1 3/8 times spike length in width. But for light or temporary work, or prospecting, ties are often no thicker than the spike length, and but 4 in longer than distance between outside spikes.

Steel ties of pressed and rolled steel, have the advantages of lightness, strength, durability (where mine water is not acid), and of requiring less depth or headroom. They should have flanges along all edges, extending into the roadbed to hold them in place. Rails are fastened to them by bolts, or clips and wedges, or combinations of these. Fig 26 shows some of the numerous designs.

Spacing of ties. Average for standard gage is 24-in centers. Underground ties are spaced from 16-in, on some main haulage ways with soft bed, to 4 and even 6-ft centers in

Table 2. Rail Joints (Cambria Steel Co)

room or stope tracks. An excessive span, with light rails or heavy wheel loads, greatly increases resistance, and the bending rails loosen spikes and cut ties. For relation of tie spacing to wt of rail to be used, see Fig 24.

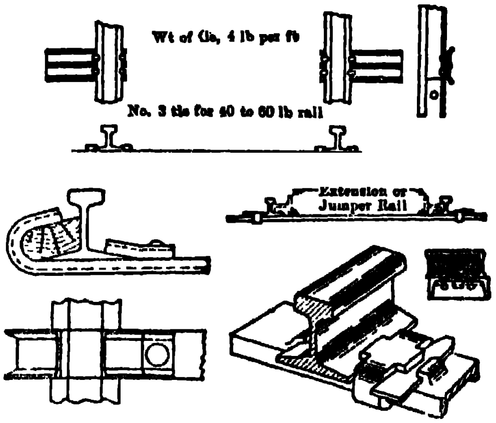

Fig 26. Steel Ties and Rail-fastenings

Track stringers. For soft roadbeds, broad, close-spaced ties are used, but in some mines a satisfactory track is made by using heavy stringers, 4 by 8 or 5 by 10 in, laid on the flat under each rail and omitting ties.

Tie plates are used to protect ties under rails and at spike holes. They are seldom used in mines, but are justified under heavy traffic, or with treated ties. RAIL BRACES, to reinforce outer rail on curves and switches, are advisable for high-speed haulage.

Life of ties. In R R service, hemlock, tamarack and white pine ties aver at least 5 yr; cypress, chestnut, white oak, and cedar, 7 to 15 yr. Generally, the timber most cheaply obtained locally is used for ties, as their life, except where animal haulage is used, is usually longer than that of the mine working. Preservative treatment is economical only in main entries or long adits. Soft ties are oftener worn out by SPIKE-KILLING and rail-cutting than by decay; in narrow-gage work, it is well to use long ties, so that they may be shifted longitudinally when relaying, to afford new places for spiking. For frequent relaying, as in room work, wood ties are spike-killed in from 1 to 5 relayings; steel ties, barring corrosion or accident, last indefinitely.

Track ballast may be of broken stone, gravel, tailing, waste, cinders or slag. The standard of Amer Ry Engs & Maintenance of Way Assoc, for Class C R Rs, is a 6-in layer of gravel and chert under 8-ft ties, with 3 to 1 slopes beyond the ends and filled to the tops at center; or, with ties at 24-in centers, 1 180 cu yd per mile. Special ballast is rarely needed for mine track. The floor is generally hard, and care of the drainage ditches will usually remedy soft spots. Ballast will not help a swelling or heaving floor. With animal haulage, roadbed and ties are worn by the hoofs and require more frequent renewal than for other haulage systems.

Track gage should not be less than half the extreme width of car or locomotive. Max gage is limited by the roadway clearance and sharpest curve.

A crude empirical rule, where wheel-base does not greatly exceed gage, is: Gage $< \sqrt{R+4}$, where R is the shortest radius. Gages range from standard, 56.5-in, down to 12-in. In metal mines, 18 to 24-in are commonest; in collieries, 36 to 42-in. Advantages of broad gage: stability, large-capacity cars, lower total cost of rolling stock and lower operating cost per ton. Advantages of narrow gage: lower first cost of entries and track, and the shorter-radius curves which are made possible. Gage on curves must be increased, to prevent binding of wheel flanges. In R R practice, for each 2° over 8° of curvature, the gage is $1/8$ in wider, to a max increase, including wear, of 1 in. For sharp curves of narrow-gage track, wheels may require all the extra play that their width of tread will allow. The increased gage is obtained by starting the curve of inner rail before the " point of curve " is reached (Sec 17).

6. LAYING OUT CURVES, SWITCHES, AND CROSSINGS

(12, 13, 14, 23, 24)

Track curves. Simple circular curves fill all speed requirements of underground tracks, and easement or transition curves are unnecessary. Degree of curvature D is the angle at the center subtended by a chord of 100 ft; but curves of less than 200-ft radius are best designated by length of radius R. Trigonometric relations between the elements of circular curves, and modes of laying them out, are given in Sec 17.

Layout of curves is done by transit methods, or in various ways requiring no instrument work. They should not be left, as they often are, to the unguided judgment of trackmen. A reasonably accurate curve layout can be made without a transit by means of offsets, by using a rod ab (Fig 27) 10 ft long, and with a right-angle offset dc at center d, of a length $= M$, as given in Table 4 for curve of required radius. The curve is started with the rod laid in prolongation of the tangent from the P C (Sec 17, Art 32) in the position ab'. Offset $d'c$ will then indicate the first point c on the curve. Subsequent points will be indicated by point b when rod ab is laid inside the curve. When the P C and P T are within sight of each other, the middle and quarter-ordinate method is most convenient. When workings are driven by directions from the engineer's office, blueprints should be furnished for placing timbering and track as indicated in Fig 28, 29, with a minimum of instrument work.

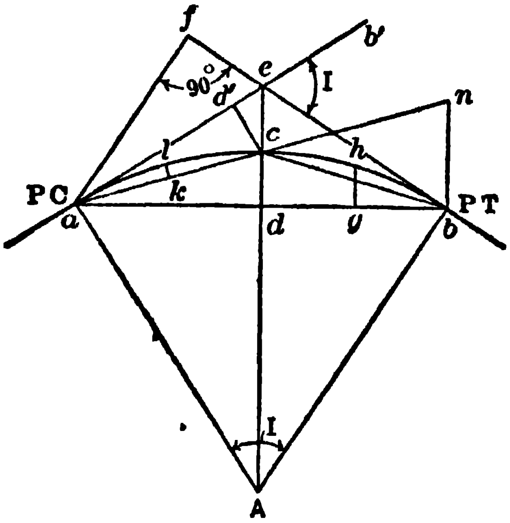

Fig 27. Laying Out Curve by Offsets

Minimum-radius curve is limited by length of wheel base, diam of wheels and flange clearance. Fig 30, from an empirical formula (Baldwin Locomotive Wks data), gives safe values for curves of same gage as on straight track. With liberal spread for gage on curves, 10 to 25% may be added to wheel-base dimensions.

Bending rails. The common rail bender, the " Jim Crow " (Fig 31a), is made in 4 sizes for different wt of rail, the span between claws being 16 to 24 in. Roller bender is a convenient modification, and hydraulic or pneumatic benders (Fig 31, b) are made for heavy rails. Rails are bent to fit curves of given radius by the middle and quarter-ordinate method (see above); or, for short radii, by laying out the curves of both rails in chalk on the shop floor, the value of M for same length of rail being greater for the inner rail (Table 4). If bent in the shop, the max length of a curved rail is limited by size of shaft compartment. Difference in length of inner and outer rails, D = gage × length of curve ÷ radius of curve.

Fig 28. Curve Layout

Superelevation of outer rail, to balance centrifugal force, is $e = dV^2 \div gR$, where c = elevation of outer rail, in; d = distance between centers of rails, in; V = velocity, ft per sec; g = acceleration of gravity, ft per sec per sec = 32.2; R = radius of curve, ft.

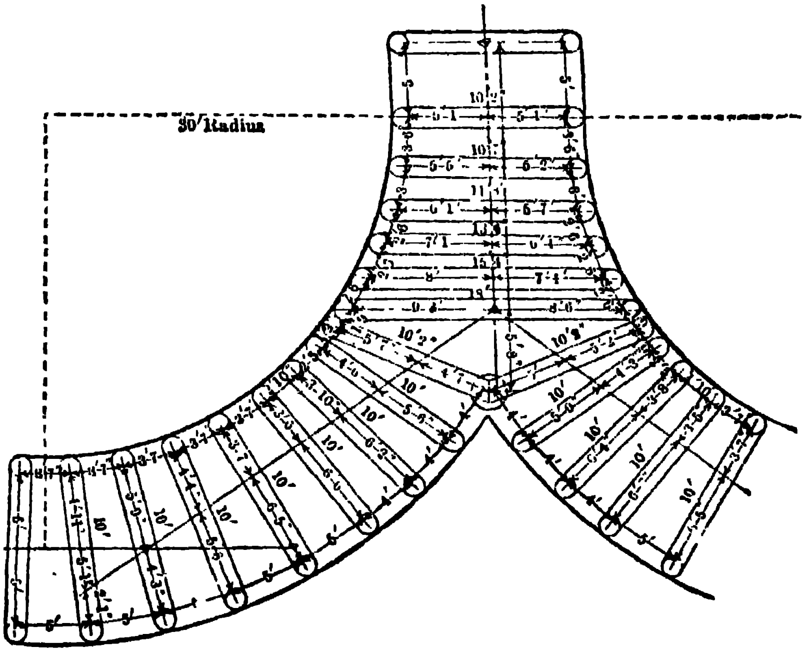

Fig 29. Layout for Double Turnout

On grades, these elevations should be reduced. With rope haulage, the cross pull of the rope on curves modifies conditions, and may even require that the inner rail be elevated (Art 18). On self-acting planes, track on curves can not satisfy requirements for travel

* Corrections are for ordinates of 10-ft rail chords, not for chords taken radially from 10-ft center-line chord.

in both directions, and level ties, guard rails and slow speed are the compromise. Fig 51*a* shows tests.

Fitting track for temporary work without cutting rails. For headings or track gaps, a loose rail is laid on its side along inner side of each track rail, with loose rail head against web of track rail. The wheel flanges then run on web of loose rail, which need not be fastened or match track joints. To put in a curve without cutting main rails, spread end rails and fasten right and left beveled switch points at required P C inside main rails.

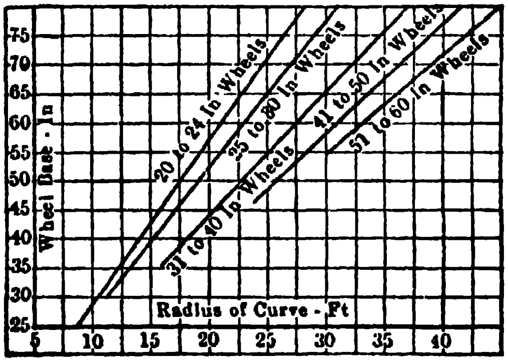

Fig 30. Minimum-radius Curve

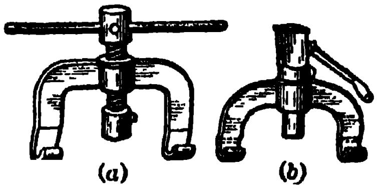

(*a*) (*b*)

Fig 31. Rail Benders

Switches (10). Standard point and stub switches and many other devices are used in mines to transfer cars from one track to another. The point or split switch (Fig 32) consists of 2 "points" or latches, lead and follower turnout rails, and frog with guard rails opposite frog. On blunt switches the toes of the frog and heels of the point rails meet, otherwise filler rail lengths are inserted. Facing a switch, it is passed from the point end; trailing, from the frog end. Standard formulas for switches and turnouts are given by American Mining Congress, May, 1932 (12).

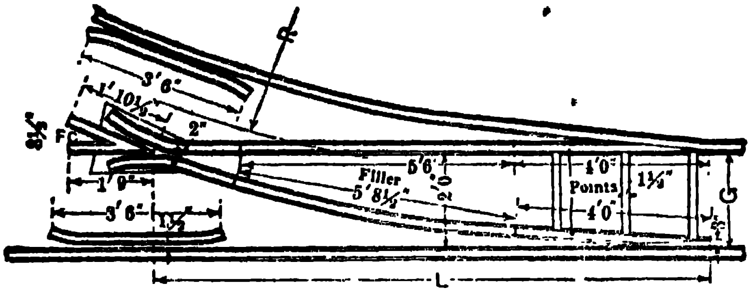

Fig 32. Point or Split Switch

Frogs. The rail crossing may be a single casting (Fig 33), preferably of manganese steel, or be built up of rails. Fixed-rail frogs may be filled and bolted, for heavy track, or riveted on plate for light track (Fig 34). Spring-rail frogs have one wing rail movable, but held by a spring against the frog point so that wheels on the main track pass over no gap. Standard frogs have straight rails, but, for narrow-gage blunt turnouts, curved frogs are better, though they are not interchangeable for right- and left-hand turnouts, and a turnout guard-rail should be provided. FROG NUMBER is the distance (Fig 34) from the point of frog to any point at which the spread between gage lines is measured, divided by that spread; or it is the total length of frog C divided by total spread $A + B$. For curved frogs the spread is measured to tangents from the frog point. Grade frogs may be avoided by raising the lead rail, and carrying the wheel-flange over the unbroken main rail by a latch (Fig 35). The sharp rise of the lead rail, and the latch closing the main rail are objections. Some mines use a reversible frog block to fill the flangeway of the closed track rail. It is effective, but causes derailments if misplaced and should be unnecessary with proper design. Fig 33*a* shows

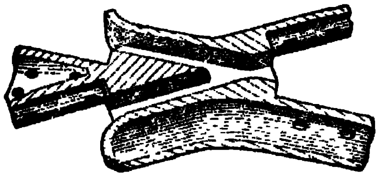

Fig 33. Cast Frog

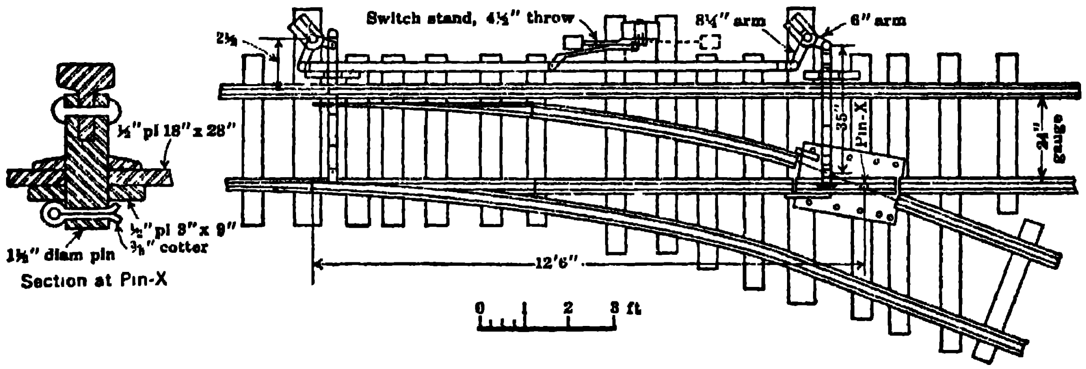

Fig 33*a*. Frogless Switch, N J Zinc Co (2)

an ingenious arrangement of a pin-swiveled piece of rail taking the place of a track frog. Fig 49 is a simple station track layout.

Switch layout (10). In Fig 32, let F be frog angle, N frog number, G track gage in ft, R radius of center line of switch curve in ft, and L switch lead in ft. The lead is the distance parallel to main line from switch point to frog point, and must be known to locate

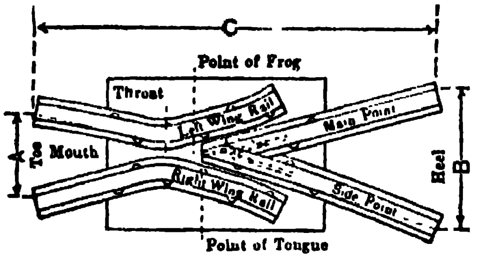

Fig 34. Fixed-rail Frog

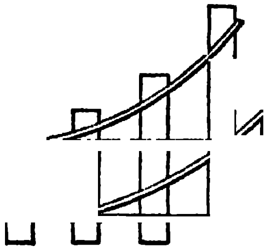

Fig 35. Grade Frog with Latch

the frog properly. Assuming a switch with curved point and frog rails, or a circular curve from point of switch to point of frog:

$$N = {}^1/_2 \cot {}^1/_2 F = L \div 2G = R \div L \quad \sqrt{R + 2G}$$

$$\sin {}^1/_2 F = \sqrt{\frac{G}{2(R + {}^1/_2 G)}} = \frac{G}{\sqrt{G^2 + L^2}} = \frac{1}{2N} \text{ (approx)}$$

$$L = 2GN = R \div N = (R + 0.5G) \sin F = \sqrt{2GR}$$

$$R = LN = L^2 \div 2G = 2GN^2 = (L \div \sin F) - 0.5G$$

Total length of lead rail from point of switch to point of frog = wing rail + point rail + filler = $\pi R\ (F + 180)$. With straight frog and point rails, values of L and R are modified:

$$R = \frac{G - w \sin F - h}{\cos \alpha - \cos F} - {}^1/_2\, G$$

$$L = (R + 0.5\,G)\ (\sin F - \sin \alpha) + w \cos F + p$$

in which α is angle of point rails, w = length of wing rail, h = heel distance, and p = length of point rail. For a DOUBLE TURNOUT or 3-way switch (Fig 36), let F_m be the center frog; then, $vers\ {}^1/_2\, F_m = \dfrac{G}{2\,(R + {}^1/_2\, G)} = {}^1/_2\, vers\ F_l = {}^1/_2\, vers\ F_r$. and distance $aF_m = R + 2\,N_m$.

Stub switch (Fig 37) is simpler than the point switch, and cheaper if both are made at the mine; if supplied by manufacturers, the stub saves little. If the switch has no locking lever, derailments may be caused by the rear wheels throwing the switch rails. This danger is reduced by making the turnout stub rails parallel to the main rails for a distance equal to the car wheel base. Special tie plates or chairs (Fig 38) should be used for stubs. A modified form of stub (Fig 39) eliminates the frog, and is good even for motor haulage, if there is enough room for the rods.

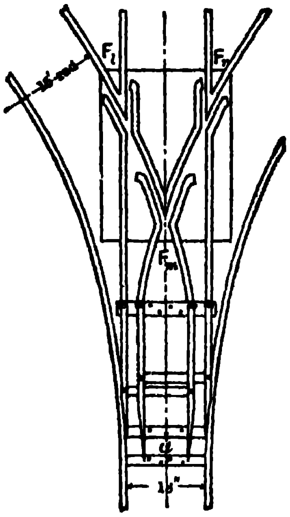

Fig 36. Double Turnout

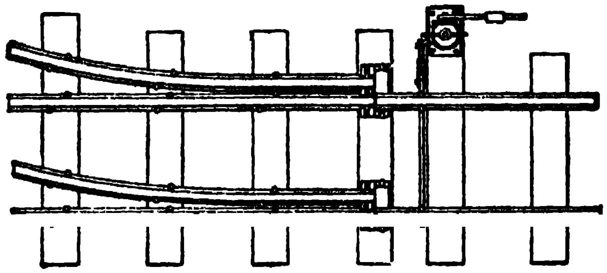

Fig 37. Stub Switch

Automatic switches have their latches or points normally held by a spring to clear one track; facing trains must follow that track, but trailing trains may pass from either track, the wheel flanges forcing the point over against the spring when coming from closed track. These switches may have a lever to engage a projection on motor or car for flying-switch work, but head tie bar should then have a spring connection to the throwing lever to reduce impact. The automatic switch is especially serviceable for by-passing at tipples, shaft stations and sidings. In Fig 40, a is a simple automatic switch; b, combined with lever throw.

Finger or single-latch switch, a modified point switch, omits one point rail and the frog. The turnout is an angle instead of a curve, but it is a cheap and good switch for light, narrow-gage work. Fig 41 shows its application to a 3-way switch; Fig 43 to a crossover.

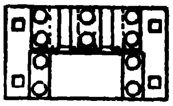

Fig 38. Stub-switch Fixtures for Light Rail

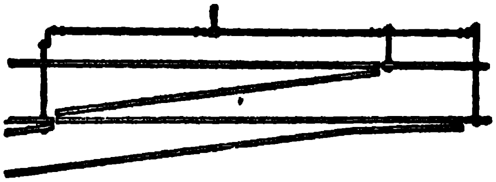

Fig 39. Stub Switch Without Frog

Fixed switch (Fig 42) is suitable only for hand tramming or animal haulage. All rails are fixed, but with liberal flange clearances at the points, and cars are crowded toward the turnout or against the unbroken main rail to take or pass the switch. Lowering the outer rails slightly at the turnout helps to protect main-line traffic.

Double crossover or diamond switch is the standard for tipples and shaft bottoms. Fig 42, 45, show cases where distance between tracks is greater than the gage, and Fig 44 where the distance is less.

Fig 40. Automatic Switches

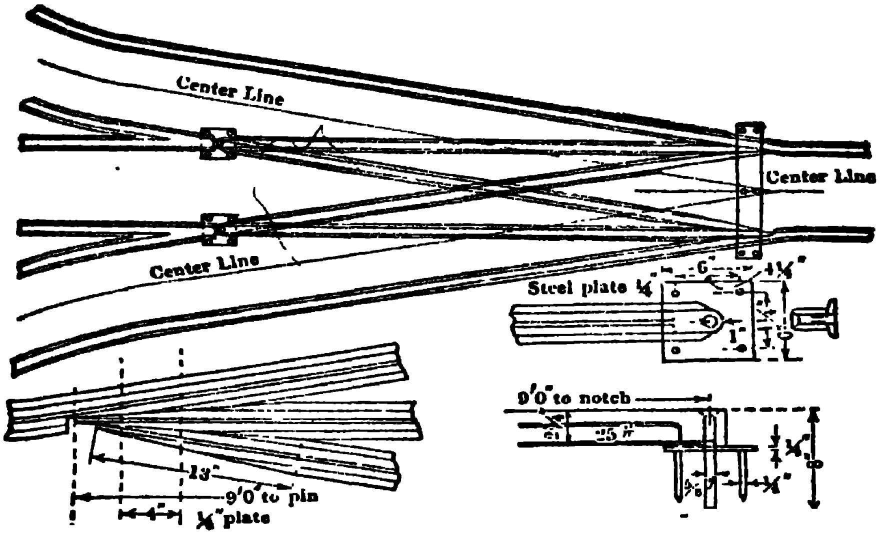

Fig 41. Three-way Finger Switch

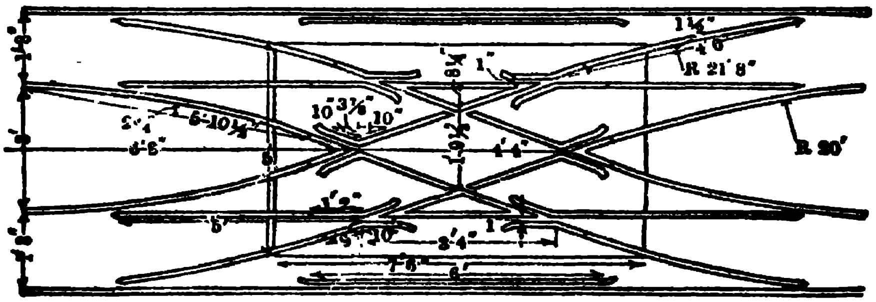

Fig 42. Diamond Fixed Switch

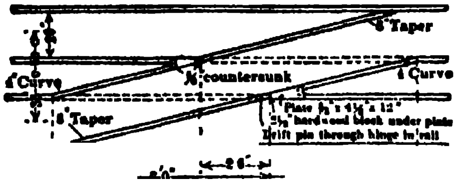

Fig 43. Crossover Finger Switch

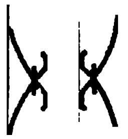

Fig 44. Diamond Switch

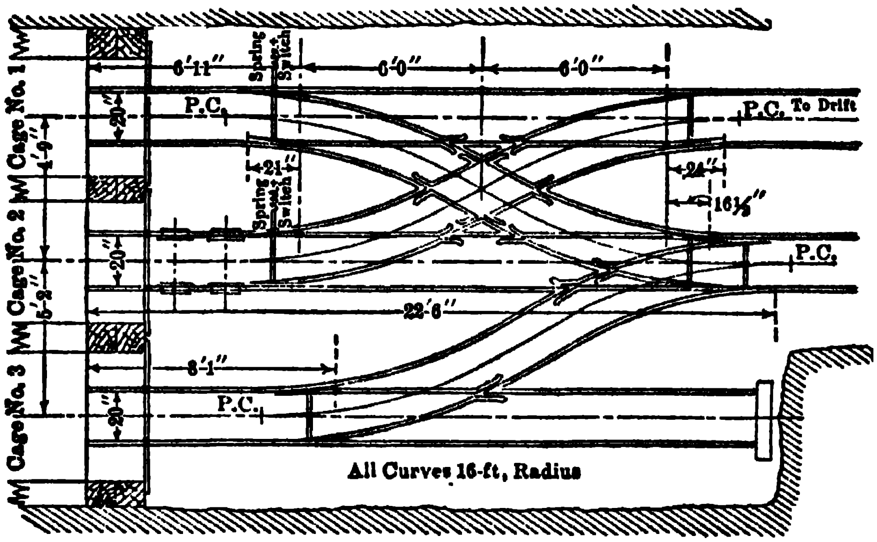

Fig 45. Double Crossover or Diamond Switch

Track crossing may be an assemblage of frogs, or a built-up riveted plate (Fig 46). A crude crossing which avoids cutting for flange-ways is made by running 1 track higher than the other by the depth of the rail, and carrying it across by one long pair or two short pairs of latches. One track is thus always blocked.

Turnsheets (tarantulas), of 1/4-in or heavier plate, fastened to sills by countersunk wood screws or drift bolts, are the simplest switching device; suitable at shaft stations, turnouts and crossings, when the gross wt per car does not usually exceed 3 000 lb. Sheets should be finished on edges and supported by planking or concrete unless the sills are closely spaced. Flared tread POINTS or rounded guards are riveted to plates to guide wheels onto tracks. Fig 47 shows a turnsheet shaft station; Fig 45, a track-laid station.

Turntables are for cars or motors too heavy to handle on a turnsheet, where there is not room for a track switch, or where ground is too heavy for the long caps over turnout curves. Construction: a pair of rails on a swivel platform of plank or steel, or a circular C-I plate, with ball or roller bearings, on a base ring, as furnished by makers of industrial track.

Transfer carriage, a low-truck car on a sub-grade cross-track, carrying rails to fill corresponding gaps in the main or side tracks by moving the carriage, thus transferring cars from one track to another. It is much used in industrial plants, and sometimes at shaft tops for loading into bins.

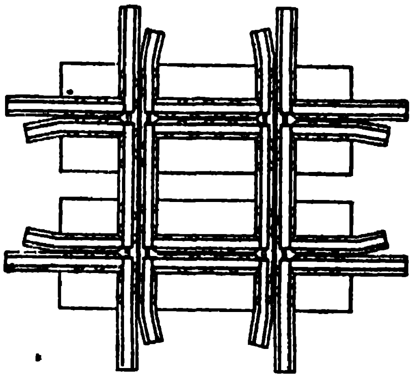

Fig 46. Riveted Plate Crossing

Shaft bottom or station track layout (13) must provide for rapid handling and minimum interference of empty with loaded cars. Standard colliery shaft bottoms have a wide through entry across wall plates, with double crossover on both sides and grades in favor of traffic, so that empties will run to the switch when pushed off the cage by loaded cars. A by-pass track returns empties, when production from both sides is not balanced. A through station with a blind end should have kick-back and spring switch in place of a double crossover. A power lift (Fig 48), to raise empties to top of return grade, makes handling rapid and automatic. Fig 49 is an end-on shaft station with 8 spring switches

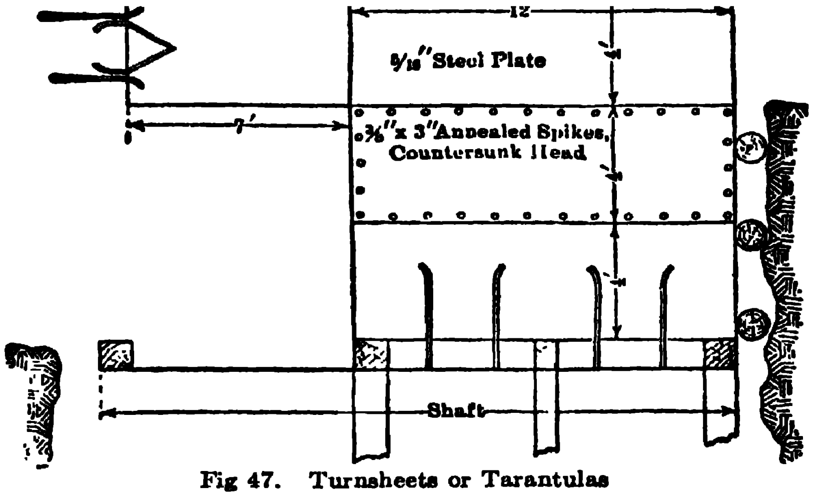

Fig 47. Turnsheets or Tarantulas

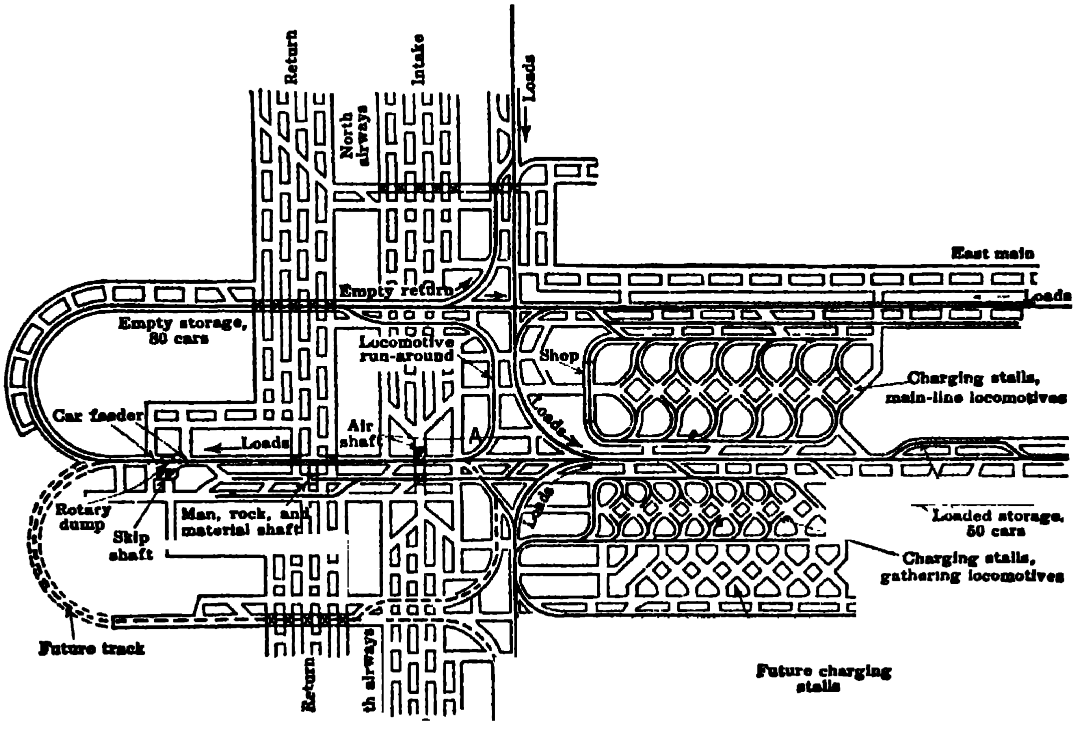

Fig 51. Shaft-bottom Layout, W Va Coal Mines (24a)

(*a*), and 2 throw switches (*b*) and (*c*), making switching of empties automatic to track *A* or *D* (see also Sec 12).

Main haulage levels in wide deposits are planned with parallel loading crosscuts, connected in loops or curved into a main return drift. Hence, the locomotive usually travels in but one direction, hauling a train of empties from the shaft, dropping the rear cars singly at loading chutes, while picking up loaded cars ahead, and pushing them around the loop and back through double-track main drift to the shaft (Fig 50, 50*a*, 51).

Fig 51 is a shaft-bottom layout in W Va, where 2 cars are dumped by a rotary dumper; using battery locomotives, 3 men handle 3 500 ton of coal per shift. Ample storage space must be provided for both loaded and empty cars.

7. MINE TRACK COSTS

Arizona. 30-lb rail, 24-in gage, ties 18 in centers; length 7 000 ft, in medium hard ground: labor digging bed and laying track, 50¢ per ft; ties, 4 by 8 in by 3.5 ft, $27.50 per M bd ft, fob mine, including 10% waste, 13¢ per ft; rails, 30 lb, at $37 per ton, plus haulage to mine, 39¢ per ft; spikes, fish-plates and bolts, 7.5¢, shop labor, etc, 1.5¢; total cost per ft (prewar), $1.11. Turnouts and points, fob factory, $20 per set.

Miami mine, Ariz (F. W. Maclennan, 1925). 45-lb rail, 24-in gage, ties 24 in centers: labor, 25¢ per ft; rails, splice-bars and spikes, $1.17 per ft; ties, 4 by 8 in by 3.5 ft, at $35 per M, 16¢ per ft; total, $1.58 per ft. Turnouts, complete, $100 ea. 45-lb rails have a life of 6 000 000 tons hauled, whereas 70-lb rail, now used for heaviest traffic, may do double that duty and still be serviceable (R. W. Hughes, 1936).

Idaho. 35-lb rail, 18-in gage, ties 2.5 ft centers: labor bringing material from surface and laying 1 mile of track, $591.00; 2 112 ties, 4 by 8 in by 3 ft, 11.2¢ ea, $236.54; 55 tons rails, at $41.08 (July, 1913), $2 259.40, 360 splice bars (4 356 lb), at $2.70 per 100 lb, $117.61; 1 440 bolts (625 lb), at $2.60 per 100 lb, $16.25; 10 560 spikes, 0.5 by 5 in, 4 140 lb at $2.75 per 100 lb, $113.85; total cost 1 mile single track (prewar), $3 334.65 = $0.631 per ft.

Mesabi iron range. Main haulage track, 40-lb rail, angle-bar joints, 4-ft round timber ties faced to 6 in thick, 2 to 3 ft centers depending on the ground, cost $45 to $50 per 100 ft. Sub-level drift, 12-lb track, fish-plate joints, 3-ft ties of half-round lagging over 3 in thick, 2 to 3 ft centers, $18 to $22 per 100 ft.

Fresnillo, Mex (1923). 50-lb rail, 36-in gage; ties, 6 by 8 in by 6 ft, 24-in centers. Cost per ft: labor, $1.66; supplies, $1.76; exclusive of rails and splice bars, which were charged to equipment.

Oliver Iron Mining Co. Tramming tracks, 60-lb rail, min radius of turnout 25-ft, with No 3 curved frogs; grade 1/2 to 1% favoring loads; ties, pine or tamarack, 6 by 6 in by 6 ft, spaced 2-ft centers. Power, 250-volt d c, delivered through feeders to 40 overhead copper trolley wires. Locomotives 6-ton elec trolley, double-end control, 30 h p; cars, 2.75 to 4-ton, gable or V bottom, with 16-in wheels, roller bearings and pocket couplers, loading normally from chutes into cars (Fig 9*a*). Main-level drifting by mechanical scrapers into cars dumped by hand into shaft pocket; tramming, max speed, 5 miles per hr; 10 to 15 cars per trip.

Cost of track varies widely; approx cost can be computed by figuring that 4 laborers and 1 welder can lay about 150 ft of track in 8 hr. To this add delivered cost to place of laying of rail, angle bars, bolts, spikes, ties and cost of special work, as switches and frogs (G. E. Diehl, 1938).

Table 5. Track Costs (*a*), Pittsburgh Coal Co, 1938 (L. E. Young)

	Rail or turnout	Creosoted ties	Accessories (*b*)		Labor	Total
Track, 60-lb, per ft....	$ 0.7249	$ 0.6720	$0.1624	$0.1125	$ 0.3117	$ 1.9835

(*a*) Prices as of Aug. 2, 1937. (*b*) Estimated.

Colliery tracks: West Va Coal & Coke Corp. Cost per ft of 20-lb rail track on 3 by 5-in ties (1938): With wood ties: rail, $0.368; spikes, $0.012; ties, $0.070; bolts, $0.006; splices, $0.020.

Total \$0.476 per ft. With steel ties: rail, \$0.368; splices, \$0.020; ties, \$0.200; bolts, \$0.006. Total \$0.594 per ft. Labor cost of 20-lb room and entry track, about 10¢ per ft; for bonding with 2/0 bonds, 20¢ per ft.

8. TRACK AND CAR RESISTANCES (25–29)

Tractive resistances comprise rolling resistance between rails and wheels, bearing or journal friction, inertia or resistances of starting and acceleration, and resistances due to grades, curves, and atmospheric friction. COEFFICIENT of tractive resistance is commonly measured in terms of lb pull per ton gross load.

Rolling resistance factors are not well determined. Resistance does not increase proportionately to wheel loads; it depends greatly on condition of track and roadbed; perfectly uniform track eliminates most impact and oscillating resistances. JOURNAL FRICTION per ton is a minimum: (*a*) with heavy wheel loads; (*b*) with minimum diam axles and max diam wheels; (*c*) with car speeds from 10 to 20 miles per hr for standard R R, and probably half that speed for mine equipment; (*d*) with perfect lubrication; (*e*) with ball bearings. According to line-shaft tests by Thomas and Maurer (Amer Soc Mech Engrs), roller bearings consume 2.2 to 3 times the power of ball bearings, and babbitt bearings 3 to 4.5 times. STARTING RESISTANCE is usually 1.5 to 3 times the running resistance; on dirty track, after long standing, or in cold weather, it may be 5 times as much. This peak load may be greatly reduced in train work by first backing and then picking up the cars one by one; this is aided by spring couplers. INERTIA (resistance to acceleration) may be computed from $P = 70\ (V_2^2 - V_1^2 + S$, or $P = 95.6\ (V_2 - V_1) + t$; where P = force, lb per ton, required to increase veloc from V_1 to V_2 miles per hr, in S ft or t seconds. If starting from rest, $V_1 = 0$. A good empirical formula (T. Robson) allowing for rotary accel of wheels is: $P = 107\ V$; where V = increase per sec of speed in miles per hr. In R R service, $V = 0.2$ to 0.5.

Track resistance. Baker's tests on perfectly clean track gave 19 lb tractive resistance per ton; same track, coated with 1/8-in fine dust, 28 lb; with 1/8-in powdered stone, 40 lb. Fies (38, p 769) reports coal cars slide with spragged wheels on damp steel rails on 12° pitch, so that wood rails are used in rooms of 12° pitch and over.

Grade resistance = wt × sine of grade. For grades under 10%, there is no appreciable error in assuming grade resistance at 20 lb per ton of moving wt for each percent of grade. At 10%, the error is + 1 lb.

Gradient of equal traction is the grade at which the resistance of an ascending empty car is equal to that of a descending loaded car. Drifts and adits should be driven at this grade, unless drainage or other considerations prevent. Exceptions: In hand tramming with poor track or cars, it is wise to keep the grade 0.1 or 0.2% above that of equal traction, so that the loaded car will move easily, and the trammer can give due attention to preventing derailments. With motor haulage, this grade may also prevent overheating motors by light running in one direction. Formula for grade of equal traction is, $\sin g = fM + (f - f')\ c + (M + 2\ c)$, where g = angle of grade in favor of load; M = net wt of mineral, tons; c = wt of car, tons; f = coeff of tractive resistance for the loaded car on level track; f' = coeff for empty car. Table 7 shows that the difference between f and f' may be considerable. An approx formula for grade of equal traction, assuming $f = f'$, is % grade = $(fM \times 100) + (M + 2\ c)$. Practical determinations of f and f' are scanty. Prevailing grades in important adits are 0.4 – 0.6%.

Angle of rolling friction, A_f = angle at which car will continue at rest or in uniform motion. *Tan* A_f = coeff of rolling friction of car = % grade of repose, and varies from below 1% for large roller-bearing loaded cars on straight heavy rails to over 4% for plain bearings on straight wooden rails, and higher on curves. F. E. Brackett reports tests of a colliery car with loose 18-in wheels, wheel base 24 in, gage 42 in, wt loaded 6 400 lb. Grade of uniform gentle descent: on 4 by 4-in wood rails, A_f = 4.23 to 4.35%; on wood rails, with 0.5 by 2.5-in straps, A_f = 1.83 to 2.03%; on steel T-rails, A_f = 1.62%.

Angle of inertia, starting car or train from rest, $= A_f + \sin^{-1}\ (107\ V + W)$, where V = accel in miles per hr per sec and W = gross moving wt, tons. ANGLE OF SLIDING FRICTION = angle at which cars with brakes set or wheels spragged will continue to coast. On grease-covered rails it may be as low as 6 to 8% for loaded cars, while with clean rails, steel-tired wheels may hold above 14%. It is usually unsafe to trust brakes alone on grades of over 6% on steel rails; on clean, dry, wooden rails, the coeff of friction is greater.

Curve resistance for standard-gage track varies from 0.5 to 1.72 lb; generally taken as 0.8 lb per ton per deg of curve. On short-radius curves used in narrow-gage tracks, the factor is variable and with worn wheel treads is considerably higher. Norris's tests (*Trans* A I M E, Vol 18, p 514) showed 21 lb per ton friction due to curve for a single car on 85-ft radius curve, and 7 lb per ton for a 20-car train moving at 1 000 ft per min on curve of 350-ft radius. For effect of flat and banked curves, with different car-wheel bearings, see Fig 51*b*, also (26).

Air resistance varies approx with end area and length of train, and the square of its veloc, and is independent of train tonnage. It is usually unimportant in mine haulage,

but because of the piston effect of cars in small-section gangways, it should be taken as equivalent to a wind veloc double that of the train. With a 20-car train at 10 miles per hr, the total air resistance may be 50–100 lb.

Coefficient of traction (ratio of draw-bar pull to wt of moving load kept in uniform motion on a straight level track = *tan A_f*) may be obtained from Table 7 and Fig 51*a* These are the best available data, but conditions as to road-bed, track, diam, hardness and smoothness of wheel treads and lubrication are factors, so that for any given case the data must be applied only as approx, unless all conditions are as specified.

Liebermann's tests (Table 7), on Hyatt-Hockensmith bearings, showed 48% saving. Coaldale Colliery tests were with new equipment, 9-car trains, on perfect surface track; starting effort determined on "almost level track." Greensburg tests were for 20-car trains, under working conditions. The Virginia Iron, Coal & Coke Co's tests, for 3 trips of 20 cars with 3.1 tons coal each, haul 3 250 ft, averaged: for trip with solid-hub wheel, 14.9 min, 21.0 kw-hr = 0.55 kw-hr per coal-ton-mile; for trip with Whitney Wonder solid-roller bearings, 7.5 min, 8.8 kw-hr = 0.23 kw-hr per coal-ton-mile = 50% saving in time and 58% in haulage power. Makers claim resistances as low as 9 lb per ton for roller-bearing mine cars; probably under working conditions 15 to 18 lb per ton on straight level track is often realized. It is the practice of mine locomotive builders to assume 30 to 40 lb average resistance in mines unless otherwise advised.

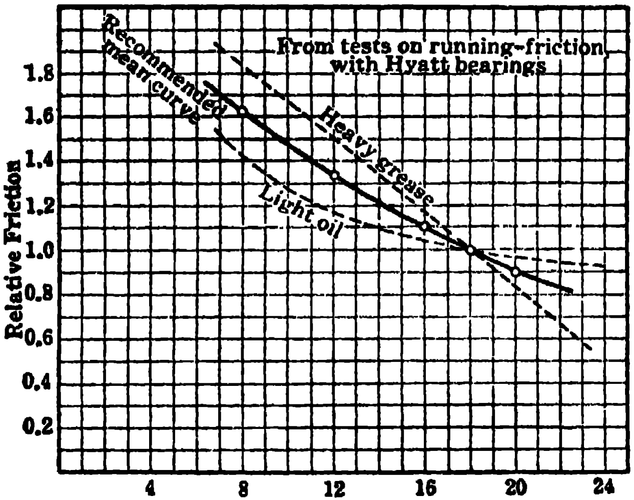

Fig 51*a*. Relative Friction for Different Wheel Diam, Compared with 18-in Diam (6)

Tests at Pittsburgh Experiment Station, U S Bur Mines, on mine car friction are summarized in Fig 51*a* and 51*b* (27). Note that in Fig 51*b* tests were on 1 car of each type, under 3.5 ton gross load, using light oil lubrication for ball and roller bearings, and semi-fluid grease for plain bearings; track, 42-in gage; curve, 16 ft rad; elev of banked rail, 3 in. Differences shown are not wholly due to different bearings, but partly to variation in rolling friction. Results with truck A are significant in showing effect of rough wheels, as actual bearing friction is probably less for ball bearings than for any other. These tests were apparently not fair to ball-bearings. Tests reported from the Charbonnages de Mariemont, France,

Table 7a. Relative Friction of Mine-car Bearings (25, 27, 29)

Type	Wt, cwt	Bearings	Speed, ft per min	Resistance ratio
Wooden pit car, empty	4.5	plain, poor lubrication	150	1 : 30
" " " "	"	" good "	150	1 : 68
" " " "	"	" aver "	starting	1 : 20
Steel car, empty	"	self oiling	....	1 : 60
" " "	"	ball bearing	....	1 : 135

Wheels in these tests were 9–12-in diam; axles, 1 1/8–2 in.

showed the economy of cars with ball-bearings over those with plain bearings, of 85% when loaded and 41% when empty. At the Big Five mine, Colo, the draw-bar pull of trucks, lb per ton, were reported by SKF Mfg Co: starting, straight track, plain bearings, 77.80, ball-bearings, 34.33; 4 miles per hr, straight track, plain bearings, 31.13, ball-bearings, 15.02; 4 miles per hr on switch, plain bearings, 37.75, ball-bearings, 18.43.

At the Cie de Mines de Courrières (29) the tractive resistance of new cars with roller-bearings was 13.4 to 20.2 lb per ton, compared with 27 to 35.5 lb per ton of old cars with journal bearings. General conclusions are: plain-bearing, loose wheels, well worn, have 1.7 times aver friction of ball and roller bearings, at 5 miles per hr, and 3 times when starting; for all types, 3 times greater on banked curves and 5 or 6 times on flat curves. Fig 52 gives resistance per ton of R R freight cars of different gross wt and at various speeds; also starting resistance of light, narrow-gage locomotives and passenger cars. Starting resistance curves for freight cars should be similar.

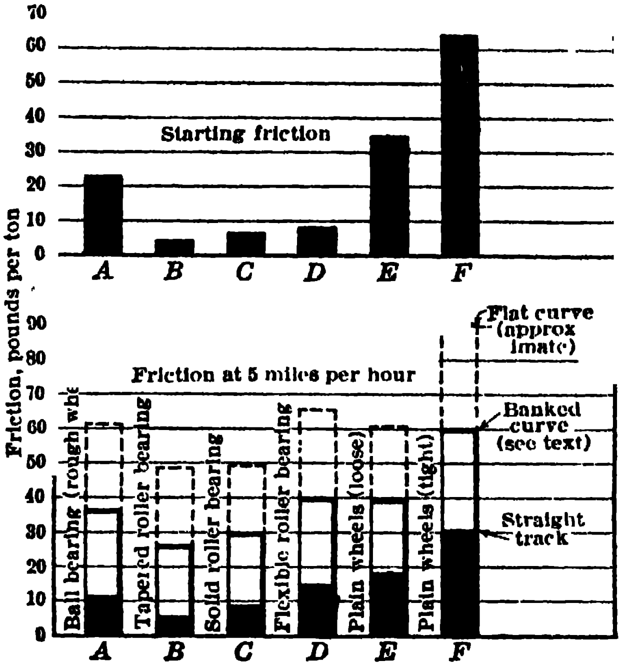

Fig 51b. Relative Friction of 6 Mine Cars (27)

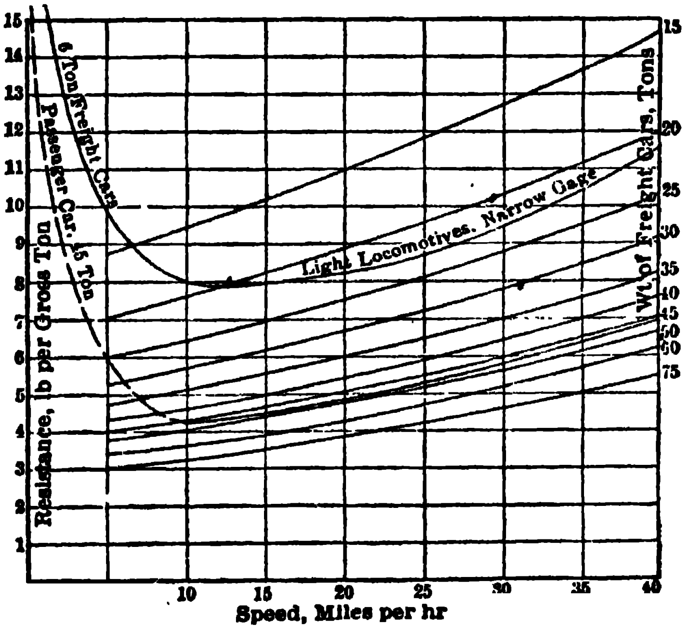

Fig 52. Tractive Resistance of R R Equipment (Baldwin Locomotive Works)

9. HANDLING CARS, CAR DUMPS (31–34)

Rapid handling of cars. For SIMULTANEOUS LOADING OF TRAINS from chutes, spacing of chutes must be exact multiple of length of car. For SWITCHING CARS IN HEADINGS, replace track switch by horiz extension bar close under roof, carrying an air-lift crawl. This lifts empties off the track, allowing loaded cars to pass; bar is quickly set and kept within 100 ft of face. See Sec 6.

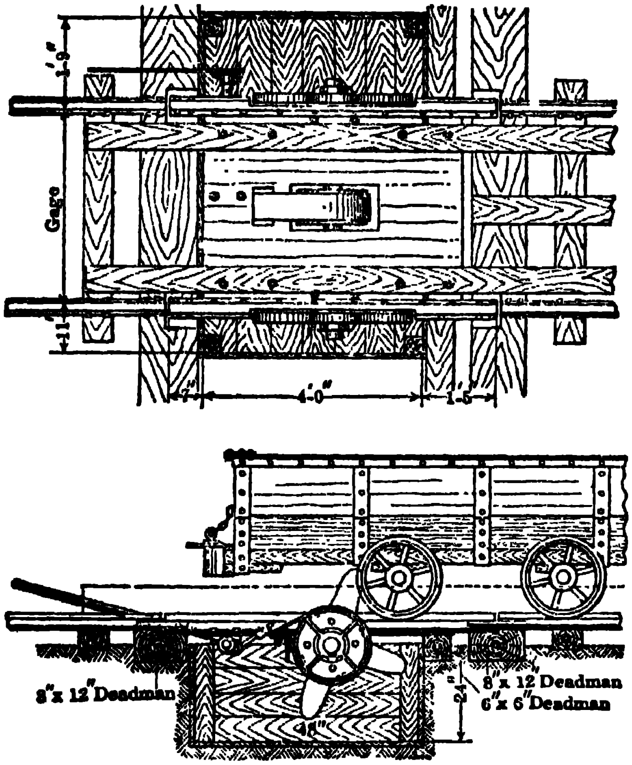

Fig 52*a*. Car Spragger

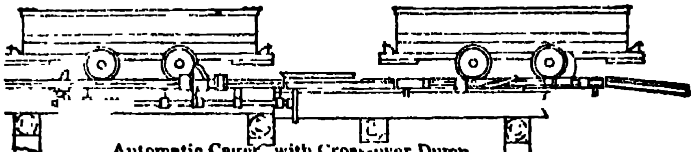
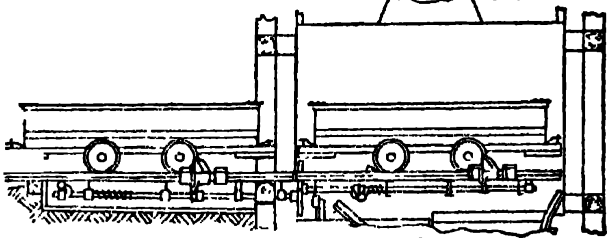
Car stops are usually required when dumping. Simplest stop for track ends on dumps and at ore pockets is a timber clamped across the rails. For small cars, a 1 by 8-in plank, resting on the cross timber and sloping back to the ties, acts as a brake engaging the axle and reducing impact. SAFETY STOPS are advisable at shaft stations, besides the usual gates, to prevent cars from running into the shaft when cage is not at the landing. A simple stop is a horn, normally raised to engage the car axle or bumper. It is connected by crank arms and a rod to a tappet projecting into the cage compartment; spotting of the cage lowers the horn and allows car to pass onto cage. There are many more elaborate mechanisms for spragging and feeding cars onto cages or tipples. Fig 52*a* shows a manual car spragger; Fig 52*b*, an automatic cager in continuation with a cross-over dump, and with a cage, as made by the Car Dumper and Equipment Co.

Car dumps (32, 33). Bottom-dump and gable-bottom cars require only a projecting door latch for dumping at bin, chute or station; they are automatically tripped by an inclined guide, which lifts the latch as car passes. Cars with doors, and bodies hinged to the truck, rarely need a dumping device; but if the mineral is sticky or frozen, an anchor rope should be hooked on at the dump to prevent overturning. Rigid-body cars require some external device to dump. Simple track dumps are used with cars like those in Fig 2, 4, 7, 8, for dumping into pockets and skips. CRADLE, HORN, OR KICK-BACK DUMPS (Fig 52*c*) are horned track ends, so pivoted that loaded car striking the horns tilts the track section and is thus emptied. Automatic forms have springs to assist the returning dump to kick back the empty car. CROSS-OVER DUMPS (Fig 52*b*, 52*d*) are an improvement, as cars continue across the dump after emptying, and are handled quicker. They are essentially seesaws, heavier than the empty car on entering side and lighter than the loaded. Track is down grade through the dump, or the empty is bumped on past the dump by the following loaded car. Many designs are made; used almost exclusively by collieries. ROTARY DUMPS are suited to doorless rigid-body cars and, rotating parallel to the track, can dump one car, or, made in multiples, a whole train simultaneously. They are



Automatic Cager, with Cross-over Dump



Automatic Cager, with Hoisting Cage

Fig 52*b*. Automatic Cagers

operated by gravity, hand or power. By shields and aprons, the mineral may be discharged with sliding contact and minimum of dusting and breakage, especially attractive in coal handling. One to 4-car dumps are now common in coal and metal mining. Fig 52*e* shows a simple type for 1 car. Other designs are available, as that of Pittsburgh Coal Washer Co.

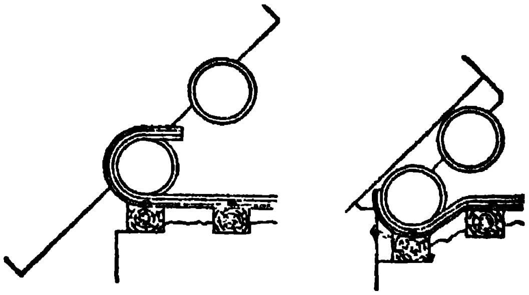


Fig 52*c*. Cradle or Kick-back Dumps

Examples. Miami mine, Trains of 25–30 gable-bottom, 86-cu ft cars run over 1 000-ton ore pockets and dump without stop; train speed, about 2 miles per hr while dumping (R. W. Hughes). Inspiration copper mine. Trains of 20 box-body, 120-cu ft cars dump in 5-car rotary tipples, at 2 shafts. Tipples are revolved in 15 sec by 35-hp motor. At Live Oak shaft, a 6-car air-operated tipple was replaced by using 3.4-ton side-dump cars, with a bridge over ore pocket (42). Snowden Coke Co, Pa, has a 26-car rotary dump, 120 ft long, and H. C. Frick Co, one for 35 cars, 400 ft long, weighing 150 tons; dumping

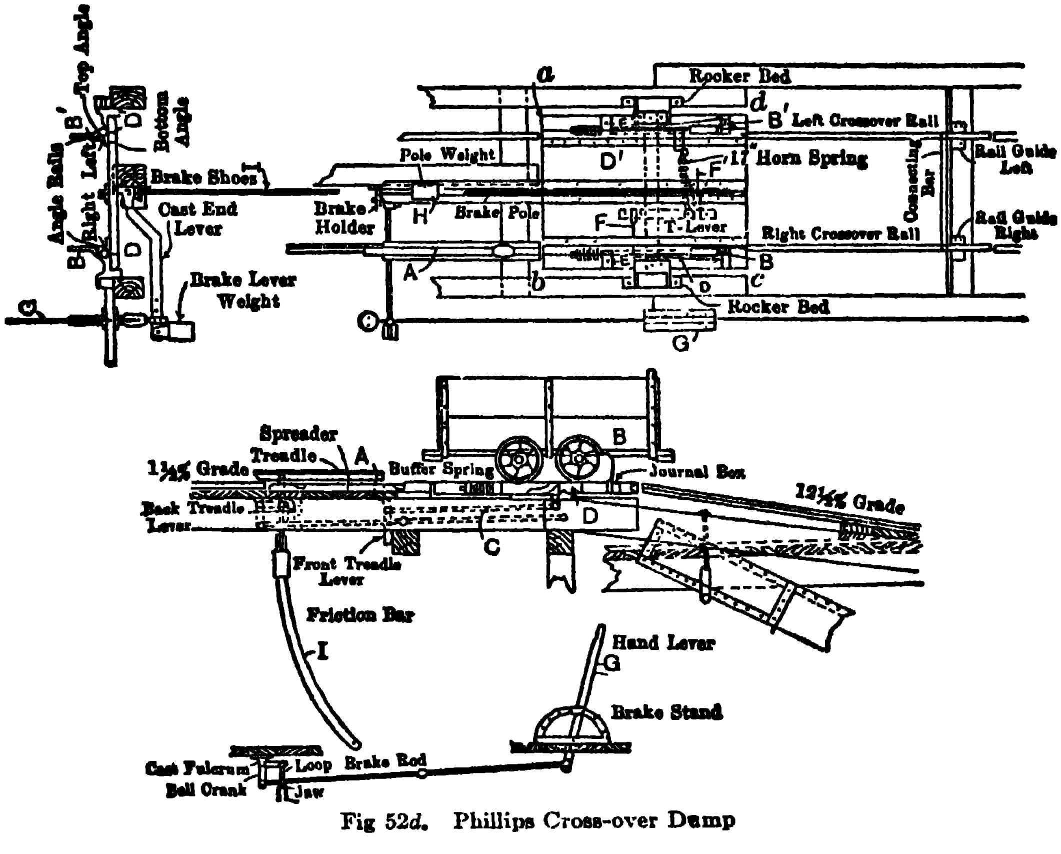

Fig 52*d*. Phillips Cross-over Dump

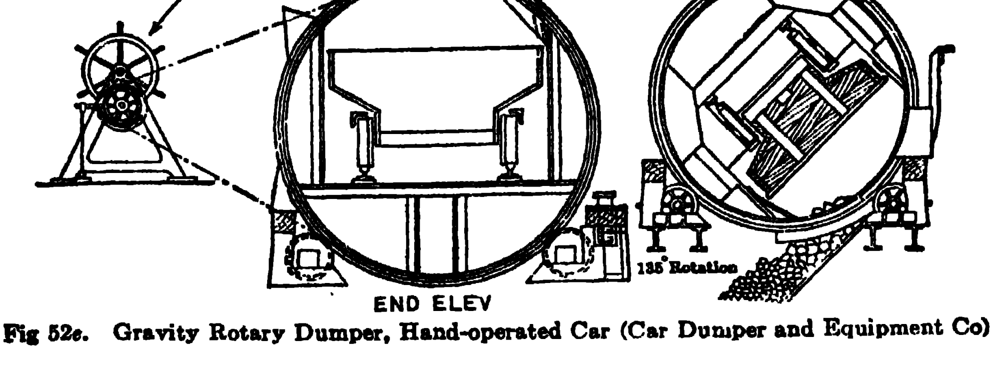

Fig 52*e*. Gravity Rotary Dumper, Hand-operated Car (Car Dumper and Equipment Co)

130–150 ton of coal; net wt of 35 cars, 60 ton; both made by Car Dumper and Equipment Co. Hollinger Mining Co uses 3 types of car: (*a*) 3-ton solid-body, dumped by rotary air-operated tipples of 2 kinds, one dumping 4 cars at once, the other, single cars, self-feeding and operated by an air-lift which pushes a train through; (*b*) 3-ton rectangular side-dump cars, operated by air jack (Fig 17*b*); (*c*) 26-cu ft V-type, rocker bottom side dump cars. Track is 18-in gage, with 15 ft min curve, and 36-in gage with 30-ft minimum curve; 35-lb rails on main haulage line and 20-lb in side headings (A. G. Irving, 1938).

Mechanical mucking and loading, which have become important in recent years, is a subject related to underground transport on the one hand and to methods of mining on the other. For details, see Sec 10, 27.

10. HAND TRAMMING (30–34)

Strength of trammer. A man pushing a car can readily exert about 20 lb aver horiz push; with frequent intervals of rest, about 50 lb; when starting, or on short spurts, over 150 lb. His useful output will depend on weight and capacity of car, which in turn are limited by character of car bearings, track, and gradients, to such amounts that the total resistances will not seriously exceed the above figures. Tramming duty with 18-cu ft cars, on 18-in gage aver mine track, varies from 0.8 to 1.4 min per ton per 100 ft; or approx one useful ton-mile per hr, minus loading and dumping time. The duty varies directly as the unit load and length of tram, and inversely as the time per cycle (Art 1). Assume a 900-lb car with plain bearings, capacity 1 800 lb, having 1.5% loaded and 2% empty tractive resistance, starting factor 3, grade in favor of load 0.625%; then the starting resistance will be 104 lb, and running resistance 23.6 lb for the loaded car, as against 48 lb and 23.6 lb respectively returning empty. When traveling at 2.25 miles per hr, the output per trammer using this car is at the rate of 8.1 useful ton-miles per 8 hr. Using a dustproof, roller-bearing car on straight, clean, perfect track with 0.3125% grade, the tractive resistance should be about 0.75% loaded and 1% empty. Hence a gross wt of 5 394 lb, or 3 600 lb of mineral, would be handled with the same exertion, and the tramming output would be at rate of 16.3 useful ton-miles per 8 hr. Such figures are practicable with perfect equipment. Certain southwestern copper mines have installed 30-cu ft cars for partial hand tramming.

Loading and dumping costs are frequently included in tramming charges, but, to compare transport methods, they should be kept separate. For loading from chutes and delivering to a shaft station, under best conditions, the aver delays at terminals through the shift will be not less than 4 min per round trip. On this basis with an 1 800-lb load 1 man can tram 32 cars 1 000 ft, or 90 cars 100 ft in 7.5 hr actual work, and his output will be 5.5 and 1.7 useful ton-miles respectively. With chutes stopped by bridging or jammed gates, or cars blocked by spill, derailment, ore shortage, or repair work, the output may be reduced to the vanishing point. Loading by shoveling. When loading intermittently, good shovelers working under contract will handle up to 4 tons per hr from steel plates into low, open-end cars, or 2 tons from a rough floor into buckets or revolving dump cars. Aver performance when tramming 200 to 1 000 ft is from 10 to 20 tons per shift. Aver daily duty of contract shovelers in the Missouri lead districts is (H. A. Guess) 18 tons, while Higgins estimates 22 tons. Mucking costs for all kinds of work usually run much higher on day's pay basis, or with irregular supply of ore or cars. On basis of loading at rate of 3 tons per hr, the duty of a man with the 1 800-lb car load would be: loading and tramming 19 cars 100 ft = 0.32 ore-ton-miles, or 14 cars 1 000 ft = 2.39 ore-ton-miles per shift. If trammers or shovelers have to help miners place timbers, or lay track or shoveling plates, their tramming output will be proportionately reduced.

Examples. In Michigan copper mines tramming is usually done on the task or minimum-wage and bonus systems, and includes loading by shoveling and handling lumps from floor or footwall into large, low, open-end cars, and tramming by 2 men to shaft station. According to J. MacNaughton (1913), the distance trammed at 11 properties varied from 171 to 900 ft, averaging 609 ft. Output per man-shift was 12.12 to 19.48 tons, averaging 14.76, and the ore-ton-miles per man-shift, including loading, was 0.47 to 2.38, or 1.676 aver. In loading from chutes into the cars shown in Fig 4 (Art 3), the duty of 2 men tramming 600 ft is 6 to 9 ore-ton-miles; when shovel-loading in drifts, 10 cars or 3 ton-miles. The standard in many Butte mines is 15 cars per shift to be shovel-loaded and trammed not over 100 ft in drifting work, and approx 50 cars when loading from chutes. Cars aver 1 600 to 1 700 lb rock, or 1 700 to 2 000 lb ore. At the Ray Consol mine, Ariz, on tramming drifts, the aver duty for a distance of 25 to 30 ft is 75 to 100 1-ton cars per man-shift, with bonus of 3 to 4¢ per car over 50 cars. On a motor level in same mine, a gang of men loaded from chutes 150 tons per man into 5-ton cars in 8 hr (*Trans* A I M E, Vol 52) In Portland mine, Cripple Creek, Col, tramming 9 425 tons ore and waste from Lee stope 330 to 530 ft to shaft or waste chute cost 15.4¢ per ton, or $1.568 per ton-mile; duty was about 2.2 ton-miles per trammer shift. In the Captain stope, 35 365 tons ore and waste were trammed an aver of 975 ft, at cost of 12.48¢ per ton, or 98¢ per ton-mile, or 3.2 ton-miles per shift. UTAH COPPER (1915, Carnahan). In loading 1-ton cars from chutes and tramming 90 ft aver to a raise, 2 men handled 65 ton per shift.

11. ANIMAL HAULAGE (35 to 38)

Duty. Mules and horses at underground work travel 3 to 15 miles per shift. With enough cars, and grades not over 2% against the empties, they often average 7 to 12 miles on main haulage lines, and usually below 9 miles on gathering work. Many records show duties from 50 to 100 gross ton-miles (total loaded and empty haul) per animal, or 25 to 66 mineral-ton-miles per shift. To justify animal haulage as against tramming, a minimum of about 15 mineral-ton-miles should be done on a given level or entry per shift, unless there are adverse grades. The economy of animal haulage increases with tonnage. Using tandem or spike teams, and longer trains, increases effic of both animals and drivers, though more cars and longer sidings are required. For duties below 200-mineral-ton-miles per day on grades less than 1.25%, it has been claimed that no mechanical system can compete in economy with animal haulage using a string team of four. The exact dividing line depends upon local conditions, and costs of labor, power, and feed.

Cost of animals. Good mules cost $150–$300 (pre-war), depending on wt, age, and general condition. Their underground working life in the U S is 3–7 yr.

Horses and ponies used in English collieries average 7 to 10 yr. It is false economy to keep an animal in the mine after it has begun to deteriorate. It should still be worth $40 to $75 for surface use. An annual deprec of 20% of first cost should prove conservative.

Cost of feed per day for mules varies from 18¢ in farming regions to 50¢ in cities, and correspondingly more in isolated mining districts. Shoeing and medicine average $1 to $2 per month, interest and deprec on mule and harness $35 to $80 per year; hence, when stable attendance and full time maintenance are charged against working time, mule service per working days costs 60¢ to $1.25, exclusive of driver and stable rental, when working 6 days per week; except for reduced use of feed when idle, the cost will be proportionately higher when time is lost by illness or shut-down.

Feeding (35–38). Horses will dangerously overfeed if permitted, especially when idle. Feed them no more than they will finish at a meal, as damp grain left in feed boxes ferments, causing illness. For same reason, and because of fire hazard, not more than 3-days' feed supply should be taken underground at one time. Allowance of hay for work horses should generally be not over 1 to 1.5 lb per 100 lb live wt. Horses of 1 200–1 300 lb, have worked hard for 8 months on 8 lb hay per head per day, plus sufficient allowance of grain (Morrison).

Ration should vary with the condition, weight, and work of the animal. Table 8 gives the ratio of protein to other food fuels for the important U S feed stuffs. Table 9 gives quantities of the various digestibles required, per 100 lb live wt of animal when idle, and at different kinds of work. With these tables and local prices of feed, the most economic balanced ration can be calculated, just as metallurgical furnace charges are determined. To provide the proper bulk, about 10 to 18 lb of the daily feed should be concentrates, the remainder roughage, the proportion and quantity of roughage decreasing and of concentrates increasing with the severity of work. Most of the roughage should be fed at night, and $^1/_2$ to $^2/_3$ of the concentrates in the morning. The mineral requirements take care of themselves for animals not in foal, except that about 0.25 lb salt should be supplied weekly. On Saturday nights, or when the animal is to be laid off, replace grain by bran and roughage. Regularity in DRINKING is more important than the time. A thirsty animal will not feed well, and it is better to allow it to drink moderately before feeding and again after.

Care (36). Most animals will respond to good treatment, and will make the best average if not over-pushed. A " bad " mule is often made so by abuse.

Some animals are not intelligent or quick-footed enough, or are too nervous or high-strung for mine work, and purchases should be made with a trial option clause. Stable boss, not the drivers, should do the feeding; he should inspect animals coming off shift, report cases of abuse, and see that harness fits well and is kept clean. Especial care should be taken of the feet, and cuts and sores should be given antiseptic dressing (21). Underground stables are always drafty, and sweaty animals should be blanketed until dry. For bedding, 100 lb straw or 350 lb sawdust per month per animal are reasonable allowances.

Underground stables (36) must be well ventilated; a separate split with direct return to the upcast is required by law in most coal mining states. Stalls should be dry, not less than 5 by 10 ft, with not more than 2 in grade to the rear for drainage, and little or no cross grade. There should be a passageway both behind and in front of stalls for handling supplies and refuse, and a raised platform for feed storage. Roof over stalls and feed storage should be watertight. There should be a pressure water supply; tracks should be flush with floor, and partitions raised above it, so that the whole floor may be hosed out.

Table 8. Average Digestible Nutrients in 100 Lb of Typical Feeding Stuffs *

Feeding stuff	Total dry matter, lb	Digestible crude protein, lb	Total digestible nutrients, lb	Nutritive ratio, 1 : —	Wt per bushel, lb
Concentrates

* Abridged from Henry and Morrison, "Feeds and Feeding," 1919.

Table 9. Modified Wolff-Lehmann Standards for Work Horses or Mules

(Henry and Morrison)

	Daily per 100 lb live weight			Nutritive ratio
	Dry matter, lb	Digestible crude protein, lb	Total digestible nutrients, lb	
Idle	13-18	0.8-1.0	7.0- 9.0	1 : 8.0 to 1 : 9.0
Light work	15-22	1.1-1.4	10.0-13.1	1 : 8.0 to 1 : 8.5
Medium work	16-24	1.4-1.7	12.8-15.6	1 : 7.8 to 1 : 8.3
Heavy work	18-26	2.0-2.2	15.9-19.5	1 : 7.0 to 1 : 8.0

Horses vs mules. Mules average smaller, require less headroom, endure heat and neglect better, and are less liable to foot lameness than horses. They will eat roughages which horses refuse, but are less apt to overeat, and hence less subject to colic or founder. Horses are heavier, better built draft animals than mules, average more reliable, haul larger loads, and require little or no more feed per 100 lb live wt than mules on similar work. They are more spirited than mules, and a nervous horse is apt to rear and injure his head against roof. Mules are more generally used underground than horses, but, where haulage ways are large enough and the duty sufficient for heavy horses, the advantages of mules are debatable, and where there is headroom many coal operators now use large horses in preference to mules.

Examples. According to the Illinois State Co-operative Reports for 1914, 1 100-lb mules costing $175 to $275, used for gathering colliery cars for locomotive haulage, are worked at high speed, and the underground working life has been reduced to 3 years, the mules then selling at about $40. Cost of feed, shoeing and harness repair is 75¢ to $1 per day. In the best managed mines, cost of feeding mules with corn @ 60¢ per 100 lb and hay @ $15 per ton averages $10 per month, some exceeding $14 per month. At one mine, 1 300-lb mules haul 75 loaded trips 700 ft on 2% grade in favor of the load. Each trip consists of 4 1 000-lb cars, with 3 500 lb coal each, or 18 000 lb gross. Gross daily ton-mileage per mule is 54.67, or 34.80 coal-ton-miles, equivalent to about 10¢ per coal-ton-mile. At another mine, 1 mule on gathering work on 0.5% favorable grades, hauls a trip of 3 cars 1 000 ft, with a duty of 24.43 coal-ton-miles, total cost being 17.6¢ per coal-ton-mile. At another mine, with 2% favorable grade, a 3-mule spike-team handles a trip of 17 1 800-lb cars, each holding 2 100 lb coal, or 22 100 lb gross per mule, corresponding to a tractive effort on the return trip of at least 300 lb per mule.

In Alabama-Tennessee mines, aver for 500 mules in 6 mines: feed and care, 34.9¢ per mule; int on cost, 3.3¢; deprec, 7.0¢; total, 45.2¢ per day; working 276 days = 59.8¢ per working day

Shoeing and harness 3 to 6¢ (aver 4.3¢) and drivers $1.762 per working day. Aver duty 3.9 to 33.2 net ton-miles per mule, as follows:

Haul, mile	Ton-miles per mule		Cost per net ton-mile, cents	Conditions
	Gross	Net		
0.32	12.4	6.9	35.7	Unfavorable
0.37	24.8	13.8	17.9	Aver
0.78	41.8	23.0	10.7	Best
0.64	35.5	21.4	11.5	Aver

In a Somerset Co, Pa, colliery, following haulage costs were reported: feed, harness, and shoeing for 10 mules, $6 per day; deprec, 20% per annum, 24 days per month, on $200, $1.38; 8 drivers at $2.25, $18; int on investment at 6%, $0.41; total, $25.79. The haul was 2 640 ft down a max grade of 2.5% and against empties 5%; aver duty, 400 tons per working day or 12.9¢ per coal-ton-mile. Total daily cost per mule on gathering work, $3.17 to $3.28, or 2.2 to 2.6¢ per ton.

In West Va, for 211 000 ton handled in 1 year, on 0.75 to 2% grades, aver haul 1 300 ft, aver travel 6 miles per day: drivers, $8 169; keep of 16 mules, $2 302; deprec, $392.50; killed, $400; int 6% on $3 020 value of 16 mules, $181.20; aver cost per ton, 5.496¢, or 22.324¢ per coal-ton-mile.

At Butte, Mont (1922), a good mine horse costs $100–$150, harness $35, collar $8, and should be shod monthly if worked daily. Cost per day: shoeing at $3 per month, 10¢; stable boss for 12 horses, 50¢; feed, 50¢; total, $1.10 per horse.

Feeding mules at metal mines (35, 38): aver for 14 mules, pulling 2 16-cu ft cars, 11 mile per shift; aver tram, 1 000 ft. Per mule per mo: hay, 440 lb; oats, 5 bu; corn, 2 bu. Aver for 22 mules, aver tram, 1 450 ft, with grades and curves, 645 lb hay, 9.1 bu oats, 3 bu corn per mule per mo.

At an Idaho silver-lead mine, mule haulage with 1 800-lb cars; 2 500 lb ore, grade 5 in per 100 ft in favor of load, and aver distance 1 400 ft, cost 16.5¢ per ton for labor, and 1¢ for supplies, feed and harness, or 66¢ per ore-ton-mile, exclusive of int and deprec.

12. LOCOMOTIVE HAULAGE (39–49)

Motive power. Steam and internal-combustion locomotives are independent; compressed air and storage-battery types require intermittent, and trolley, constant connection to outside sources of power. For special service, trolley and storage-battery, or adhesion and rack-rail drives, are combined in a single locomotive. **Conditions.** Locomotive haulage is justified at mines with easy track grades and large output. Compared with hand tramming or animal haulage, the high speed, large tonnage per trip and few men required, may balance the larger interest and deprec charge on installation. Compared with rope haulage, especially if there are branches or many curves, it is more flexible, and easier to extend and maintain. It requires less headroom, but heavier rails and easier curves (Art 6), than animal haulage and can not compete with it in thick seams on daily output of less than about 175 net ton-miles on grades below 1.25%, or with rope haulage on grades averaging over 4% against or 5% in favor of loads. Short grades, that can be taken by momentum, may be 1 to 3% steeper. Geared locomotives can work up to 12% grades in gathering cars.

Hauling capacity of a locomotive is determined by its draw-bar pull, speed, and the resistance per ton of loaded cars. If it has enough power to make its driving wheels slip, its max drawbar pull is limited by the adhesion of driving wheels to the rails. **Coeff of adhesion** is the tractive force required to slip drivers ÷ wt on drivers. Table 10 gives approx values for mine locomotives. Makers' tables are usually based on 20 and 25% adhesion, and 20 to 40 lb per ton resistance for train on the level.

Table 10. Approx Coeff of Adhesion (Baldwin Locomotive Works, 43)

Condition of rails	Chilled C-I wheels		Steel-tired wheels	
	Without sand	With sand	Without sand	With sand
Covered with dry snow	0.10	0.15	0.10	0.15
Covered with sleet	0.15	0.20	0.15	0.20
Greasy, moist	0.15	0.25	0.15	0.25
Outdoor, moist	0.18	0.22	0.18	0.22
Thoroughly wet, clean	0.20	0.25	0.25	0.31
Clean, dry	0.20	0.25 to 0.30	0.25	0.31 to 0.37
Best condition, max values	.....	0.38 to 0.42	.....	0.47 to 0.52

General formulas applicable to all types of adhesion locomotives: Let A = coeff of adhesion; C = force required to move complete train, including locomotive, lb; D = drawbar pull, lb; E = fric resistance of locomotive, lb; F = fric resistance of train, lb per ton; G = grade resistance, lb per ton; H = dynamometer or drawbar hp of locomotive; L = wt of locomotive on drivers, tons; S = speed, miles per hr; T = gross wt of train, tons. Then:

$D = T\,(F \pm G)$ .... (1) $C = D + E \pm (L \times G)$ .... (3)

$L = D \div (2\,000\,A - G)$ ...... (2) $H = D \times S \div 375$ .... (4)

Total dynamometer hp-hr for M miles, @ aver drawbar pull D, $= DM \div 375$ (5)

From (1) and (2), $T = L\,(2\,000\,A - G) \div (F + G)$ .... (6)

Effect of grade on locomotive capacity. Assuming a max tractive effort on the level of 25% of wt on drivers in Eq (6), then locomotives can move per ton wt on drivers the gross train tons given in Table 11. Multiply these weights by tonnage on drivers for the locomotive under consideration, and for satisfactory running deduct approx 25% from the total to allow for acceleration and contingencies. For greatest effic in power haulage, the grade should be that of equal traction (4, 5) (Art 8). The rapid loss in effic with increasing grades makes the economic grade limit for locomotives usually below 3%. There is also liability of runaway accidents on steeper grades.

Table 11. Tons Hauled per Ton on Drivers, Besides Wt of Locomotive, when Drawbar Pull on Level = 25% of Wt on Drivers

Resistance of trip, lb per ton	10	15	20	25	30	40	Factor for $D = 0.2\,L$
On level track	50.0	33.0	25.0	20.0	16.6	12.5	0.80
Up 0.5% grade	24.5	19.6	16.3	14.0	12.2	9.8	0.79
" 1% "	16.0	13.7	12.0	10.7	9.6	8.0	0.79
" 2% "	9.2	8.4	7.6	7.1	6.6	5.7	0.78
" 3% "	6.3	5.9	5.5	5.2	4.9	4.4	0.77
" 4% "	4.6	4.4	4.2	4.0	3.8	3.5	0.76
" 5% "	3.6	3.4	3.3	3.2	3.1	2.8	0.75
" 6% "	2.9	2.8	2.7	2.6	2.5	2.3	0.74

Rack-rail locomotives have much better effic on grades than others, because the draw-bar pull with ordinary drivers can not exceed the adhesion, and while the power output of a locomotive, $D \times S$, is not constant for varying speeds, the rack-rail type, being geared to the track, can, by decreasing S, increase D above the adhesion limit, or for a given value of D can decrease locomotive wt below the adhesion requirement. Rack rail is advantageous on long moderate grades, or in rolling seams; it is the only practical type on grades over about 6%, and can be safely but not economically used up to 15 or 16%. These locomotives are little used. Rope haulage is their alternative.

13. STEAM LOCOMOTIVES (43)

Steam locomotives are usually impossible underground because of their exhaust gases and vapor, but may be used in adit mines having large entries and abundant ventilation. Oil burners are preferred to coal burners, because of better control of combustion. Theoretical MAX TRACTIVE FORCE of a steam locomotive is $C = (d^2 \times l \times p \times B) \div W \ldots (7)$; where, d = diam cyls, in; l = stroke, in; B = boiler press, lb; W = diam driving wheels, in; p = 0.85 for simple, 0.6 for cross-compound, or 1.2 for Mallet compound engines, d being for high-press cyls. Substitute for C its value from Eq (3) in Eq (7), Art 12, to determine sizes of cyls and drivers. MACHINE FRICTION E = loss between cyls and draw-bar; it increases with the ihp, but its ratio decreases with increasing load. Tests on a consolidation locomotive show E = 10% of ihp with heavy load and 22% with light (*Bull* 82, Ill Exp Sta).

Fuel and steam consumption of simple R R locomotives aver approx 4.5 to 8 lb coal, or 2 to 5 lb fuel oil and 27 to 32 lb water per hp-hr. Superheaters save approx 5 or 6% for every 110° superheat. Compounding saves 10 to 20% over simple engine, if in good condition, but advantage may be more than balanced by poor repair. The overall consumption of locomotives, including stops and roundhouse delays, is approx 50 to 100% more than above figures.

Examples. State Coal Reports of Pa (1912) showed 45 steam locomotives underground in anthracite and 5 in bituminous mines. Many were oil burning and some were being converted from coal to oil.

On Mesabi iron range, 25 6-wheel switch locomotives, with 62 tons on drivers, were used in stripping ore. Following are aver results for 3 yr: round trip, 4.5 miles; grade against loads, 2.25%; trains, 4 16-cu yd 49 000-lb cars = 90 tons material per trip; 18 trips per double shift handled 12 563 gross or 3 645 net ton-miles. Daily cost of operation per engine: coal, 6 tons; water, 48 tons; oil, 5.32 pints; grease, 4 oz; waste, 1 lb; wages (engineer, fireman, and brakeman), $9.95 per shift; locomotive maintenance, $50 to $70 per month, and $900 per year for tires, boiler, machinery, and painting.

14. GASOLENE LOCOMOTIVES

Gasolene locomotives have the flexibility of steam locomotives in radius of travel, and for mining work are geared for speeds of 3 to 12 miles per hr. They have no open fire, consume no fuel when idle, and are less dangerous than steam engines in gaseous mines. The exhaust gases and cost of gasolene are the limiting factors in competing with other types. The max volume of CO produced when feeding gasolene to the explodible limit is 5.75% of the piston displacement, and, under the worst conditions of carburation, 13.5% of the exhaust gases are CO as against 4 to 6% normally. CO should be diluted by 2 000 volumes air for continued breathing and should never exceed 0.01%. Hood therefore concludes that gasolene locomotives require from 7 840 cu ft of air per min for 4-cyl, 5 by 5-in motors, to 35 140 cu ft per min for 6-cyl, 8 by 7-in motors, to maintain the 0.01% dilution. Stopping in dead air, or traveling with the air current or behind a motor, may be dangerous. The exhaust should be washed and cooled by passing through a spray deodorizer before discharging, which does not, however, eliminate any of the CO. Size of motor should be limited by the available air current. Precautions should be taken against leakage at the carburetor and when charging tanks.

Rating of the Assoc Licensed Automobile Manfrs for gasolene motors is: brake hp $= d^2n \div 2.5$, where d = diam cyl, in; n = number of cyls, with piston speed assumed at 1 000 ft per min. This formula is conservative for automobile motors, but the simple carburetor unfortunately used in many mine locomotives makes them less efficient than good automobile motors. The uncertainty of the products of combustion of lower distillates or fuel oils prohibits their use for underground locomotives. Makers claim fuel consumption to be 0.1 gal gasolene per hp-hr. Hood's tests (Bureau of Mines, *Bull* 74) show 0.73 to 1.2 lb gasolene per brake hp-hr for full load and full speed, 1.2 to 2.2 at half load and half speed, and 3.5 to over 6.0 lb at one-eighth load and half speed.

Table 12. Gasolene Locomotives *

Wt, ton	Cylinders	Draw-bar pull, lb	Wheels, in		Speed, miles per hr	Overall dimen, in			Price, factory
			Diam	Base		Length	Width	Height

* Baldwin, Milwaukee, Vulcan and Whitcomb, 4-cyl, 4-cycle engines.

Examples. Righter Coal & Coke Co, Lost Creek, W Va. 6-ton Vulcan locomotive; 25-lb rails; undulating grades of 1 to 2.5%; sharp curves; trains, 12 cars, each 0.5 ton empty, 3 tons loaded; haul, 1 800 ft one way; output, 23 trains = 687 tons per 9-hr day. Operating cost: 1 motorman, $2.50; coupler, $2.00; 10 gal gasolene, $1.60; oil, $0.30; total, $6.40 per day = 0.93¢ per ton or 2.72¢ per coal-ton mile, to which add repairs, deprec, and int.

Herbert mine, Pa (*Coal Age*, Vol 8, p 415). 5-ton Milwaukee locomotive, 44-in gage; 400 cars, wt 2 000 lb, coal 4 000 lb; daily output = 2 × car capacity. Operating cost per motor per day: 2 men, $5.35; 11 gal gasolene, $1.32; oil and waste, $0.11; total, $6.78 for 500 tons coal hauled 2 700 to 3 000 ft, showing saving of $8.64 per day over horse haulage.

Shinnston, W Va. 6-ton Whitcomb locomotives; 25-lb rails; 36-in gage; 20 trips of 17 cars each, gross 52.6 tons; haul 3 100 ft. Cost per month of 10-hr days: gasolene, 629 gal; oil and waste, $10.99. Aver cost per ton for year 1914: labor, 1.44¢; gasolene, 0.66¢; oil, 0.08¢; repairs, 0.40¢; total, 2.58¢ per ton = 4.92¢ per coal-ton-mile.

Shade Coal Co, Pa. 7-ton, 4 4-in cyls, 4-cycle Milwaukee locomotive, 36-in gage; 30-lb rails; haul, 3 400 ft one way; max grade, 6% in favor of loads, 5% against empties, aver 2% and 2.2% respectively; daily output, 375 tons. Cost: motorman and trip tender @ $2.75, $5.50; 16 gal gasolene @ 15.5¢, $2.48; oil, grease, and waste, $0.41; repairs @ $35.81 per month, $1.50; int and deprec @ 16% per annum, $1.94; total cost per day, $11.83; cost per ton, 3.15¢, or per ton-mile, 3.79¢. Under similar conditions, but hauling only 145 tons per day, so that equipment was idle about 40% of total working time, cost was 11.73¢ per ton-mile.

Eagle Mining Co, Canton, Ill. 5-ton Milwaukee locomotive, 36-in gage, hauls 20 to 22 cars; loaded wt, 3 500 lb each; train is split at a 3% grade against loads near shaft; duty, 500 tons per

8-hr day; round trip, 6 000 ft or 284 coal-ton-miles. Operating cost, including runner, trip rider, gasolene, oil, and grease = $7.25 per day = 2.6¢ per ton-mile.

Shiloh, Ill. 6-ton Whitcomb locomotives; 42-in gage; 20-lb rails; 0.5% grade in favor of load. Duty per motor per 8-hr day, 36 trips of 16 cars = 42.4 tons gross, 8 tons empty, haul, 2 436 ft. Cost per motor per mo of 110 working hr: gasolene, 194 gal, $25.05; oil, waste, and repairs, $11.46; 2 men, $85.52; total, $122.03 = 1.5¢ per coal-ton mile (approx).

Cleveland Co, Wis, zinc mine. 4-ton Whitcomb locomotive; tonnage (1913), 123 150; total distance traveled, 6 970 miles; cost, labor, supplies, and maintenance, 2.0¢ per ton.

Trojan Co, S D. 7-ton Milwaukee locomotive; 18-in gage, wet track; 4% grade in favor of loads; bad curves limiting return to 8-car trips. Cost for 25 days: engineer, $106.50; gasolene, 382 gal; engine oil, 16 gal; lubricating oil, 10 gal; total, $76.97. Total miles, 612; ton-miles, 3 516; cost per ton-mile, 2.2¢ not including int or repairs.

Huerfano Co, Colo. 6-ton locomotive; 15-car trips, of 41.25 tons gross; 3 000-ft haul; max grade, 5.5%, using engine plane to pull locomotive and train. Cost, 4.94¢ per coal-ton-mile.

Joplin, Mo. 6-ton gasolene loco was most popular for long hauls. Cost, 4 mo, 1917, for 1 750 ft, 7¢ per ton; against mule haulage, 700 ft, 4.58¢.

Ill coal mines, 1921, used 18 gasolene locos on main haulage.

15. COMPRESSED-AIR LOCOMOTIVES (44, 45)

Characteristics. They carry their own power supply, are flexible in operation within the radius of travel from charging stations for which they are designed, require no fire, do not spark nor emit noxious exhaust, but aid ventilation, and are the safest type for gaseous, dry timbered, or poorly ventilated workings, inflammable buildings, or magazines. (For data on air pressure, tank capacity, reheating air, tractive force, storage, pipe lines, charging stations, see Sec 15 and Bib (45).

Operating requirements: (*a*) a multi-stage compressor to furnish air at the aver rate of consumption and at approx 200 lb greater press than the locomotive requires; (*b*) stationary storage tanks, or a transmission line large enough to act as storage, near charging station; (*c*) one or more charging stations so located that the locomotive can always return to a station before its charge is exhausted; (*d*) a locomotive heavy and powerful enough to exert the max required drawbar pull and with sufficient tank capacity and press to make a round trip at full load to the point most distant from the station. Because of the high press, the ordinary mine compressor can not be used, except that it would be economic for the multi-stage compressor to takes its supply from a cool receiver at the mine press, rather than from the atmos.

Required wt of locomotive is determined as in Art 1, and size of cyl by Eq (7) Art 13, substituting the auxiliary tank press for *B* and 0.95 to 0.98 for *p*, because the air at full stroke does not lose heat by radiation as steam does. REQUIRED TANK CAPACITY of locomotive is determined by the total work done per max load and longest round trip. RADIUS OF TRAVEL can be increased by adding an air-tank tender, together with corresponding increase in vol of stationary storage (45).

Table 13. Compressed-air Haulage Plants

Compressor, 3-stage		Air line		Locomotives			Total cost	Round trip, ft	Train, tons		Cost, ¢ per net	
Cu ft free air per min	Press, lb per sq in	Length, ft	Diam, in	No cyl	Size cyl, in	Wt, tons			gross	net	ton	ton-mile

(*e*) 450	1 000	5 000	4	2	. .	.....	15 800	.. ...	......	......	.....	2.17

* Gross. (*a*) *Mines & Min*, Vol 18, p 538. (*b*) Baldwin Locomotive Wks. (*c*) Peele, Compressed Air Plant. (*d*) Morris, *Trans* A I M E, Vol 30, p 566. (*e*) Two-stage locomotive, operating cost, int and deprec, 2.17¢ per ton-mile, as against 2.56¢ for single-stage, with coal @ $3 per ton (estimates by H. K. Porter Co).

Coal mines of western Pa and West Va were using 150 compressed air locos in 1921 (38). In U S metal mines, the only important compressed air haulage plants now operating are at Homestake mine, S D, and Inspiration mine, Ariz (42).

16. STORAGE-BATTERY LOCOMOTIVES (39, 41, 46, 48, 49)
(See also Sec 16)

Characteristics. They are flexible prime movers, cheaper to install than trolley or air locomotives, simple to operate and safer than any type except compressed air. Suitable for short hauls in temporary workings, as in gathering, or for infrequent long hauls where trolley lines are not warranted or low-roofed wet workings make them dangerous. Grades must be easy; max speed per hr, 5 miles. They require 1 man on gathering work, while cable-reel locomotives (Art 17) need 2. Wt of locomotive is greater than $D + A$ (Art 12), because of the necessary battery wt; hence it has lower useful load capacity on grades than other types, and is limited to low speed by battery output rate.

Battery capacity depends on: (*a*) max rate of current discharge required; (*b*) the kw-hr required to operate on 1 charge. For details, see Sec 16. Storage-battery locomotives usually develop 4 hp max per ton of wt, and 3.5 mile per hr at rated drawbar pull; as against 10 hp per ton and 6 mile per hr for trolley type. With recent improvements in batteries, they are being more widely adopted, replacing the trolley system in heavy ground, where maintenance of track-bonds and trolley wire and its dangers are excessive.

Examples. In Copper Queen tests (*Trans* A I M E, Vol 48, p 295) a storage-battery locomotive required 1.6 kw-hr at power station per useful ton-mile, or 1.28 at locomotive, as against 1.1 and 0.875 for trolley locomotive. Big five tunnel, Col, two 17-hp, 4-ton locomotives and tenders; full-load speed, 4.5 miles per hr; train, 20 to 30 cars, each 2.5 tons gross; 20 and 12-lb rails; grade, 0.25%. Storage battery was used underground and trolley on surface. Operating costs for 6 months: labor, $1 098; material, $113; repairs, $33; power at 1.2 to 5.5¢ per kw-hr, $306; total, $1 551; duty, 18 914 ton-miles, at 6.5 to 12.2¢; aver, 8.2¢ per ton-mile. Sterling Coal Co, O. 11 2.5-ton storage-battery locomotives are used for gathering cars from 12 to 15 rooms, each handling 96 cars per 8 hr. 4 trolley locomotives are detailed to serve 11 entries, requiring 19 men. 11 reel locomotives (Sec 16) could do the work, saving 4 locomotives (approx cost $7 200) but requiring 22 men to operate. Grant mine, Ind. A 5-ton locomotive, with 63 Edison cells, averages 75 volts @ 60 amp normal discharge; train of 16 cars of 1 600 lb each, carrying 3 600 lb coal, used 90 amp on level, 160 up 1% grade and 220 on curve up 1.5%. Some Cœur-d'Alene mines, and others with conditions favorable to trolley haulage, have adopted storage-battery haulage, because of casualties from trolley current. Hecla mine, Idaho. Cars weigh 4 040 lb, 8 wheels, 5.2 ton capac; trains of 8 cars make 7 trips per 8-hr, but can make 10; grade against empties, 0.75% speed 4 mile per hr; loaded trains, 6 mile per hr; using Baldwin-Westinghouse storage-battery locomotive, 7 000-lb chassis, 2 000–3 000 drawbar pull; track, 24-in gage, 35-lb rail. Alaska Gastineau mine (1919). Six-ton storage-battery locomotives haul 8–10 4-ton cars, aver 590 ft. Operating cost per ton-mile: maintenance locomotive, 3.19¢; charging station, 0.22¢; power, 0.89 kw-hr, or 0.132¢; total, 3.54¢. Cripple Creek, Colo. Three-ton storage-battery locomotives have long been used satisfactorily; crew of 2 men haul 125 16-cu ft cars per shift 2 500 ft and dump at shaft pocket for 7–8¢ per car for labor. Eureka Standard, Utah (E. D. Gardner, 1935). Storage-battery locomotive on main haulage levels; aver train, 10–12 cars of 0.9 ton (18 cu ft); dump with turntable; track, 18 in, 12-lb rails, steel ties 4 to 5 ft centers; tramming labor, 17¢ per ton.

17. ELECTRIC TROLLEY LOCOMOTIVES (40–42, 46, 48, 49)
(See also Sec 16)

Characteristics. These are the prevalent type in mines. They are compact, simple to operate, have high effic and usually the lowest power cost of all types. Disadvantages: cost and danger of the trolley circuit; danger from sparking at commutator or trolley wheel; necessity for wired and bonded track.

About 80% of all mining trolleys use 250-volt d c, which is slightly more economic in design of motors and control and less dangerous than same nominal a-c voltage. A few 500-volt circuits are used, and there is at least 1 3-phase 2-wire underground installation in U S. Motors are of approx 10 hp per ton wt of locomotive. Main haulage locomotives weigh 3 to 30 tons. Gathering locomotives are 2 to 8 ton (approx), and can enter rooms 200 to 400 ft off trolley line by using a reel of single or double cable to hook on trolley and track. For rapid work and to prevent overrunning the cable, reel should have a gear to feed out and rewind cable as the locomotive moves. Crab locomotive has a flexible wire rope on a geared drum, and hauls cars from rooms without entering. Combination gathering locomotives have both cable-reel and crab attachments, to serve rooms driven on either dip or rise.

Power plant and transmission requirements for a number of locomotives are found by correction factors similar to those used for compressors, but each case demands special study. Fig 53 gives Oliver Iron Mining Co practice under conditions stated.

Examples. Duty of electric locomotives on main haulage in 18 Illinois coal mines (condensed from State Reps) is given in Table 14. Most cars have wood body, with plain bearings. Differences in length of haul, grades, curves, coal or car supply, and in ratio of empty to loaded car from 20% to 46%, account for varying results. Bunker Hill & Sullivan mine, Idaho. Haulage through Kellogg Mill adit 11 000 ft (1937), of 386 576 ton ore by trolley locomotives; total cost, $40 015, or 10.4¢ per ton, principal items being, trammers $17 343, repairs $7 550, supplies $6 061 (Stanly A. Easton). Zinc mines of Tenn (66). Main haulage at Mascot and Newmarket mines: 4- and 6-ton trolley locomotives, powered by 250-volt dc double unit motors; trolley wire of figure 8 type supported by insulated hangers spaced 10 ft. Track 24-in gage, 40-lb rails, 0.5% grade in favor of load, min radius curve, 50 ft; electric welded track bonds replacing flexible bonds; Mascot box cars are 40-cu ft, of extra heavy steel with railway type journals, 14-in wheels, steel incased oak bumpers, hook couplings with spring cushioned draw-bars. Newmarket cars are 80-cu ft, Granby type. Morenci, Ariz (67). 10-ton cars are hauled on a 20-in track, in 300-ton trains by Jeffrey 12-ton tandem locomotives. Cars are 200 cu ft capac, with 24-in wheels; empty wt, 9 700 lb; M C B journals; rail, 60 lb; 100-ft radius curves; grade, 0.4% with load. Alaska-Juneau. 10-ton cars are assembled in trains of 40 cars and hauled to the mill 2 miles distant by 18-ton articulated trolley locomotives, on 30-in track of 75-lb rails (P. A. Bradley, 1938). Homestake. A new waste haulage system has 30-in track, 50-cu ft Granby cars and 10-ton Goodman trolley locomotive (E. G. Ross, 1938).

Power consumption tests: Oliver Iron Mining Co, for 1 week of 17 8-hr shifts, with 4-ton, 250-volt electric locomotives. Cars, 55 cu ft, gable-bottom, weigh 3 560 lb (Fig 13); aver net wt ore per car, 5 600 lb; prevailing grade, 1% in favor of load; total, 890 trips, 5 544 cars, 15 523 tons of ore; aver haul, 1 488 ft = 4 375 ore-ton-miles = 10 943 gross ton-miles, including locomotive. Total tramming energy, 2 423 kw-hr, aver = 0.554 kw-hr per ore-ton-mile, including empty return haulage. At a southwestern copper mine, the current per useful ton-mile was 0.875 kw-hr at the motor. Copper mine in Ariz. 10-ton trolley locomotives, making 10 trips per 8-hr day, hauled 18 cars, each of 101 cu ft, or gross load of 108 tons (empty, 30.6 tons including motor); aver haul one way, 2 900 ft; power, 3 000 kw-hr per locomotive per month of 240 working hr, at 0.97¢ per kw-hr; total operating cost per motor per month, $212; aver repair cost, $20 per motor per month; aver total operating and repair cost, 4.5¢ per ore-ton-mile, not including trolley line maintenance and repairs. Copper mine in Ariz: 3.5, 6, and 7.5-ton electric locomotives hauled aver distance of 3 000 ft (max, 8 475 ft) at cost, for 67 700 ore-ton-miles, of 13.9¢ per ton of ore, or 21.78¢ per ore-ton-mile, including repairs on locomotive track and ditch. At Bisbee, Ariz (1912), cost for 408 000 useful ton-miles, in cents per ton-mile, was: for maintenance of locomotives, 2.95¢; cars, 1.64¢; track, 5.24¢; trolley, 3.60¢; power, @ 1.1 kw-hr, 1.6¢; total, 20.03¢. Copper mine in Mich. 4-ton locomotives hauled 15.4 tons gross, 2 000 ft one way, 7.8 ton return round trip in about 30 min; 420 working hr per month, 1 040 kw-hr per locomotive, repair costs, aver $6. Iron mine on Gogebic Range; track gage, 24-in; 30-lb rail; 1% grade; 5-ton locomotive; gross trip, 42 tons; empty, 20 tons; aver haul one way, 1 450 ft; 12 trips in 8 hr; monthly cost per locomotive, 200 working hr, 1 854 kw-hr at 1.5¢; oil and waste, $2.25; motorman and trip tender, $122.50; aver repairs (approx) per locomotive, $12.50; per car, $0.91. Aver total cost, 81.8¢ per ore-ton-mile. Mine operating on half time for period reported. Iron mine in Mich. 4 and 6-ton locomotives; track gage, 24-in; 30-lb rail; grade, 1% aver in favor; reverse, 4%. 8 trips of 8 cars, weighing gross 37.3, empty, 11.3 tons; haul, 900 ft one way; 3 750 kw-hr per locomotive per month of 200 hr; operating and repair cost, $124.75 = 14.06¢ per ton-mile. Motor haulage costs in anthracite collieries (Gen Electric Co) are given as follows, deprec @ 5% for 200 working days:

Company	Cost per day		Duty, tons	Cost per ton, ¢
	Operating	Deprec		
Glen Ridge, Scranton, Pa...	$7.96	$1.90	288	2.76
N Y & Scranton (Sturges)..	5.05	1.52	250	2.62
" " (Tunnel)..	4.67	1.75	600	1.07
Hillside, No 2 shaft........	16.47	5.20	989	2.19*
" F C slope...	9.37	2.60	541	2.21*

* Actual operating costs (140 days, approx) were 4.56 and 4.65¢ per ton.

Butte, Mont. About 200 trolley locomotives are in use, 4-ton size being standard. Since about 1920, use of storage-battery locomotives has increased. U S Coal and Coke Co's mine No 6, Pa. Usually, a 13-ton trolley locomotive gathers from mouth of working places and delivers 600–700 ton coal per day; round trip not over 4 mile; 5–7 men and 7–10 mules gather coal hauled by 1 locomotive. Rahn Colliery, Pa. Aver, 6 mo: 2.474 kw-hr per ton are used for transport of coal. United Verde mine, Ariz (1919). Six-ton trolley locomotive, hauling 35-ton trailing load of 20 18-cu ft cars, 18-in gage, a distance of 850 ft to skip pockets, costs 10.79¢ per ton, against hand-tramming 200 ft @ 12.7¢ per ton, and storage-battery locomotive, 9.6¢. Illinois. In 1921, 280 shipping coal mines used 1 424 trolley locomotives on main haulage lines, handling over 71 million ton.

18. ROPE HAULAGE (50–52)

Systems: (*a*) self-acting or gravity plane; (*b*) engine plane; (*c*) tail-rope; (*d*) endless-rope. Of these, (*b*) and (*c*) are commonest, (*d*) being obsolescent. Conditions: large tonnage, and grades which make locomotive haulage inefficient (Art 12, Table 9). Straight haulways and uniform grades are desirable, but not necessary.

Ropes, sheaves, and rollers. Ropes on flat grades, or wherever especially subjected to abrasion, as in dragging on the ground or over track ties, should have 7 or 12-wire strands. The small-gage wires of standard 19-wire hoisting rope wear too fast (Sec 12). A short length of chain at the coupling protects rope from damage by sharp bending, if the cars overrun. Horiz sheaves or vert rollers on curves should be properly alined, and of large diam, to reduce bending stresses; 1 large sheave is better than several small ones. Where rope crosses the rail on curves, guide strips should be provided, to minimise friction (Fig 56, *b*). Track rollers aver 5 in diam by 12 to 18 in long, spaced 15 to 25 ft on straight track; closer on curves. At points of special wear, C-I rollers are used (often made of a pair of car wheels, bolted together with flanges outside).

Self-acting or gravity plane. Descending loaded cars raise the empties. It is often used on the surface, is effective in slopes or long rooms on pitches too flat for mineral to run in chutes by gravity, and in general serves to transfer cars to a lower level, on main haulage lines, or from a blind level to main level.

Angle of flattest self-acting slope. *Sin* α = (total friction F, lb) + (wt of mineral − wt of unbalanced portion of rope R, lb), in which F = [(wt loaded and empty cars + wt rope on both tracks, lb) × $\cos\alpha + f'$ (wt rollers + drums, lb)] × f; where $f' = 0.1$ approx, f = coeff rolling friction = 0.012 to 0.025. Friction is often figured on basis of cars and rope only, in which case f should be larger. This equation shows that profile of plane should be concave, and that heaviest trip, highest ratio of useful load, shortest distance, and lowest coeff of friction, give flattest workable slope. Use of a tail-rope cancels unbalanced R, but increases F. Flat slopes are steepened at top, or " knuckle," so that the grade exceeds angle of inertia (Art 8) for starting trip promptly. Acceleration $a = (T_l - T_e)g \sin \alpha \div T_l + T_e + R =$ approx $(P_d - P_a)\, g \div T_l + T_e + R$, where $a =$ accel, ft per sec per sec; $P_d =$ descending pull, lb $= T_l\,(\sin \alpha - f \cos \alpha)$; $P_a =$ ascending pull, lb $= (T_e + R)\,(\sin \alpha + f \cos \alpha)$; T_l and $T_e =$ wt loaded and empty trips, lb; $\alpha =$ slope angle. If slope changes, take value for α at top for T_l, at bottom for T_e, and aver for R. Length of slope l (ft) required to attain veloc v ft per sec is $l = v^2 \div 2\,a$. Max tension R_s in rope will occur when starting or stopping with a jerk, otherwise $R_s = (T_l + R)\,(\sin \alpha - f \cos \alpha)$. Number of cars per trip to operate a self-acting plane is

$$N = \left[\left(\frac{\sin \alpha}{f} + \cos \alpha\right) R\right] \div \left[\left(\frac{\sin \alpha}{f} - \cos \alpha\right) W_1 - \left(\frac{\sin \alpha}{f} + \cos \alpha\right) W_2\right],$$

where $\alpha =$ slope angle $R =$ wt rope, lb; W_1 and $W_2 =$ wt of 1 loaded and 1 empty car respectively; $f =$ coeff of rolling friction.

Arrangement of tracks (Fig 54, *a* to *i*). It is best to avoid switches on planes by double tracks as in (*b*) and (*c*). In (*d*) a simple automatic switch is used at L, as shown in detail at (*i*); steel-faced timbers pivoted at KK are thrown by the descending car for either track. At (*e*) is shown a track plan for narrow slopes, avoiding switches and saving room below turnout. Fig 54 (*f, g, h*) illustrate a single main track, with inner counter-wt track, the counter wt being heavy enough to haul up the empty car and unbalanced rope. The balance car (*h*) has a bell-crank "growler" or safety pin P, to stop car if rope breaks.

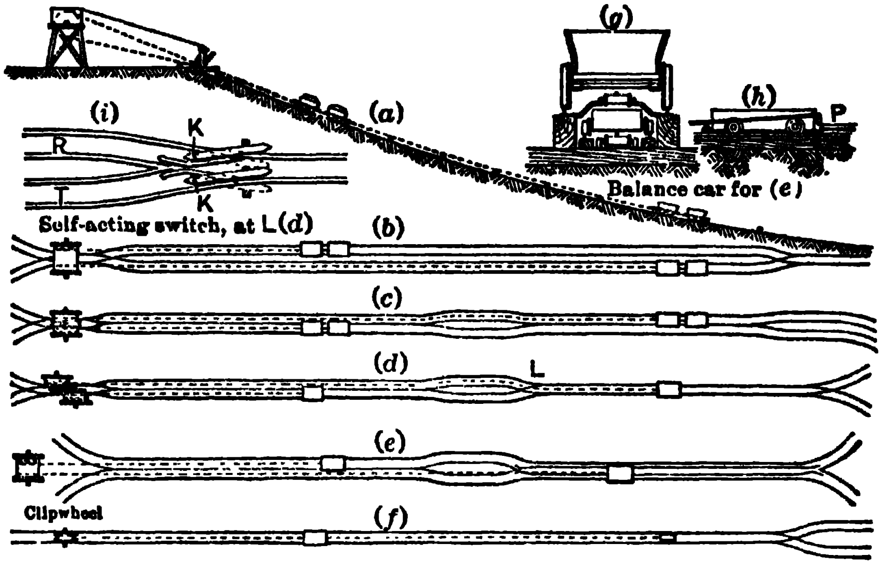

Fig 54. Track System for Self-acting Planes (Hildenbrand, except *e*)

Engine plane. Loads are raised or lowered on a slope by a stationary engine and wire rope, as in an inclined shaft. Simple engine planes require single track, with 1 rope = length of plane, and use power only for raising load. The plane may have curves, and varying grade (if all are against the load), provided minimum grade is greater than the angle of rolling friction; it may serve different levels or entries by switches from main slope, with rollers or sheaves to guide rope around turns (Fig 55). On a straight surface plane, 5 000 ft long, under aver conditions, trains of 25 to 30 loaded cars ran at satisfactory speed on 1.75% grade, while empty cars required 2.25% (22). Small British colliery cars (tubs) require 3.5%. A double engine plane has double track, or 3 rails and turnout; the descending trip assists engine to raise ascending trip, thus eliminating dead load, except rope. With engine at head of plane, the max rope pull at drum is: (*a*) for single track, $D = (T_l + R)\,(\sin \alpha + f \cos \alpha + P)$, where $P =$ coeff of accel $=$ 0.1 to 0.25; (*b*) for double-track plane, $D = (T_l - T_e + R) \sin \alpha + (T_l + T_e + R)\,(f \cos \alpha + P)$. With engine at foot of plane, D is the same as in (*a*), but rope is balanced and engine pull is $D = T_l \sin \alpha + (T_l + 2R)\,(f \cos \alpha + P)$. For signification of factors, see under Gravity Plane, above.

Tail rope, the commonest rope haulage system, is applicable on straight, curved, inclined, level or undulating tracks, to a single main line, or including branches (50, 52). MAIN ROPE hauls loaded trip of 1 to 75 cars, with attached TAIL ROPE, to shaft bottom or surface, and tail rope, passing around a large RETURN SHEAVE, returns empties. The engine should be reversible, with separate drums, clutches and brakes, and may be placed anywhere on the line, or on the surface with ropes run through a shaft, slope, adit, or bore-hole. If main and tail-rope drums and engines are at opposite ends of run, each rope = length of run; or, with a double-drum engine at one end, the tail rope = 2 × length, and both ropes = 3 × length of run. Trips are run 8 to 16 miles per hr. When main rope is hauling a loaded trip, the tail-rope drum clutch is loose, and with light braking the train can be kept in tension, to prevent cars from bumping or over-running on grades. The return run of tail rope, from tail sheave to drum, is carried on small sheaves, 10 to 16-in diam, spaced 25 to 60 ft apart, and attached to roof or timbering. MAX TENSION on haulage rope is: $D = Tl\ (\sin\alpha + f\cos\alpha) + r\ (h + f \times 2\ l) + (T_l + 2\ rl)\ P$, where α = max slope angle; h = total drop of line, ft; l = length of line, ft; r = wt of rope per ft, lb; T_l = wt of loaded trip, lb; P = coeff of accel. Fig 56 (*a*) shows the Sherrard mine tail-rope system; sheaves and rollers for curves in detail (*b*). BRANCH ROADS have separate tail ropes = 2 × length of branch, with tail sheaves at ends, and couplings to connect to trip and to main tail rope (Fig 57).

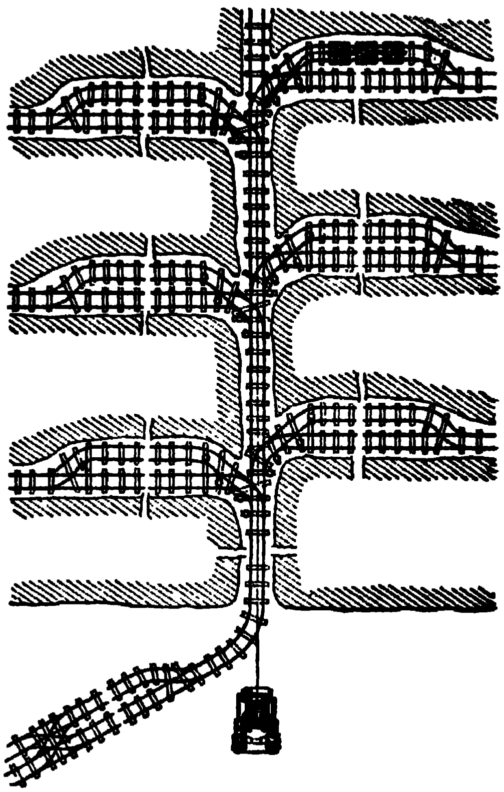

Fig 55. Engine Plane (Leschen)

Endless-rope system. Rope is driven by a grip wheel or pair of multiple-groove sheaves at engine, passes around a return sheave at end of line, and may be over or under the cars. Cars are attached singly, or in short trains, by grips or lashings. On double track, this is done without stopping rope, which is in constant motion. Aver speed, 4–5 miles per hr; max, 10 miles. Length of rope is $^1/_3$ less than for tail rope. Chain, instead of rope, occasionally used for short hauls (catalogs Jeffrey Mfg Co, Robins Conveying Belt Co, and Link Belt Co). This system has almost disappeared in the U S.

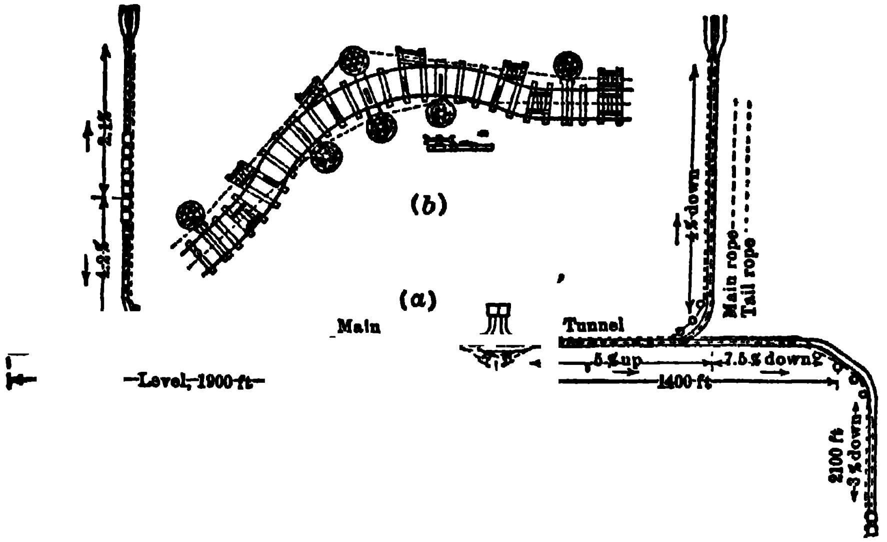

Fig 56. Tail-rope System, Sherrard Mine, Ill (part)

Rope-haulage costs. All types of rope haulage are obsolescent, as indicated by the fact that, in Ill in 1908, 32 mines used rope for main haulage, as against only 1 mine in 1921.

At Sherrard colliery, Ill (Fig 56), when hauling by tail ropes 700–800 ton per day, aver haul 4 000 ft, max 2.25 miles, the cost, including maintenance of track, wear of ropes and sheaves for rope and auxiliary mule haulage, was 14¢ per ton; rope speed, 10–16 mile per hr.

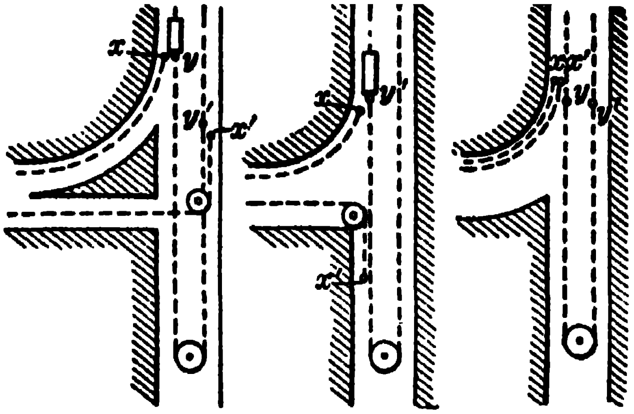

Fig 57. Modes of Attaching Branch Ropes x, x' to Main Rope y, y'

19. MISCELLANEOUS HAULAGE METHODS

Gravity roads must have sufficient grade in favor of loaded cars to keep cars in motion, the empties being returned by hand, animal haulage, or power.

Grade at the top or " knuckle " must be greater than angle of inertia (Art 8), or the car must have a starting push; aver slope must exceed the angle of rolling friction. Grades required vary with quality and condition of rolling stock and track; for safety, unless the slope is short, max grade should be less than the probable minimum angle of sliding friction. In rooms or slopes on flat rising pitch, cars can be delivered to loading point by trammer, animal, or locomotive, and returned to the drift or entry by gravity. On steeper pitches, ropes should be used.

Telphers or **monorails** with buckets are used occasionally where tracks or cars are impracticable. CONVEYER HAULAGE in recent years has developed rapidly, and is suitable for large tonnages. See Sec 27 for details.

Composite methods. It is seldom practicable entirely to eliminate hand tramming underground, but development and exploitation should be planned to minimize use of manual labor. IN METAL MINES, tramming is usually the only possible method of handling ore, waste, and timber in flat-back or slice stopes, sub-levels, and short, temporary workings (Sec 10).

Chutes, raises, and trackage should be so placed that all material will reach its destination with minimum handling between working places and main-haulage system. Thus, at Homestake mine, hand tramming averages about 300 ft for ore and 500 ft for rock from development; at the Copper Queen mine, less than 200 ft; at the Miami, Ray, and other systematic copper developments, 25 to 100 ft for normal stopes; on the Mesabi iron range top-slice mines, 50 ft for regular work and seldom over 150 ft in irregular bodies (see also Sec 10). Modderfontein B Gold mine, Rand (39); hand tramming on stope tracks: aver 200 ft, max 400 ft, by contract to central or branch track; lowered by single rope to level below. Cars, 20 cu ft, with low fixed truck, loose Rowanbotham self-oiling 15-in wheels, 30-in gage, 30-lb rails. Cars per shift vary up to 20 per "boy"; aver, 7.45; contract price for lashing, loading and tramming, 2.5d–3d per 1-ton car in 1915. Horses take cars from the single rope to the main (and tail) rope, by which trains of 60–100 cars are hauled. In COAL MINING, the miners' contract commonly includes tramming between the face and room neck or breast road. Mules or gathering locomotives then haul cars to the nearest make-up siding on the main haulage and return the empties. Crab, storage-battery, or compressed-air locomotive often hauls to the working face; but, where there is headroom for animals, the necessary delays and small tonnages handled in gathering work require careful analysis of cost of gathering and returning cars, to prove whether such extension of locomotive service is profitable. The proper limits for rope haulage systems are more definitely determined by the gradients, tonnage, and layout of workings, than when the more flexible prime movers are used. In undulating coal seams, frequent examples are found of alternating animal and rope haulage, and there are unusual cases where locomotives with their trains are taken up grades by rope haulage.

20. TRAMMING COSTS

(p) figures for 1931 are not Miami's lowest, but are more representative, as they cover the last year of nearly normal production. R. W. Hughes, 1937. (q) *I C* 6601. (r) *I C* 6666. (s) *I C* 6735.

21. HAULAGE ACCIDENTS (72–80; also Sec 23)

Underground haulage accidents in all kinds of mines and underground quarries in 1935 and in 1936 were as follows in accompanying table.

See also Sec 23	Fatalities		Non-fatal injuries	
	1935	1936	1935	1936
Anthracite mines	30	26	1 909	1 914
Bituminous mines	198	202	10 950	12 097
Metal and non-metal mines, except coal	9	13	897	1 445
Underground quarries	......	2	29	35
	237	243	13 785	15 491

Haulage accounted for 20.7% of all fatal and 23.36% of all non-fatal underground accidents in 1935, and 17.12% of fatal and 20.8% of non-fatal accidents in 1936.

To reduce accidents. (*a*) illuminate haulage ways, so that men will not need individual lights on motor tracks; (*b*) have head light on motor and on rear car of train; (*c*) standardize equipment, so that bumpers, couplings, etc, are alike on all cars, with handles so that the hand can not be caught; (*d*) have safe clearance between cars on one or preferably both ribs of entry (a close rib is better than one with unsafe clearance); *Bull* 75, U S Bureau of Mines, recommends refuge bays with 2.5 ft clearance at not less than 300-ft intervals; (*e*) keep track tamped and clean, to prevent derailment; (*f*) timber and supplies, stored alongside, should be at least 2 ft from rail; (*g*) transport long tools and material only on special trucks, not on locomotive or ore cars; (*h*) use block fillers to top of rail-web in flangeways and wedge spaces in frogs and switches; (*i*) use low-voltage trolley current; support wire at short distances, so that sag will not exceed 3 in, and, when less than 8.5 ft above rails, guard with boxing 3 in lower than wire; do not run wire over footway side of track; avoid trolley system for low-roofed, wet workings; (*j*) have gong on all motors, and start locomotive only on signal from trip rider and after giving warning bell, and sound bell before all junctions; (*k*) keep car doors and latches in repair and inspect reclosing; an open side door is especially dangerous; (*l*) keep record of haulage delays, and offer bonus to driver having minimum derailments and locomotive repairs. In mines of large output, where many trains operate on main levels, a dispatching and block-signal system are essential (75, 77–80).

HOISTING PLANT, SHAFT POCKETS AND ORE BINS

1. HOISTING SYSTEMS

Unbalanced hoisting is done in one-compartment shafts, where there is no descending wt of empty car and cage to help lift the ascending cage, car and contents. It is the simplest form of hoist, and is used for prospecting, handling men and supplies, and for mines with small outputs.

Balanced hoisting is done in two-compartment shafts, where the wt of ascending skip, or cage and car, and material is offset by empty skip, or cage and car, descending in the other compartment. It may be used with all shapes of drum or reels, and is the commonest method. With cylindrical drums it is very flexible. For hoisting from one level, 1 or 2 drums are keyed to the shaft. For hoisting from several levels, 2 drums are necessary, one of them clutched and the other keyed or clutched. Advantages: simplicity, low first cost, and adaptability to variation in hoisting conditions. Disadvantage is the large variation in rope load in deep shafts.

Slack-rope hoisting (3), practiced in a few coal mines for self-dumping cages, consists in operating with a certain amount of slack rope, so that one cage strikes bottom and its empty car is uncaged, and a loaded car is caged while the cage in the other compartment is dumping its load, the hoist being at rest only momentarily. The motor must therefore start the loaded cage without the counterbalancing effect of the empty cage and car after landing at the bottom, thus requiring a larger motor and greater power. Its purpose, to increase the tonnage output per unit time, is questionable, since time for retardation is longer. It is not recommended.

Static hoisting moment is the product of load on rope in lb and the drum radius in ft, at the point where the rope leaves the drum. Resultant static moments for balanced hoisting are equal to the difference of the moments for each rope. STATIC MOMENT DIAGRAMS show resultant static hoisting moments for definite positions of cage or skip in a shaft (see Fig 14). Serving to compare hoisting systems from standpoint of balance, they are not always indicative of relative power requirements, because equalization of hoisting load may be obtained by using additional weights in drums and tail-rope, requiring large h p for acceleration. If W = wt of skip or cage and car; w = wt of load; wr = wt of rope; and R = radius of cylindrical drum; then for balanced hoisting with cylindrical drums:

$$\text{Static moment, load at bottom} = (W + w + wr - W)\,R = (w + wr)\,R$$

$$\text{Static moment, load at top} = (W + w - wr - W)\,R = (w - wr)R$$

Tail rope, used with cylindrical drum, gives perfect equalization throughout the hoist. It hangs in a loop in the shaft, its ends being attached to bottoms of cages. The cages can not move independently, as for hoisting from different levels, whence its chief use is in shafts where hoisting is from one level only (2). A large sheave, resting in the bight of the tail rope, and supported in sliding bearings below bottom landing, steadies the rope.

While theoretically good, the tail rope has been rarely used in the U S. There are a few in South Africa (1), but they are not favored, due to difficulties of inspection, cost (due to short life), lashing and vibration, and extra weight and space required for bottom sheaves (Fig 1, 2, 4).

Counterweight hoisting. The skip, or cage and car, in a one-compartment shaft is counterbalanced by a weight sliding in guides at one side of the shaft. Advantages: it eliminates one compartment, increases efficiency, decreases size of engine required, but requires a reversible engine, since power is necessary to lift the counterweight.

Design. As ordinarily designed, the static hoisting moment diagrams for lowering empty and raising loads are the same. Hence, the resultant static moment with load at bottom must equal that with counterweight at bottom. If C equals wt of counterweight and other symbols are as for static moments, then

$$\text{Static-moment, load at bottom} = (W + w + wr)\,R - CR \tag{1}$$

$$\text{Static-moment, counterweight at bottom} = (C + wr)\,R - WR \tag{2}$$

Equating Eq 1 and 2 gives $C = W + \frac{w}{2}$, which means that if the wt of counterweight equals wt of skip (W) plus 1/2 wt of load $\left(\frac{w}{2}\right)$, then the hoisting and lowering diagrams will be equal. Counterweight plus tail rope give perfect equalization of rope load. If the counterweight is equal to $W + \frac{w}{2}$ then the unbalanced load, whether hoisting load or counterweight and, in all positions of hoist, is $\frac{w}{2}$ or one half the weight of the ore. This therefore is an economical hoisting method from the power standpoint and has application for small capacities. Counterweight plus chain hoisting is intended to do away with tail-rope. A chain, attached to the counterweight, piles up on the shaft bottom as counterweight is lowered. It has merit in reducing hoisting power required, but adds to stress in hoisting rope, and is not used at present.

Koepe system of hoisting (Fig 1). In this old European system, which has not been used in America, the drum is replaced by a large, single-groove driving sheave. A single rope passes around 190° to 200° of sheave circumference, with cages attached to the ends.

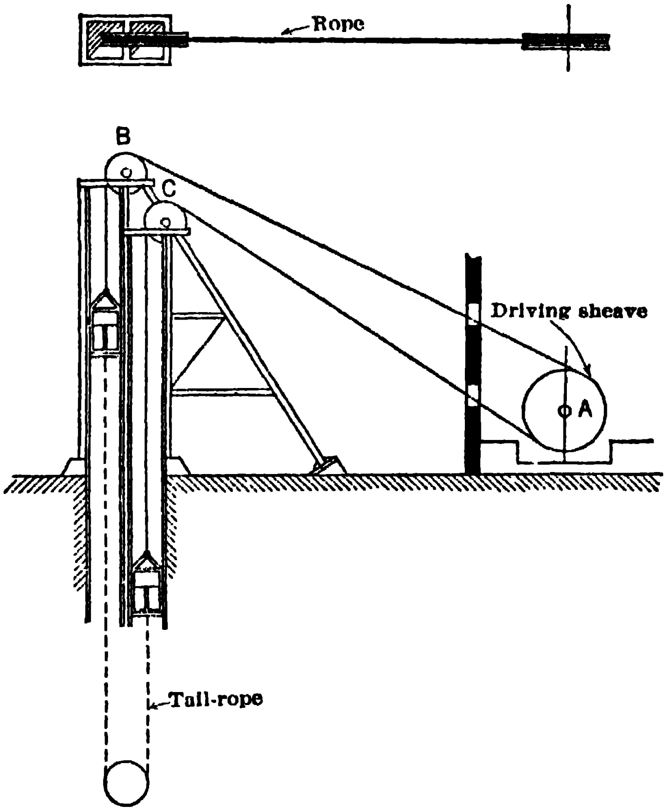

Fig 1. Diagram of Koepe Hoist

The system is suited only to mines of one level, and a tail-rope is essential. Head sheaves are placed tandem, so that both parts of hoisting rope are in same vertical plane. To prevent slippage of rope on driving sheave, the wt on loaded side plus its accelerating force must not exceed wt on empty side minus its accelerating force by more than a certain percentage, depending on arc of contact on driving sheave and coef of friction. Ratio of the greater to the smaller pull must not exceed e^{fa}, in which e is the base of Nap log (2.71828), a the angle of contact on driving sheave, and f the coef of friction (0.18 to 0.25). Advantages: since in the sheave there is less mass to be accelerated and retarded than in a drum, more rapid accel and retardation are possible, smaller foundations and buildings are required, and wear on rope due to bending is minimized. Disadvantages: cages can not move independently; if rope breaks both cages fall, and drag of rope over the head sheaves is likely to prevent operation of safety catches. The system is best suited to electric hoists, which have constant torque (4).

Whiting system (Fig 2), designed to overcome the disadvantages of the Koepe system, has two 3 to 5-grooved driving sheaves, placed tandem and coupled to engine by connecting and parallel rods. The rope has ample frictional grip by passing several times around both sheaves. To adjust or change distance between cages, or let out rope as shaft is deepened, a slow-motion geared fleeting engine is used. Abnormal stresses, due to creep of rope on sheaves and to unequal wear of grooves, are compensated by steel rings in the

grooves of one sheave. The rings slip under unusual stress, but are tight enough to resist the ordinary rope pull. Advantages: tail-rope is unnecessary to prevent slipping; can be used for sinking and for shafts that are periodically deepened.

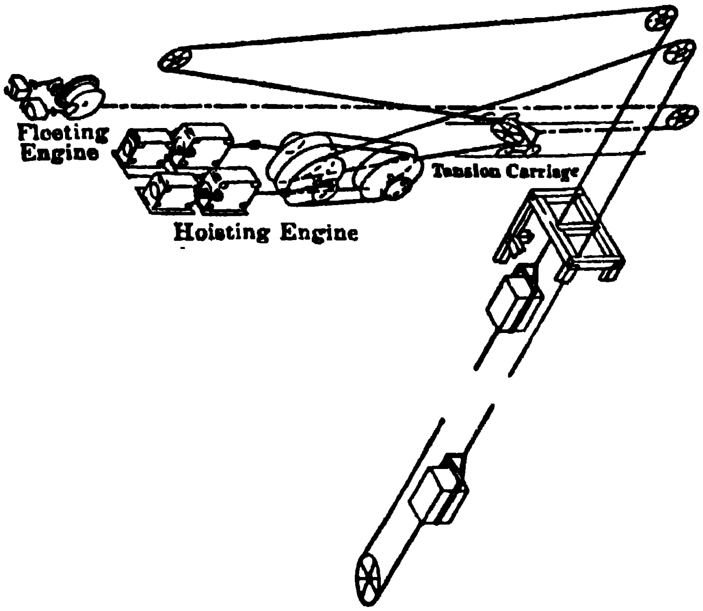

Fig 2. Whiting System

Whiting system with tail-rope requires rope of uniform section; hence is not applicable when the depth is such that the useful strength of the rope is too small for a load required to give the output. With rope of high tensile strength the system has advantages to a depth of 6 000 ft, especially if hoisting is from the bottom only. A tail-rope is necessary to give constant load throughout the hoist. Advantages: lower first cost, smaller engines, and less energy for accelerating the comparatively light driving sheaves. The system is rarely used.

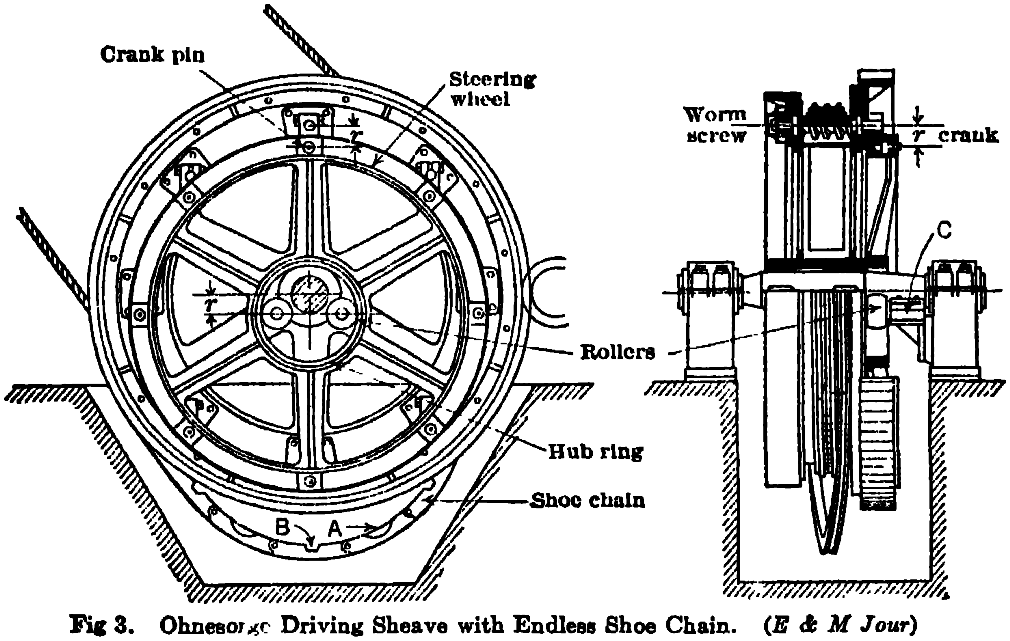

Fig 3. Ohnesorge Driving Sheave with Endless Shoe Chain. (*E & M Jour*)

Koepe hoist with Ohnesorge sheave (Fig 3) (5). This recent modification provides for a number of rope wraps on the driving sheave; the rope is kept in the center line of the sheave, and travels in a vertical plane over the head sheaves. There is a set of independent, semicircular grooves in the form of an endless shoe-chain, set spirally in a number of turns on the sheave face. For 1 1/2 rope turns, there are 3 chain turns on the sheave; for 2 1/2 rope turns, 4 chain turns. Inside projections *A* (Fig 3) of the chain links fit in threads of worm-screws, and rectangular recesses *B* fit on a rectangular cleat on sheave face, which keep the chain from slipping. A number of worm-screws on sheave periphery engage inside the face with certain links of the chain. Pitch of worm equals width of chain link, and one side of each worm-shaft ends in a crank of radius r. A single eccentric steering wheel, hanging freely from the ends of this crank, revolves with main sheave about its own axis, and is kept in position by small rollers, revolving in bearings c, which are integral parts of main sheave bearings. As the worm-screws thus make one complete revolution in a direction opposite to that in which the rope would tend to travel, due to direction of rotation of main sheave, there is no fleet angle.

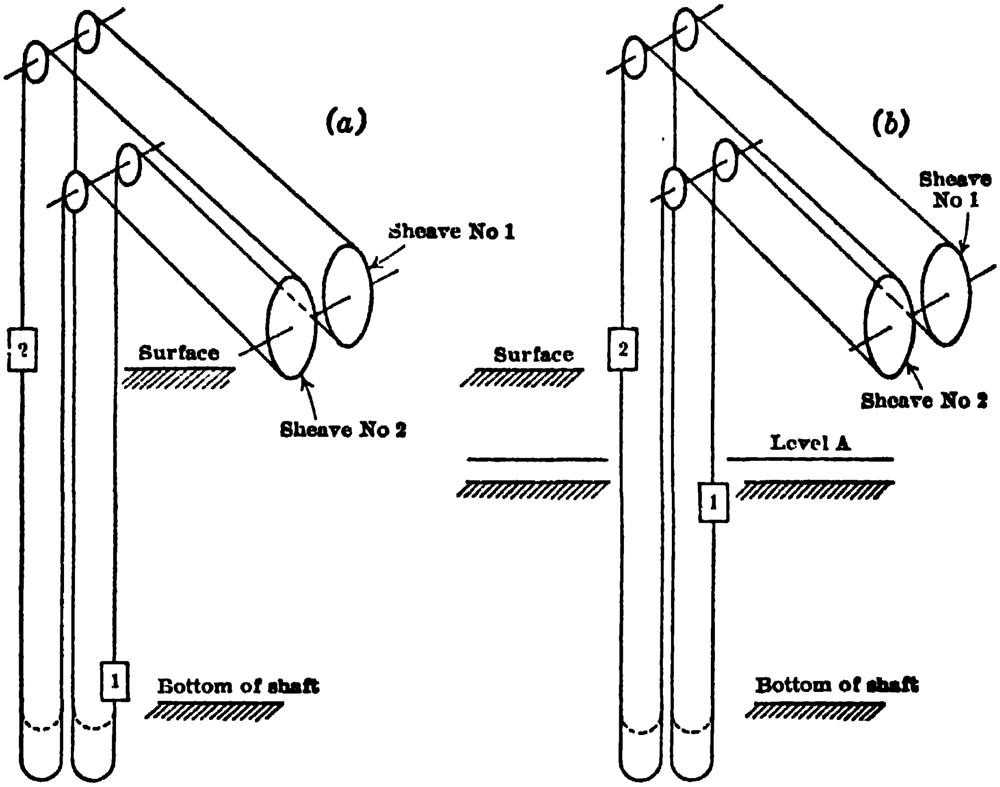

Fig 4. Diagram of Ohnesorge System for Hoisting from Different Levels. (*E & M Jour*)

Advantages. Since the frictional grip of rope on the Ohnesorge sheave may be varied at will by controlling the number of rope turns, it permits: (1) high-speed hoisting; (2) greater acceleration; (3) elimination of tail-rope, if desirable; (4) hoisting of light or heavy loads; (5) perfect rope lubrication; (6) a smaller sheave than the regular Koepe; (7) hoisting from different levels, as in Fig 4, where 2 Ohnesorge sheaves are clutched on the same shaft. [Skip 1 is at the bottom, skip 2, at top. Counterclockwise sheave rotation causes skip 1 to rise and 2 to descend. To hoist in balance from an intermediate level, place skip 2 on rope of sheave 2 and unclutch sheave; then pull skip 1 to level desired. Clutch sheave 2 and proceed to hoist in balance]; (8) permits occasional cutting off a piece of rope near cage or skip, for testing; (9) may be operated with 2 or more ropes, making it also suitable for elevators. Costs in Germany, 1932: for 40-in diam driving sheave and 1-in rope, with 3 turns of shoe chain, $700; for 8.2 ft sheave and 1.6-in rope, with 3 turns of shoe chain, $2 900. An extra shoe-chain turn on 40-in sheave adds $50 to cost; an extra shoe-chain turn on 8.2-ft sheave adds $150.

Tandem system of hoisting in deep shafts (Fig 5) consists in having 2 skips in the same compartment, the upper skip with a rope equal to half the depth of shaft, the lower with its rope attached to bottom of upper skip. Upper skip receives its load from pockets at middle point of shaft, into which the lower skip dumps. Both are loaded and dumped simultaneously. The upper rope carries its own weight and that of both skips. Both ropes may be tapered. The drums need be only large enough to hold rope equal to half the total depth. With conical drums, the ratio of small to large diam is less than with a single lift, and the moment of inertia of drums is thus reduced. There is a theoretical economy in steam consumption of about 9% over hoisting in a single lift, and the hoist is smaller, with consequent lower first cost. Offsetting this is the cost of extra loading pockets, shaft arrangements and labor attendance.

Two-stage hoisting (Fig 6) requires 2 engines, one hoisting from the bottom and dumping into a bin at an intermediate station, from which the other engine hoists to the

surface. The engines may be duplicates, by which first cost is materially reduced. With conical drums (Art 2) this condition may make it necessary to sacrifice equality of static moments. The two lifts must overlap by about 65 ft. This system gives better steam economy than the single lift, by about 10.5%, but against this is increased cost of shaft construction and extra attendance at surface and intermediate station.

This is the commonest system for deep hoisting, especially where the shaft changes from vert to inclined. Engine for the lower lift is usually placed in an underground station, and driven by elec, sometimes by compressed air, steam being out of the question. Even with elec hoists special ventilation is necessary, due to the heat generated.

Fig 5. Hoisting in Tandem

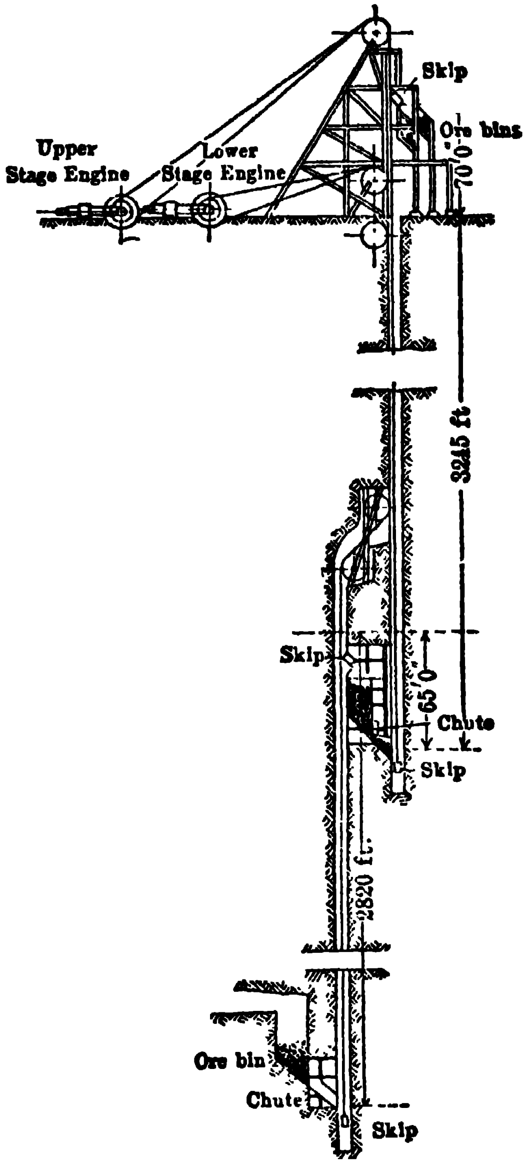

Fig 6. Two-stage Hoisting

Single-lift, tandem, and two-stage systems compared. SINGLE LIFT. Advantages: simplicity, flexibility, absence of attendance at intermediate station and elimination of cost of this station. Disadvantages: high first cost, on account of large engines and drums; excessive ratio of end diameters; danger of whipping of the ropes; increase in cost of headframe; engines are proportionately less economical when handling men, tools, and supplies. TANDEM SYSTEM. Advantages: smaller size of engines and very much better ratio of end diameters of drum, thus reducing first cost; engines more economical; no whipping of ropes; may be used for greater depths than single-lift system; steam demands on boilers are more equally distributed than in single-lift system. Disadvantages: extra first cost of, and attendance at, intermediate station; high cost and size of headframe; lack of flexi-

bility, so that the system is not suited to sinking, or hoisting from different levels. Two-stage system. Advantages: greater flexibility than the single lift; favorable drum proportions (equal to the tandem system); tail ropes could be used in both upper and lower stages; use of brakes is attended with less loss of energy; is suitable for sinking; hoisting may be done by either stage from intermediate levels, without interfering with operation of other stage; first cost of 2 small engines is probably not much greater than 1 large engine, for a single lift; engine for upper stage could be installed first, and second

engine not purchased until needed; steam demand on boilers is more uniform, requiring smaller boiler plant.

Other hoisting systems (37), the Schitko, Despritz, Monopol, Gerhard and Tillson, are modifications of the preceding; diagrammatically shown in Fig 7.

2. HOISTING DRUMS

Drums (3) may be cylindrical, conical, cylindro-conical, or reel (Fig 8).

Cylindrical-drum hoists may have: (*a*) one drum, keyed to driving shaft; (*b*) two drums, both keyed to shaft; (*c*) two drums, 1 clutched and 1 keyed; (*d*) two drums, both clutched. Keyed drums are used for single-level mines; clutched drums, for hoisting from more than one level and for adjusting rope stretch. (A novel design is shown in Fig 9 (6). The drums are bi-cylindro-conical, mounted on parallel shafts geared together and driven by motors coupled to the gear pinions.) Drums have flanges to prevent rope running off end. Winding surface may be smooth, grooved, or lagged with wood. A smooth surface causes rope to chafe and wear. With wood lagging, there is less wear, as rope makes its own groove. Grooved metal drums are best. The winding of rope on itself (in more than one layer) is poor practice, and rarely admissible. Brake surface forms part of the drum, and is of a diam and width sufficient for the hoisting load. Minimum drum

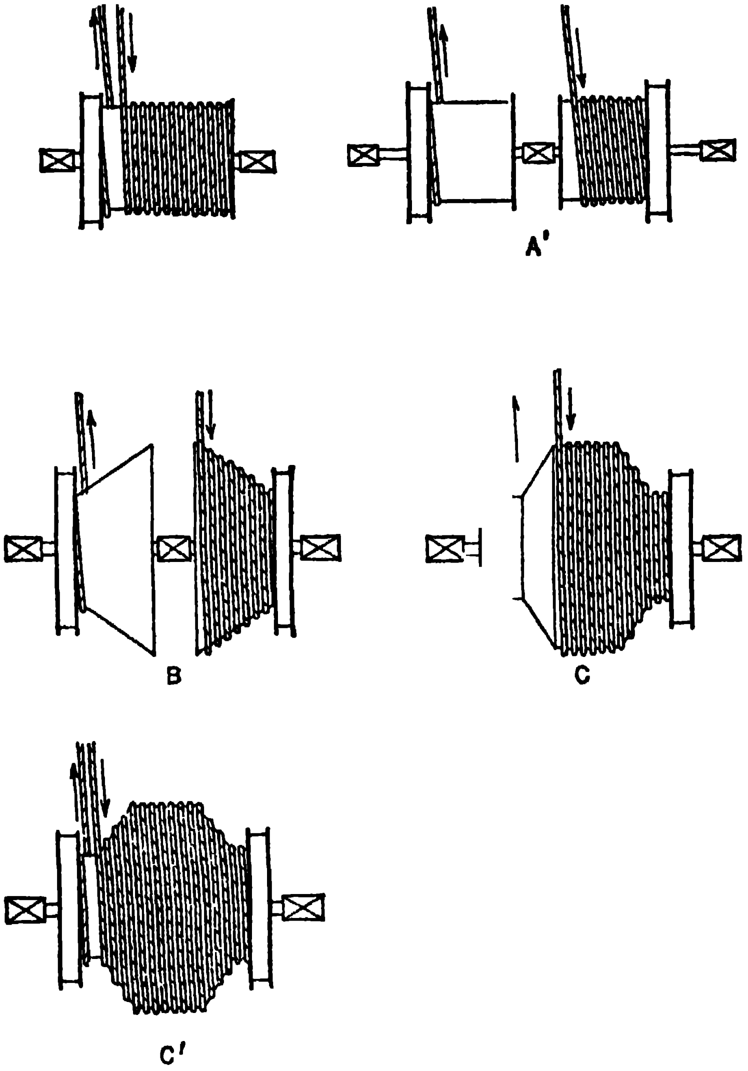

Fig 8. Common Forms of Hoist Drums

A—Single cylindrical. A'—Double cylindrical. B—Conical. C—Cylindro-conical; ropes starting on different diams. C'—Cylindro-conical; ropes starting on same diams. D—Reels

diameter, D, is at least 60 times rope diam r (in); general ratios are: 70 in coal mines and 85 in metal mines. If L = length of rope, and N the number of turns of rope on drum,

$$N = \frac{L}{\pi(D + r)} \tag{3}$$

Allow 2 extra turns to protect rope fastenings, and 2 turns against overwinding; then, length (W) of a smooth-face drum between flanges = $(N + 4) \times r$ (4)

For a grooved drum, allow $^1/_4$ in between adjacent coils of rope; then,

$$W = (N + 4) \times (r + {}^1/_4\,\text{in}) \tag{5}$$

Conical drum. In theory, the varying radius of a conical drum should be such that the static hoisting moment is constant. But this is true only when the element of the conoidal surface is a curved line. Curve-faced drums are costly and difficult to make, and are not used. A single, straight-faced cone gives perfect equalization only at beginning and end of hoist (Fig 10); moments at all intermediate points exceed the end moments. A pair of cone drums (in double compartment shaft) equalize also at passing point of cages (Fig 11); at all other points, equalization is only approximate. To design a conical drum, depth of shaft, weight of cage, car, ore, and size and weight of rope

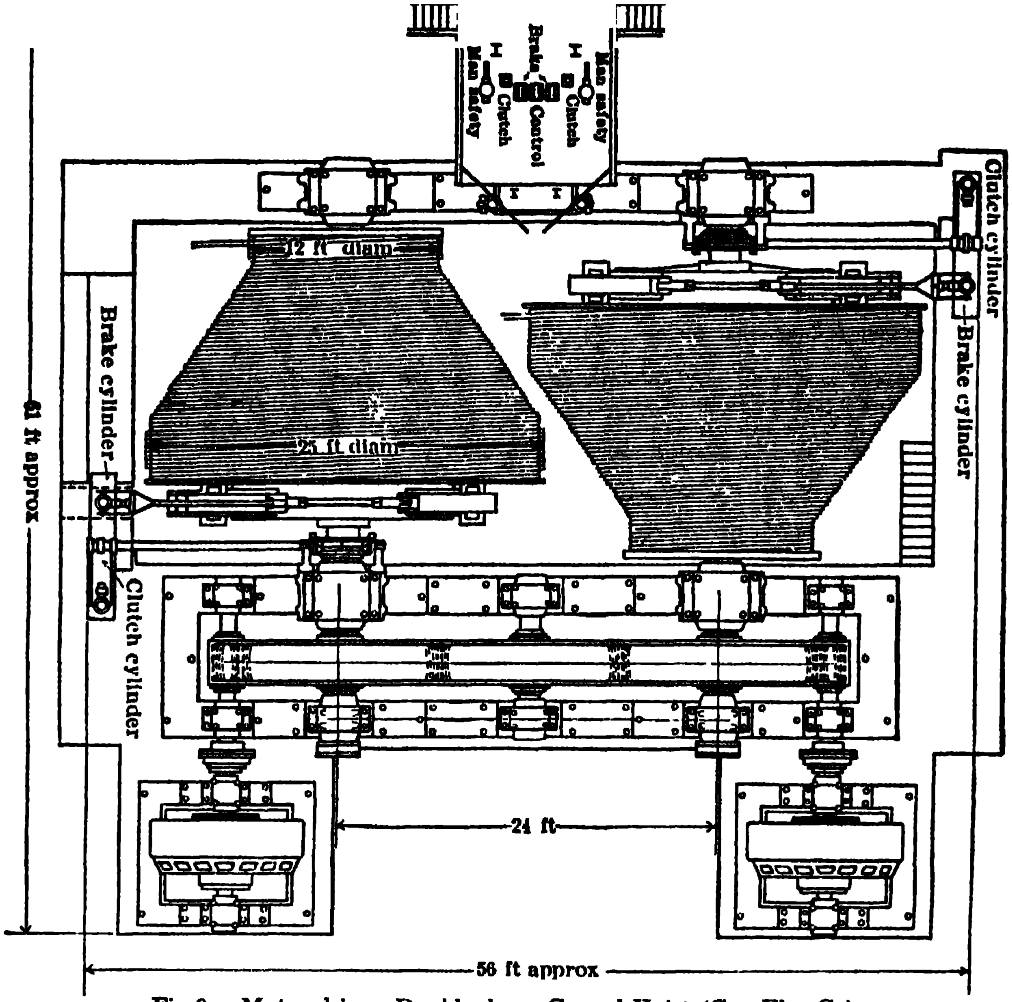

Fig 9. Motor-driven Double-drum Geared Hoist (Gen Elec Co)

must be known, and the resulting cone is suitable only for the given depth of shaft. Hence, economically, conical drums lack the range of service of cylindrical drums.

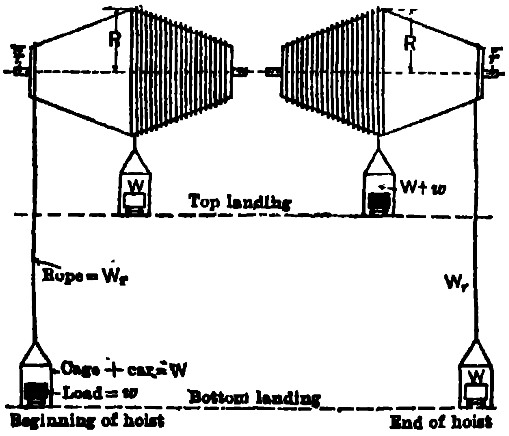

Fig. 10 Design of Conical Drum

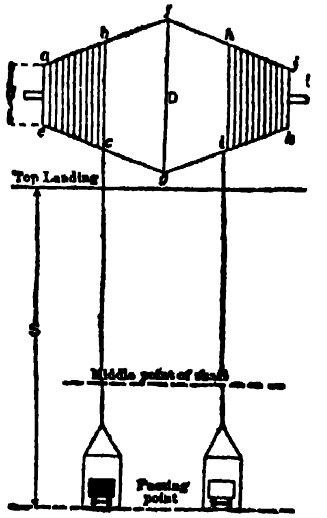

Fig 11. Passing Point of Cages

Design. Assume small diam of drum, which should generally be not less than 60 times diam of rope (Art 5 and 7). Let R = radius large end of drum, ft; r = radius small

end of drum, ft; Wr = wt of one rope between top and bottom landings, lb; W = wt of cage and car, or skip, lb; w = wt of ore, lb. From Fig 10, to fulfill the conditions, the algebraic sum of the static moments in the two positions of loaded and empty cages at top and bottom of shaft must be equal:

$$(Wr + W + w)r - WR = (W + w)R - (W + Wr)r \tag{6}$$

whence,

$$R = \frac{r(2Wr + 2W + w)}{2W + w} \tag{7}$$

in which R is the only unknown quantity. Since rope weight appears in only two terms of Eq (6), the drum as designed equalizes only for the assumed depth of shaft. Width of drum depends upon depth of shaft, size of rope, and angle of drum face. For angles under say 30°, the horiz pitch of grooves need not be more than $^1/_8$ to $^1/_4$ in greater than rope diam; for large angles, pitch may be 2 to 2.5 times rope diam, to make grooves deep enough to prevent displacement of rope. Number of grooves = rope length divided by mean circumference of drum.

Passing point of cages. Let S = distance of passing point below surface, ft; l = distance between top and bottom landings, ft; d and D = respectively small and large diam of drum at bottom of groove, ft; a = rope diam, ft; n = number coils of rope on one drum with cage at top (2 or 3 extra coils at each end being usually allowed).

Then (Fig 11)

$$n = \frac{l}{\pi\left(\frac{D + d}{2} + a\right)} = \frac{2l}{\pi(D + d + 2a)} \tag{7a}$$

At passing point (which is below middle of shaft) the number of rope coils on $abce$ = number of coils on $bfgc$, since passing point is reached when drum has made half the revolutions required for a complete hoist, and both ropes are winding on mean diam. Length of rope unwound from $bfgc$ = S, whence:

$$S = \frac{\pi(bc + fg)}{2} \times \frac{n}{2} \quad \text{and} \quad \frac{bc + fg}{2} = \frac{\frac{d + D}{2} + D}{2} = \frac{3D + d}{4}$$

Substituting,

$$S = \frac{\pi n}{8}(3D + d) \tag{8}$$

If D and d be taken as diam of rope coils,

$$n = \frac{2l}{\pi(D + d)}, \quad \text{whence,} \quad S = \frac{l}{4}\,\frac{(3D + d)}{(D + d)} \tag{9}$$

Cylindro-conical drum (Fig 8, 9, 12) is a modification of the conical type and used for the same general purpose. Advantage: it is cheaper and lighter than the simple conical drum, because both ropes may use any and all portions of drum surface. This is accomplished, however, at the expense of true equalization of hoisting load.

To increase rate of acceleration, and attain max speed sooner, drums are sometimes coned steeply for a few rev, remainder of drum being cylindrical. This is more useful for electric than steam hoists, as it reduces the heavy starting current required, especially with induction motors. Common practice with electric hoists is to make the first few turns, at the small diam, cylindrical in form; then a steeply-inclined portion, and ending with a few turns on a cylindrical surface at the large diam. Each drum must be designed to suit conditions of load, speed and electric current factors. Fig 12 shows a steam-driven cylindro-conical drum at No 5 shaft, Tamarack Mining Co, Mich. Drum weighs 300 000 lb. Each cone holds 2 125 ft of 1.5-in rope; the center, 3 875 ft. Total length of each rope, 6 000 ft. At No 2 shaft, Quincy mine, Hancock, Mich (23), the drum is cylindro-conical, small diam, 16 ft; large diam, 30 ft; length, about 30 ft. Each cone has 42.5 turns; the common cylindrical part, 76 turns. One cone, plus cylindrical surface, holds 10 000 ft of 1 $^5/_8$-in rope.

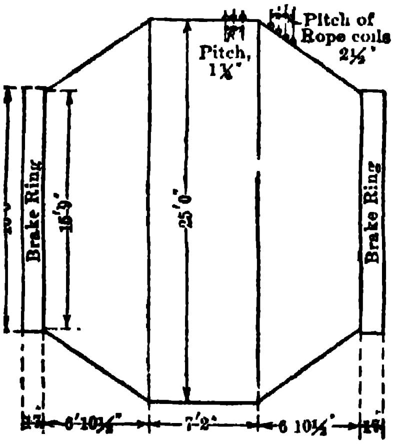

Fig 12. Cylindro-conical Drum, Tamarack No 5 Shaft

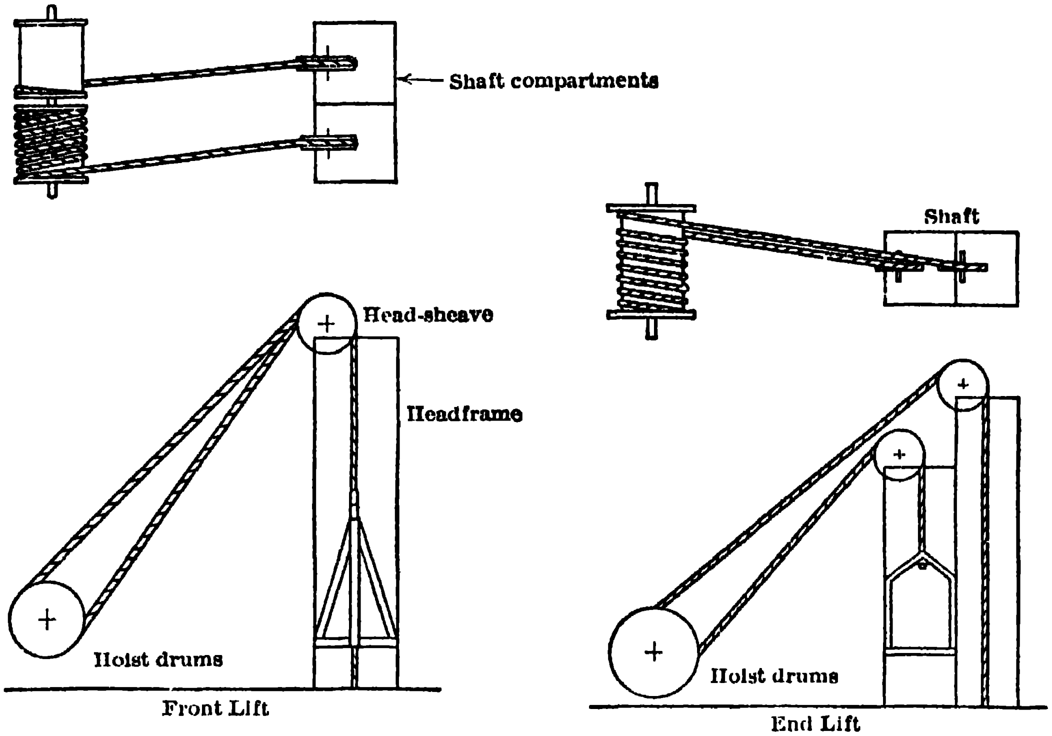
Fleet angle is the angle through which the rope travels across the drum face, measured in a plane through the drum and sheave centers, between sheave center and extreme position of rope at ends of drum face. The angle generally varies between 1.5° and 4°; when excessive, it increases wear on rope and makes even winding on drum difficult. Methods of decreasing fleet angle: (*a*) increase drum diam, with consequent decrease in length; (*b*) increase horiz distance between drum and head-sheave; (*c*) wind rope on drum in more than one layer, or use reels; (*d*) increase height of headframe; (*e*) use Koepe hoisting system, with or without Ohnesorge wheel (Art 1); (*f*) end-lift sheave and drum arrangement (Fig 13). Most common methods are *a* and *b*; *c*, *d*, and *f* are used only under severe topographic conditions; *e*, with Ohnesorge sheave, is used in Europe, but not in U S. *Fleet-angle determination.* If d = horiz distance between sheave and drum-shaft centers (ft), h = vert distance between sheave and drum-shaft centers (ft), w = width of drum covered by rope (ft), and F = fleet angle, then

[illegible] (10)

Drum and head-sheave arrangements, Fig 13, are referred to as front and end lift. End lift (drum in line with shaft compartments) is used to reduce the fleet angle when required by topographic conditions around collar of shaft.

Reels for flat rope have same effect as conical drums in tending to equalize static hoisting moment. Advantages: small space occupied; smaller cost; due to absence of fleet angle, hoist may be placed close to shaft; weighing less than drums, less power is required for acceleration. Disadvantages: flat rope costs more, is heavier and has shorter life than round rope of same strength. A few reel hoists are still used, but no new installations are being made.



Front Lift

End Lift

Fig 13. Diagram of Two Arrangements of Hoist with Reference to Headframe

Flat rope (Art 6, 7) increases winding radius at each rev by an increment equal to rope thickness; hence, the result is theoretically the same, and same calculations apply, as for round rope and conical drum. But in making flat rope, practical considerations fix its thickness for a given width, thus modifying the winding increment, so that equalization is even more imperfect than with conical drum. Disadvantage: lack of steadying effect on engine produced by heavier drum (4). Also, rope troubles are serious (Art 7).

Design. Diam of reel hub d should be at least 60 times the rope thickness. Having selected rope of proper strength, following are the relations between small and large winding diam d and D, length of rope l, and its thickness t, all in in. Annular area between inner and outer surface of coiled rope = lt; whence,

$$lt = 0.25\,\pi\,(D^2 - d^2) \tag{11}$$

and, if

$$D = xd, \quad lt = 0.25\,\pi\,d^2\,(x^2 - 1)$$

whence,

$$d = \sqrt{\frac{lt}{0.25\,\pi\,(x^2 - 1)}} \tag{12}$$

in which $x = D \div d$, found from Eq 8. Knowing d, $D = xd$.

Example. Rope, 2 000 ft = 24 000 in of 4 by $^3/_8$ in, 2.65 lb per ft = 5 320 lb. Ore, 6 000 lb; skip, 3 000 lb. Then $x = (2 \times 3\,000 + 2 \times 5\,320 + 6\,000) + 2 \times 3\,000 + 6\,000) = 1.88$. Substituting in Eq 13:

$$d = \sqrt{\frac{24\,000 \times {^3/_8}}{0.7854\,(1.88^2 - 1)}} = 67.2 \text{ in} = 5.6 \text{ ft} \tag{13}$$

Hence,

$$D = 1.88\,d = 1.88 \times 67.2 \text{ in} = 10.52 \text{ ft}$$

Comparison of systems of equalization. Fig 14 shows static moments for different depths, based on calculations for a 3 000-ft shaft, skip 3 000 lb, ore 8 000 lb; hoisting in balance. Working stress in rope, including bending stresses, is taken at 50 000 lb per sq in of steel section, as near as standard size can be selected. Conditions: Cylindrical drums, 9 ft diam, rope 1.25 in @ 2.45 lb per ft. Conical drums, 9 by 18.45 ft, rope 1.25 in, 69.6 coils. Reels, small diam 60 in, large diam 144 in, rope $^3/_8$ by 5 in @ 3.25 lb per ft, 112.4 coils. Whiting sheaves, 12 ft diam, rope 1 $^1/_8$ in @ 2 lb per ft. Koepe sheave, 24 ft diam, rope 1 in @ 1.58 lb per ft, with 1-in tail rope. Thus the Koepe sheave, because of its large diam, requires largest engine; its static moment is greatest, but is uniform. Curves for conical drums and reels show good equalization when hoisting from shaft bottom; but the dotted lines, giving moments when hoisting in balance from half the depth, show that larger engines are necessary for hoisting from intermediate levels in balance than for hoisting from bottom only.

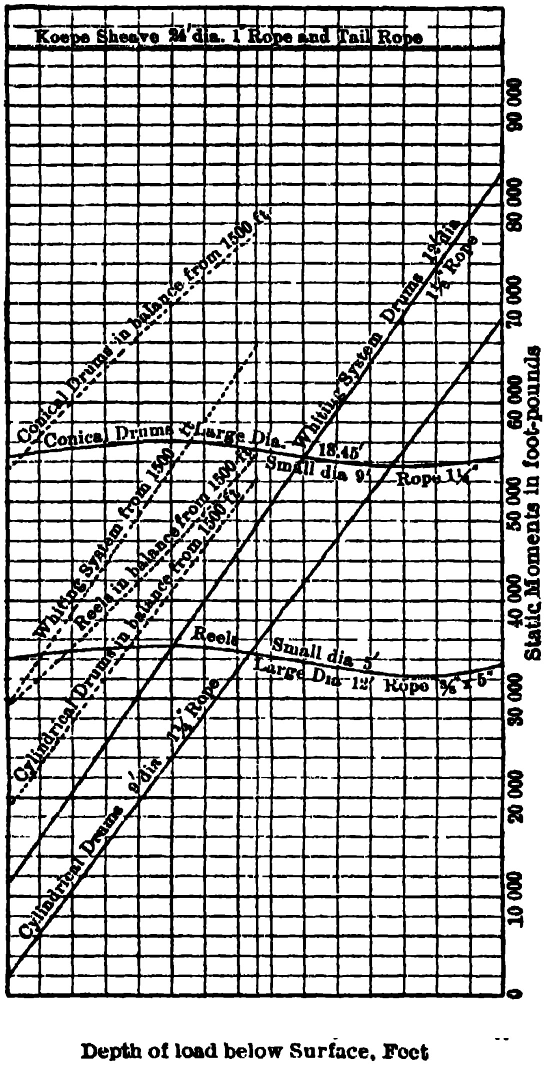


Fig 14. Static Hoisting Moments

Drum construction. Small drums are cast in one piece, with brake ring and clutch surfaces. Large drums are cast in parts, to prevent shrinkage stresses and for convenience of transport. The shell and flanges may be cast in one piece and each spider separately, or shell itself cast in segments. To reduce wt, the shell may be of steel plate (Fig 14a), and large drums (especially when conical) may be of cast steel instead of iron. If drums are loose on shaft and controlled by clutches the hubs are bushed with brass or bronze.

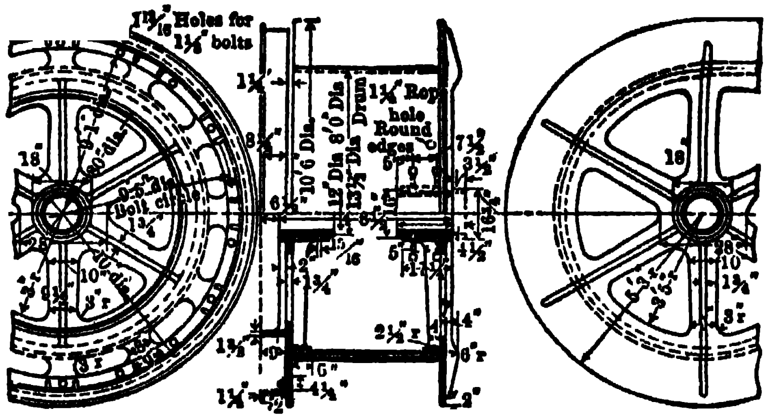

Fig 14a. Drum, 8 ft Diam × 4 ft Face

Main drum may have a small internal drum, on which is wound extra rope to be let out as shaft is deepened. Rope life is increased by grooving the drum.

Drums at Belmont Mine, Butte, Mont (9) are steel plated cylindrical, 12 ft diam by 93 in face. The shells are grooved, fitted on the inside with 3 expandable wedge rings and bolted to CI spiders provided with removable bushings. Drum shell, end rings and spider are made in halves and split

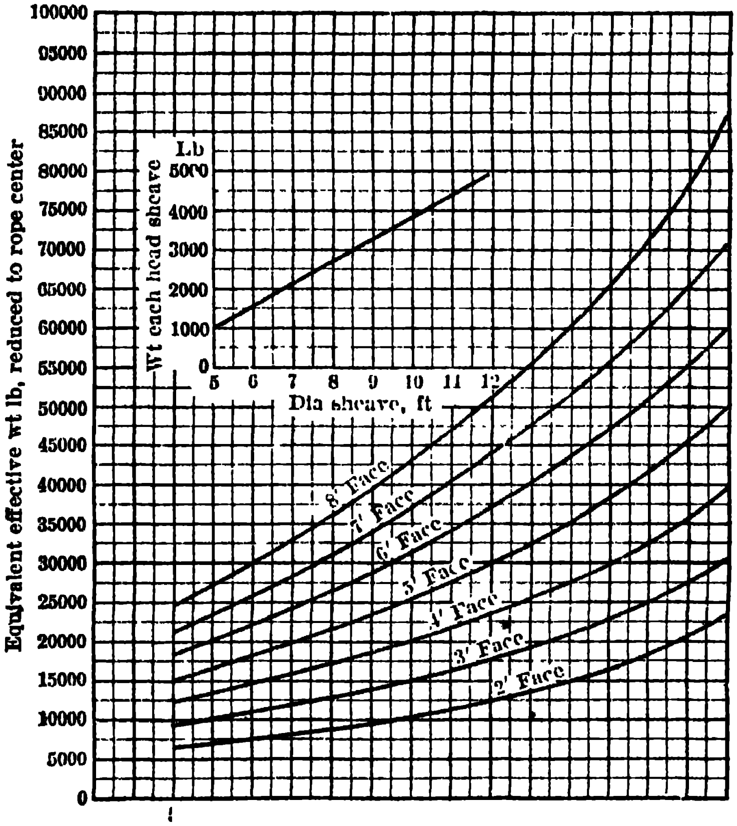

Fig 15. Effective Weight of Drums (Single-cylinder) and Head Sheaves, for Estimating Purposes Only (Gen Elec Co). For gears, add 10%; for double drums, add 100%

parallel to drum-shaft axis. The iron brake and clutch rings are cast integral and bolted to drum end flanges, which are of cast steel. The drum holds 5 500 ft of $1\frac{7}{8}$-in rope in 3 layers.

Inertia effect (3) of the drum, important in calculating duty cycles, is influenced by design and varies with different makers. Hence, for final calculations, the inertia effect

is determined by the maker. For estimating purposes, Fig 15, 16 are included here, but it should be remembered that the accuracy may not be better than 1 to 2. G. Bright (8) suggests obtaining the inertia of a cylindrical drum by allowing 200 lb per sq ft of drum surface with a radius of gyration assumed 3 inches inside the drum surface.

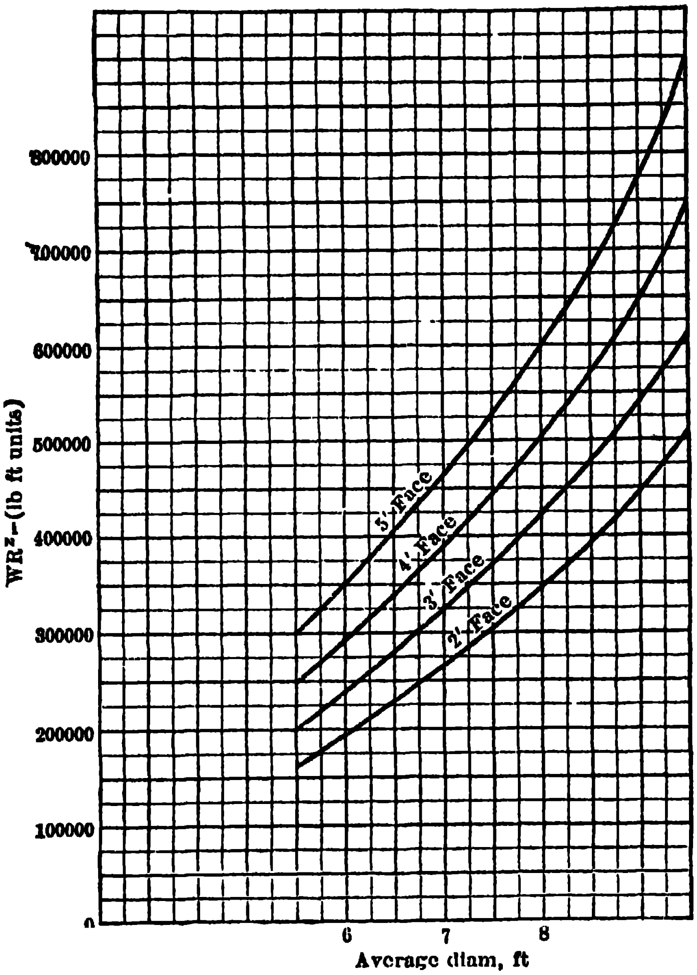

Fig 16. WR^2 of Conical Drums (double faced). For estimating purposes only. For gears, add 10%. (Gen Elec Co)

3. BRAKES AND CLUTCHES

Brakes are of band or post type (Fig 17, 18), applied for small hoists by hand or foot, through systems of simple levers. Brakes of large hoists are power-operated; applied by a weighted lever and released by lifting the weight with an air, oil or hydraulic cylinder. Band brakes are used for both large and small hoists, post brakes only for the larger sizes. The levers of band brakes are sometimes designed to increase the brake pressure by a constant application of braking force; more desirable for hand than for power brakes. Hand emergency brakes, on hoists equipped with power brakes, may have a differential motion tending to tighten the brake automatically after being applied. Their instantaneous action is objectionable.

Band brake. Assuming diam of brake surface is same as that of drum, the band and anchorage must stand greater tension than that of the rope (Eq 14, 15).

Let W = friction between band and brake surface = pull on rope,
T_1 and T_2 = tension respectively at anchorage and at end of brake band,
e = base of Naperian system of logs = 2.71828,
f = coefficient of friction, wood on iron = 0.30,
c = ratio of length of arc of contact of brake to radius of brake surface,
a = angle of arc of contact, deg.

Then $$W = T_1 - T_2 \qquad (14)$$

But $$T_2 = T_1 + e^{fc}, \quad \text{or} \quad \frac{T_1}{T_2} = e^{fc} = e^{\left(f\frac{\pi}{180}a\right)}$$

and $$\log_{10}\left(\frac{T_1}{T_2}\right) = f\frac{\pi}{180}a\log_{10}(2.71828) = \frac{\pi}{180}(0.4343)fa$$

or $$\frac{T_1}{T_2} = 10^{\frac{\pi}{180}(0.4342)fa} = 10^{0.00758fa}$$

When $$a = 270° \quad \text{and} \quad f = 0.30, \quad \frac{T_1}{T_2} = 10^{0.6139} = 4.11 \tag{15}$$

Substituting in Eq (14), $W = 0.757\ T_1$; whence, T_1 is about 1.3 times the rope pull under best conditions and with drums nearly at rest. If braking surfaces are in poor condition, f is reduced and T_1 increased. If brakes are applied suddenly, with hoist in motion, T_1 may be doubled or tripled, if tension T_2 be sufficient. Hence, with heavy loads, the limit of hand braking with practical leverage ratios is soon reached. If hoisting in balance, with over and under ropes on one drum, brake band should be in halves (Fig 17), so that the anchorage will always take the load due to either rope, otherwise one rope will pull against the brake lever.

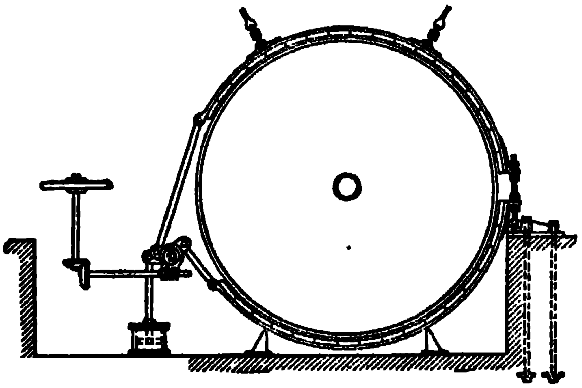

Fig 17. Band Brake

Post brake requires a smaller movement for necessary clearance from brake ring. Also, the load is always carried by the anchorage, regardless of direction in which the rope winds upon drum. Frames of post brakes should have PARALLEL MOTION, to secure uniform pressure over entire surface of brake shoe. This is done by supporting the frames on swinging links (Fig 18, in which the weighted lever for applying the brake is not shown). Post brakes increase first cost of hoist 4–8%, but are now used on nearly all large hoists.

Clutches are of jaw or friction type. JAW CLUTCH is simple and safe, but, because of its positive action, both drum and engine must be at rest, or nearly so, when clutch is thrown in gear, and the two parts of clutch must be in certain relative positions before they will mesh. It is suitable where hoisting is generally in balance and from one level. Simple jaw clutch is used only on the pinion shaft of geared hoists. Multiple-tooth clutch, with large number of teeth in a circle near periphery of drum, and a sliding member on shaft, is sometimes used. Nearly as close adjustment can be had as with friction clutch. FRICTION CLUTCH is preferable where relative positions of cages are changed frequently, or a nice adjustment of distance between them is necessary. It is best suited to general mining purposes. CONE FRICTION CLUTCH is satisfactory for drums up to 48 in diam, and may be used on larger drums. But, with large drums, heavy loads, or high speeds, the end thrust on drum-shaft bearings and friction on thrust pin cause trouble. Cone friction is always operated by hand power. BAND FRICTION CLUTCH costs more, but is otherwise preferable. It is readily inspected and adjusted for wear. Fig 19 shows the Lane type. It comprises a cast-iron spider *a*, keyed to drum shaft, and fitted with fixed arm *b*, and movable arm *c*, pivoted at *d*. The arms carry steel band *e*, lined with wooden blocks. Inner end of *c* is connected to

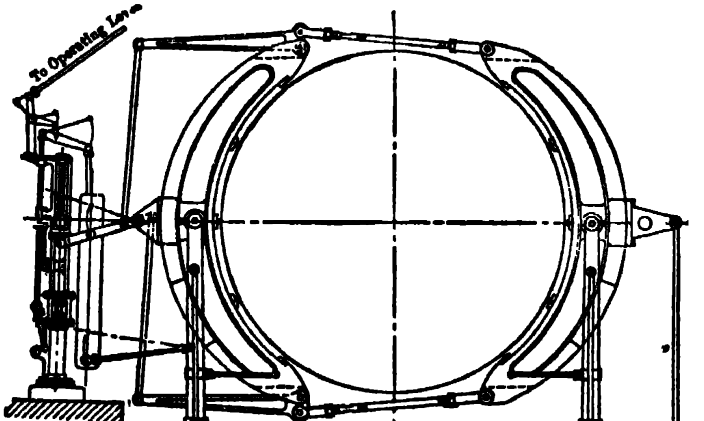

Fig 18. Parallel-motion Post Brake, Operated by Comp-air Cylinder (Nordberg)

sliding sleeve *f* by toggle *g*. When the sleeve is moved toward drum the band tightens on the friction ring *j*. When released the band is prevented from sagging by the lifters *k*. On drums 8 ft diam and over, the band is usually made in halves. As toggle levers *g* approach the normal the tensile strain in the band becomes very great, with risk of excessive stresses if clutch is set too early. Since clutch path may be greasy, coeff of friction is assumed at 0.2. With the rope pull reduced to its equivalent at periphery of clutch path, the tension at ends of band may be calculated as for band brakes. The rope should be so wound on drum that the greatest pull is on fixed end of band; less tension is then required in the clutch. It is recommended that the leverage between end of band and the sliding sleeve be 20 to 1. Assuming effic of 50% for the clutch gear, when the band tension and force required on the sliding sleeve are known, the size of clutch-engine cylinder is determined by working back through the leverage system.

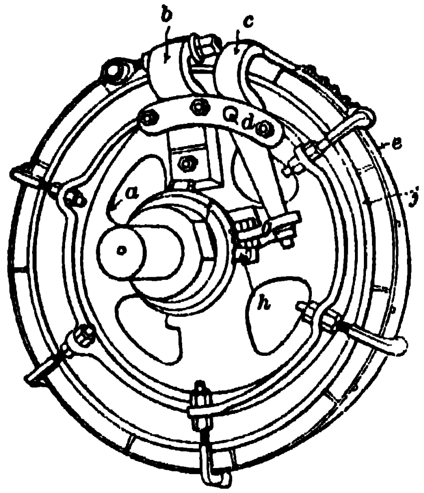

Fig 19. Lane Band Friction Clutch

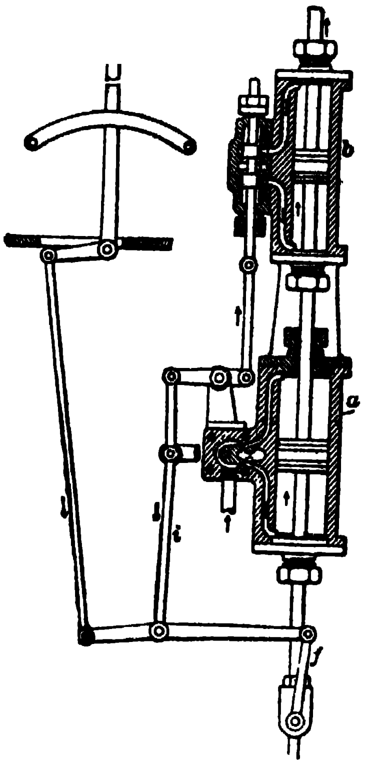

Fig 20. Auxiliary for Hoisting Engine Control

Multiple-arm disk clutch is often used on large hoists. A driver, keyed to drum shaft, carries two ribbed rings supporting wooden blocks, between which works the steel clutch-ring of drum. The ribbed rings are actuated through toggles, moved by a sleeve sliding on the driver hub. Clutch is self-locking when thrown in, and stresses do not tend to disengage it; it is superior to the Lane type, in that it works equally well whether the hoisting rope is wound under or over.

Auxiliary engines (Fig 20) for brakes, clutches and reverse are operated by steam, air or oil under pressure. Brakes should always be applied by a weight and released by power, so that they are set automatically if power fails. In steam hoists the same form of engine often operates brake, clutch and reverse.

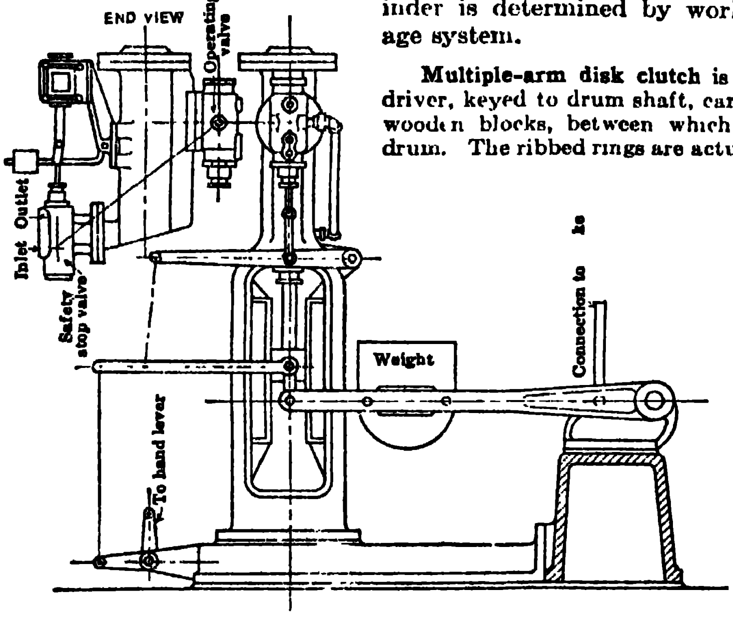

Fig 21. Oil-operated Brake Engine, with Automatic Stop, for Electric Hoist

Steam and air operate expansively Because of cylinder condensation of steam, operator can not definitely control motion of piston of auxiliary engine; hence, a cataract cylinder (Sec 40) is placed tandem with steam cylinder. Valves of both cylinders are controlled by one hand lever with a "floating lever" motion. Opened by hand, the ordinary valves are automatically closed by motion of the pistons. Fig 20 shows valve motion of auxiliary engine; *a* is steam cylinder and *b*, oil cataract cylinder. Hand lever opens steam and cataract valves, and motion of piston rod, acting through *f* and *i*, closes them after a movement proportional to that of hand lever has taken place.

Auxiliary engines operated by oil (Fig 21), under pressure from an accumulator or oil-pressure reservoir, do not require a cataract cylinder, as the liquid is non-expansive and only one cylinder needed. Control is by a floating lever, to make motion of piston coincident with that of operator's lever, so that any pressure can be applied and held. Recent types have auxiliary valves for applying brakes automatically, in connection with safety devices against overwinding (Art 34), or failure of steam pressure, or current in case of electric hoists.

4. MOTOR AND HOIST CONNECTIONS (3)

First-motion or direct-acting hoists have the engine or armature shaft directly connected to drum shaft, through rigid flanged couplings keyed to or forged on the shafts, or the armature is pressed on an extension of drum shaft. First-motion steam hoists are used for large outputs, or depths requiring high hoisting speeds. First-motion electric hoists always use D C motors, because of the poor electrical characteristics and high costs of induction motors for these purposes. In the DUAL-MOTOR DRIVE, sometimes used for large hoists, half the motor capacity is coupled at each end of drum shaft. This better distributes the shaft stresses, lessens rotor inertia effects, and insures against complete interruption of service.

Second-motion hoists have one gear reduction. With herringbone gears, which permit high tooth speeds and large gear reduction (15 to 1), double reduction is rarely needed except for small capacities. This type is well adapted to an A C high-speed motor or a steam engine. The motor has two bearings, and the armature shaft is connected to pinion by a flexible coupling.

Conversion of steam hoists to elec drive may be made by bolting a gear to the crank disk, and coupling the motor to the shaft of a pinion meshing with the gear. The drag-link connection has been used in So Africa. The link connects the engine crank to a similar crank on the motor or to an intermediate gear shaft.

5. HOISTING SHEAVES

Sheaves are generally of the bicycle spoke type; of C I in one piece, a C I-rim with W I spokes, or of a welded structural-steel skeleton type (10). Tread or bottom of groove must be true, with a radius slightly larger than the rope. Voigtlander (11) recommends:

Diam of rope	Tolerance of groove diameters
1/2 in and smaller	+1/32 in minimum to +3/32 in max
9/16 in to 1 in	+1/16 in minimum to +1/8 in max
1 1/16 in to 2 in	+3/32 in minimum to +3/16 in max
Over 2 in	+1/8 in minimum to +1/4 in max

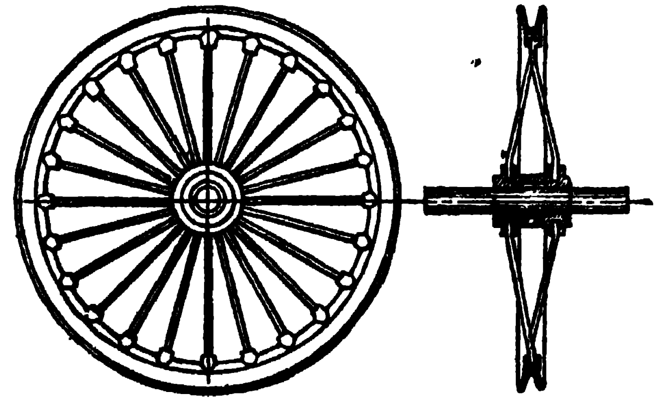

Fig 22. Wrought-iron Spoke Sheave

Sheave grooves may be lined with wood blocks, grain on end, or steel liners. Depth of groove and width at rim are 3.5 to 4 times rope diam. Sheaves of minimum wt should

be used to reduce the inertia effect on rope when engine stops, which causes a scrubbing action and wear on the rope. Spokes of W-I sheaves are cast into rim and hub (Fig 22 and 23), making an angle of about 7° with plane of sheave. Sheave shaft or arbor is solidly keyed in the hub, and supported in heavy bearings. Hub is sometimes held between 2 collars on the arbor, one being turned solid on arbor, the other split, fitting in an annular groove in arbor, and bolted to hub (11).

Bearings are of the post type (Fig 24), with the cap at 45° to plane of base, or of the ordinary horiz type, depending on design of headframe (Art 23). Post bearings may be used in either vert or horiz position, having the advantage that the resultant of the rope pull always falls approx in bottom of bearing. Journals should be so proportioned that the unit press does not exceed 200 lb per sq in, to permit proper lubrication.

Costs of sheaves may be computed at 10 to 12¢ per lb for weights in Table 1.

144	"	....	5	....	4 500	6 000

Diameter of sheave, measured at bottom of tread, depends upon diam and type of rope. It should be as large as conditions will permit, considering economy of first cost with respect to life of rope. Makers' lists advise a minimum ratio of diam of rope to diam of sheave of 1 : 48 for 6 × 19, and 1 : 84 for 6 × 7 cast- and plow-steel rope. With these ratios, bending stresses are approx 10% of ultimate strengths of rope for crucible cast steel, and 8% for plow steel. For economical wear, the ratios should not be less than 1 : 75 for 6 × 19 rope and 1 : 125 for 6 × 7 rope; equivalent to a ratio of 1 : 1125 between individual wires and sheave diam. For flat ropes, diam of reel hub should be at least 80, and of sheave 150, times rope thickness.

U S Bur of Standards (13) recommends sheave diam for steel rope as follows: for 6 × 7 rope, 85 times diam of rope, 6 × 19 rope, 50 times diam of rope, and never less than 20; 6 × 37 or 8 × 19 rope, 30 times diam of rope.

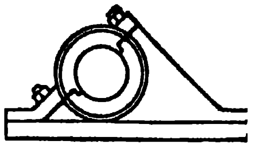

Fig 24. Sheave Bearing, 45° Type

6. VEGETABLE-FIBER ROPE

Materials, in order of strength: manila hemp, or fiber from *abaca* plant (sometimes erroneously called aloe), Baden split hemp, Russian and Italian hemp, American hemp, sisal, and cotton. Many grades of each material are used, price depending upon strength, length of fiber, and care in cleaning.

Construction. Hemp rope is of 3, sometimes 4 or more, strands, each composed of many fibers; which may be individual fibers, for very small rope, or yarn spun from a number of fibers. Original fibers rarely average over 3 ft long, so that strength of rope depends upon the binding action of the twisted fibers under tension, and friction between them. For same diam, 4-strand rope has greater wearing surface and strength than 3-strand. Manila rope is 25% stronger than sisal.

Strength. Following formulas (C. W. Hunt) give the relations between strength, size, and weight of rope:

$$T = 720\,C^2 = 7\,106\,d^2 = 22\,500\,W = 9\,048\,A$$
$$W = 0.032\,C^2 = 0.316\,d^2 = 0.000044\,T = 0.402\,A$$

T = ultimate strength, lb; C = circumference, in; A = nominal area, sq in; d = diam, in; W = wt, lb per ft.

C. Bach gives modulus of elasticity of rope as follows:

New manila, 1.97 to 2.17 in diam, loosely twisted,	113 806 lb per sq in
" " " " " hard "	135 145 " "
New Baden split hemp 1.97 to 2.17 in diam, loosely twisted	149 371 " "
" " " " " " hard "	177 822 " "

Table 2. Ultimate Strength and Weight of Best Manila Rope (av of different makers)

Diam, in	Wt per 1 000 ft, lb	No of ft and in in 1 lb	Ultimate strength, lb	Diam, in	Wt per 1 000 ft, lb	No of ft and in in 1 lb	Ultimate strength, lb

1 3/8	597	1–9	14 000 " 15 400	......	......	......	....

Uses. For mining in America fiber rope is used chiefly for windlasses, whims, and light crane and derrick work. Chief advantage for prospecting is that the rope is uninjured by kinks, which would destroy wire rope, and there are no projecting broken wires to injure workmen's hands. For same strength a 6-strand, 19-wire cast-steel rope is as flexible and weighs less than manila. The only advantage of tarring a rope is prevention of contraction and expansion in wet and dry weather. Tarring increases wt 20 to 25%, and decreases strength. Some makers apply a dressing of graphite and tallow or fish oil to the fibers, as the rope is made, to act as lubricant and prevent excessive internal wear, when rope runs over sheaves. In Belgium, flat vegetable fiber ropes are used for hoisting from deep colliery shafts. These taper in both width and thickness; ratio of width to thickness is constant, and is from 6.4 : 1 to 8 : 1. Manila rope is now rarely used, except for prospecting, winze hoisting, etc. Steel rope is always employed in shafts.

7. WIRE ROPES (14, 22, 24–29)

Materials are charcoal iron, Swedish iron, and various grades of cast steel. Iron ropes are still used for special purposes, but steel is practically universal for mining. General trade names are: "iron" (commonly meaning low-carbon steel), "cast steel," "extra strong cast steel," "plow steel," and "extra plow steel." Makers have various trade names for their extra plow-steel quality. Different tensile strengths are due to methods of manufacture and treatment of wire. Plow steel is lower in P and S, and higher in C and Mn, than crucible steel. Toughness of wire is obtained by tempering, and tensile strength is increased by repeated drawings, so that from same grade of steel the finer wires are stronger than the larger.

Modulus of elasticity in tension is 28 500 000 to 30 000 000 lb per sq in. Experiments with nickel and vanadium steel and other alloys for rope wire have not been successful.

Table 3. Ultimate Tensile Strength of Rope Wire, lb per sq in

Size of wire	Charcoal iron	Crucible steel	Plow steel
No 6 to No 8	80 000 to 85 000	120 000 to 160 000	200 000 to 240 000
No 9 to No 16	85 000 " 95 000	130 000 " 180 000	220 000 " 280 000
No 16 to No 18	95 000 " 98 000	150 000 " 190 000	240 000 " 300 000
No 18 and finer	98 000 " 115 000	180 000 " 200 000	260 000 " 320 000

Structure, or number and arrangement of wires in a rope, depends upon use for which it is intended. It is usually designated numerically by stating number of strands and number of wires per strand. Thus, 6-strand rope with 19 wires per strand is called a 6 × 19 rope, and one with 6 strands of 7 wires per strand, a 6 × 7 rope. Except for special purposes, the strands of all hoisting and running ropes are laid around a HEMP CORE, which absorbs and holds lubricant, and acts as a yielding cushion in which the strands may embed, thus preventing frictional wear when bending on sheaves and drums. The hemp center adds no appreciable strength. Ropes with a wire center are suitable only for standing ropes, lacking the flexibility necessary for hoisting or running ropes.

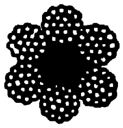

Fig 25

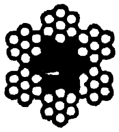

Fig 26

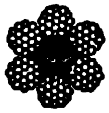

Fig 27

Wire core adds about 10% to wt and cost, but less than 10% to strength. ORDINARY TYPE comprises 6 strands of either 7 or 19 wires, with hemp center. In 6 × 7 rope each strand has 6 wires twisted around 1 wire (Fig 26). In 6 × 19 rope each strand has 12 wires around 6 wires around 1 wire (Fig 25). A modification known as "three-size wire," or WARRINGTON STRAND, has the 7 inside wires of one size, the outer 12 being alternately larger and smaller (Fig 27). This increases area of metal and strength about 10%. For same diam of rope, the 6 × 7 has wires of about 64% greater diam than the 6 × 19, and hence better withstands surface wear; but is less flexible, requiring larger sheaves and drums. Thus, 6 × 7 rope is used for slopes and inclined planes, where surface wear is great; 6 × 19 is best for vert shafts, and wherever flexibility is important. A 6 × 16 two-size wire rope is often used on slopes, as it wears better than a 6 × 19 and is more flexible than a 6 × 7. TWIST or LAY of the strands in a rope may be either right- or left-hand, right-hand lay being standard (Fig 28); Fig 29 shows left-hand lay. ORDINARY LAY rope has the strand wires twisted in opposite direction to twist of strands in the rope.

Fig 28

Fig 29

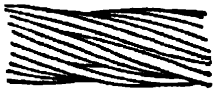

Fig 30

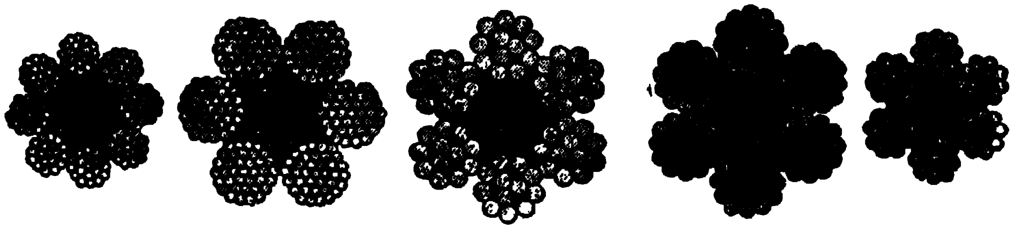
In a LANG LAY (sometimes called "Albert" lay) the strand wires are twisted in same direction as the strands (Fig 30), giving larger area to resist wear than ordinary lay rope. The latter is more elastic and resists shocks better, does not tend to untwist so much as Lang lay, and is preferable for hoisting with buckets, where spinning is objectionable. (A rope which no longer spins is termed "dead.") With Lang lay a broken wire may project farther and do more damage than in ordinary lay, but the rope is more easily inspected for internal wear and corrosion.



(a) (b) (c) (d) (e)

Fig 31. Special Forms of Wire Rope

LENGTH OF LAY (pitch of helix) of wires in a strand is 8 to 12 times the diam of strand; lay of strands is 7 to 9 times the rope diam. Long-lay rope wears better than short-lay, but short-lay is more flexible and elastic, and broken wires can not project so far. In 6 × 7 rope the diam of individual wires is $^1/_9$ diam of rope; in 6 × 12 and 6 × 19 rope the diam of individual wires average $^1/_{12}$ and $^1/_{15}$, respectively, of rope diam. This is for new rope; after use, the rope wears smaller, and strands pack into the core, so that the ratio is increased.

Special ropes. Extra flexible, 8 strands of 19 wires, with hemp core (Fig 31, *a*). Special flexible, 6 strands of 37 wires, with hemp core, for use on small drums and sheaves (Fig 31, *b*); also 6 strands of 12 wires (Fig 31, *c*). Tiller rope, 6 strands, each being a complete 6 × 7 hemp-center rope; for use where extreme flexibility is necessary and where there is but little abrasion. Steel hawser, 6 strands, of 12 wires in a single layer about a hemp center (Fig 31, *d*); usually galvanized, and suitable only for standing rope or tow lines. Seale lay rope (Fig 31, *e*), 6 or 8 strands of 19 wires, each having an outer layer of 9 wires, about an inner layer of 9 smaller wires, about 1 central wire; wears well, and is intermediate in flexibility between 6 × 7 and 6 × 19 standard rope. Flattened-strand ropes are of two forms: one has 5 strands about a hemp core, each strand having 1 oval center wire, surrounded by 8 wires (Fig 32, *c*), or 2 layers aggregating 27 wires (Fig 32, *a*), the outer wires being the larger; the oval wire is sometimes replaced by 3 small wires. The other forms in Fig 32 have 6 strands, each composed of a central triangular wire, surrounded by 7 wires (*d*), or an outer layer of 12 wires, on an inner layer of 12 smaller wires (*b*). These ropes are as flexible as 6 × 7 and 6 × 19 standard rope of same diam. The center or "form" wires in the strands are of soft metal, and no account is taken of their strength. The shape of these strands exposes a larger wearing surface than the ordinary lay, with probable increase in durability. Flattened-strand ropes are always Lang lay, and about equal in strength to standard rope of same quality of wire.

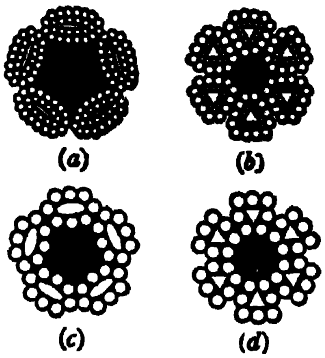


Fig 32. Flattened-strand Wire Ropes

Flat ropes have been used to some extent for equalizing load in deep shafts (Art 2), but few are now in service. They consist of a number of 4-strand, 7-wire round ropes, without cores, side by side, and sewed together with soft iron wire. Ratio of width to thickness depends chiefly on number of component round ropes. The latter are alternately right and left lay, to counteract tendency to twist. The lay of their strand wires, and of the strands themselves, is longer than in standard round rope. Flat ropes are usually ripped apart, cleaned, and re-sewed 1 to 4 times before being discarded; records at a mine in Montana show 3 to 4 re-sewings in a total life of 2 years.

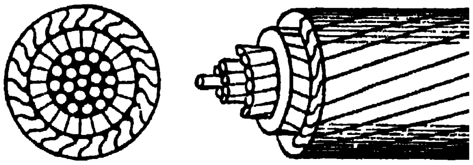

Fig 33. Locked Coil Track Cable

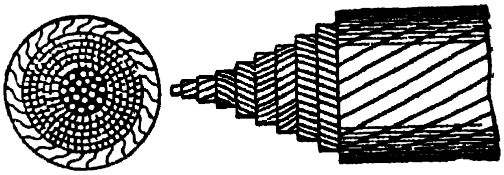

Fig 34. Locked Coil Hoisting Rope

Locked-coil rope (Fig 33, 34) has no strands, the specially shaped wires being in layers, having alternately opposite lays, about a wire core. The rope in Fig 34 has the larger number of wires, of smaller gage; hence more flexible than that in Fig 33. The surface wires interlock, so that if one breaks its ends can not project. But, when outer wires are worn slightly smaller by abrasion, broken ends begin to project, and the rope is rapidly destroyed. Entire surface of the rope is available for resisting wear. Inspection of condition of interior wires is practically impossible. These ropes are not suitable where exposed to action of acid mine water, and have rarely been employed for shaft hoisting in the U S; chief use is for track cables of aerial tramways (Sec 26). In So African shafts they sometimes serve as guide ropes.

Taper ropes, formerly used to some extent in Europe and So Africa, are now rare. In the U S a few have been employed in drilling deep bore holes; none for shaft hoisting. There are two forms: in one the rope has same number of wires throughout, the taper being effected by brazing on wires of smaller diam, no two brazes coming at same point; in the other, one or more wires at a time are cut off, at regular distances.

Preformed wire rope (15, 16) consists of preformed strands. Advantages claimed are: resistance to kinking, no spinning, broken wires lie flat, ease of splicing (as it will not untwist), and use of processed fittings, small initial stresses in the rope. John A. Roebling's Sons claim no material increase in strength for their preformed rope.

Tests of rope wire are for tensile strength, per cent of elongation at rupture, torsion and flexure. Bending of a wire through 90°, and back to original position, around a radius equal to diam of the wire is considered one flexure. U S Govt specifications give following test for torsion (13): Steel wire when uncoated shall

Material	Min number 360° turns
Cast steel	2.6 + diam of wire, in
Extra strong steel	2.4 + diam of wire, in
Plow steel	2.2 + diam of wire, in
Extra plow steel	2.0 + diam of wire, in

not break when one end is held and the other rotated the number of complete 360° turns stated in table. Distance between jaws of testing machine, 8 in. For importance of fatigue and wearing tests see (12), and Boomsliter (14) states that the ability of steel to withstand repeated stress decreases greatly when stress exceeds elastic limit. Adams (22) states that a high fatigue limit is not the most important property of hoisting rope wires, because they are destroyed by overstressing and wear.

Strength of wire rope can not be taken as the sum of strengths of individual wires, because of their angular position with respect to rope's axis, and difficulty of making the rope and attaching fastenings so that each wire will take its proportionate load. In standard round rope each wire at some point makes an angle of about 28° with the rope's axis, so that the useful strength of the wire is its actual strength multiplied by cos 28°, or 0.883. Strength of the rope is therefore about 88% of aggregate strength of the wires. Tests by U S Govt indicate that ultimate strength of 6 × 7 rope is 90 to 92%, and of 6 × 19 rope 80 to 85%, of ultimate strength of the wires. Tables 4 and 5 (American Cable Co) give wt, approx breaking strength, list price and minimum sheave diam for 6 × 7 and 6 × 19 standard ropes (1932). Data from John A. Roebling's Sons are approx the same, with slight differences in prices.

1/4	09	.10 1/2	.12	13	.10	2 1	2 3	2.5	2 9

Note—For galvanized rope, add 25% to list price; for rope with wire-strand center, add 10%; for independent wire center (any construction), add 15%.

Stresses in hoisting rope are due to dead load, accelerating force, starting factor for slack rope, friction and bending stresses, depending on sheave diam, kind of construction, kind and size of wire.

Dead-load stresses. Let W = wt of 1 cage and empty car or 1 skip; w = wt of ore; Wr = wt of 1 rope; a = acceleration, ft per sec per sec; F_1 = accelerating force in ascending rope; F_2 = accelerating force in descending rope; g = acceleration due to gravity; then

Dead-load stress $$W + w + Wr \qquad (16)$$

Accelerating stress in ascending rope, F_1 $$\frac{(W + w + Wr)}{g}\,a \qquad (17)$$

Accelerating stress in descending rope, F_2 $$\frac{W a}{g} \qquad (18)$$

Boomsliter (14), Perry & Smith (23), Hogan (24), and others show that acceleration stresses in hoisting are much larger than usually assumed, because the elastic properties

Note—See under Table 4.

of rope introduce considerable periodic acceleration stresses. Boomsliter gives following formulas:

$$S\ (\text{max}) = W\left[1 + \frac{a}{g} + \frac{\sqrt{a^2 + 2ag\,(m+1)}}{g}\right] \tag{19}$$

S (max) = greatest stress in rope when upper part is uniformly accelerated; m = ratio of slack or stretch in rope to its stretch under wt of cage; W, a and g, as above. If no stretch or slack is assumed, then

$$S\ \text{max} \tag{20}$$

Compensation for slack rope by the use of springs is of little value. Following dynamometer tests show effect of slack; total length of rope below sheave not stated.

Bending stress. Its effect and amount is a controversial question, on which authorities differ (12, 17). Practice tends to as large sheaves and drums as possible. With ample safety factor, the computed bending stresses and other more or less indeterminate factors are often disregarded. Reasons for uncertainty respecting bending stresses are: differences of opinion as to whether modulus of elasticity of the rope or of the wire should be used (although that of the rope is generally conceded to be correct); and doubt as to correctness of published data on moduli. Assuming that the modulus of elasticity of the rope should be used, and that published values are correct, then bending stress is expressed by: $S = E_R(d \div D)$, in which S = stress in wires due to bending, lb per sq in; E_R = modulus of elasticity of rope; d = diam of largest wire, in; D = diam of bend over sheave or drum on center line of rope, in. If A be aggregate area of wires (sq in), and S_R bending stress in rope (lb), then for any rope the total bending stress is:

$$S_R = E_R \times (dA \div D). \tag{21}$$

Table 6 gives values of A for standard 6 × 7 and 6 × 19 rope. American Steel and Wire Co give E_R = 12 000 000 maximum for new 6-strand rope. Various authorities give E_R = 35% of the modulus of elasticity of steel wire = 10 150 000. According to A. W. Brown (18), 11 180 000 is a good aver of E_R for the entire rope, after it has been in use long enough for the strands to bed into the core; 19 000 000 being modulus for old rope. Boomsliter (14) states that stressing wire rope to $^2/_3$ of the ultimate strength results in modulus reaching values between 14 000 000 and 18 000 000.

In Eq 21, $A = 42 \times 0\ 25\ \pi d^2$, and if d_R = diam of rope, then $d = d_R \div 9$ for 6 × 7 rope. Substituting, and taking E_R = 12 000 000 for 6 × 7 rope, $S_R = 542\ 880\ (d^3{}_R \div D)$.

For 6 × 19 rope, $A = 114 \times 0.25\ \pi d^2$, $d = d_R \div 15.50$ and $S_R = 288\ 000\ (d^3{}_R \div D)$.

For 6 × 37 rope, $A = 222 \times 0.25\ \pi d^2$, $d = d_R \div 21.7$ and $S_R = 204\ 000\ (d^3{}_R \div D)$.

For 8 × 19 rope, $S_R = 172\ 500\ (d^3{}_R \div D)$.

Fig 35 (American Steel and Wire Co) shows bending stresses in 6 × 19 rope, as calculated by above formulas.

Frictional stresses F may be assumed as 1% of sum of dead load and acceleration stresses and are often neglected.

Total rope stresses may now be expressed as follows, wl being wt of rope:

$$P = S_r + \left[W + wl + a \times \left(\frac{W + wl}{g}\right)\right] \tag{22}$$

Factor of safety. Past practice has been to use safety factor of 3.5 to 4 for hoisting ore and 6 for men, when stresses are determined as in Eq 22. U S Bur of Mines (19) recommends a factor depending on LENGTH of rope (Table 7). Mining Regulations of Transvaal require factor of 6, bending and accel stresses being disregarded, but Vaughan (1) recommends making exception to this for deep shafts, especially if "capacity factor" (breaking load of rope ÷ load at lower end of rope) is above 12. R. B. Greer (20) recommends a sliding-scale factor of safety for depths exceeding 2 500 ft, since the elasticity of a long rope in part compensates the stresses due to starting with slack rope, the wt of cage and contents and bending stresses being practically constant for all depths. Conference on Wire Rope (21) brought out the fact that rope with a safety factor of 2.1 had a 6-month life as against 7 years with a 10.7 factor. It is evident that the relation of safety factor to life of rope should be seriously considered.

Rope design. Present practice is to determine values of W, a, and L for working conditions. Assume a rope size and drum diam. Then from makers' tables (or Tables 4, 5) and Eq 21 determine wl and S_r. Apply these in Eq 22, and determine P, total stress in rope. Multiply by safety factor required, and compare with ultimate strengths in tables, selecting rope of a strength nearest that calculated. With this size rope, recalculate bending stress and wt of rope, and check result. There is no fixed economical ratio between bending stress and load. In shallow shafts, the bending stress may economically be 0.33 to 0.40 of total rope stress; but in deep shafts such a ratio leaves too little of the rope's strength for net load, after wt of rope is deducted. Boomsliter (14) recommends rope design based on the empirical formula:

$$S\,(\text{max}) = W\,(1.5 + 0.1\,a) \tag{23}$$

Table 7. Hoisting Rope Safety Factors for Various Depths of Shaft

Length of rope, ft	Minimum factor, new rope	Min factor when rope is discarded
500 or less.......	8	6.4
500 to 1 000.....	7	5.8
1 000 to 2 000....	6	5.0
2 000 to 3 000....	5	4.3
3 000 and more...	4	3.6

Example. Assume wt of load W = 21 600 lb; wt of 1 3/4-in rope wl = 2 160 lb; acceleration a = 8 ft per sec per sec. Then, from Eq 23, $S\,(\text{max}) = 21\,600\,(1.5 + 0.1 \times 8) = 49\,700$ lb

Friction (approx)..	500
Bending stress, 1 3/4-in rope on 8-ft sheave...........................	14 960
Total stress..	65 160 lb

With safety factor of 4, 260 640 lb is the ultimate strength of rope required; satisfied with a 1 3/4-in extra strong plow-steel rope. Using Eq 22 and the same values:

$$P = 14\,960 + \left[21\,600 + 2\,160 + 8\left(\frac{21\,600 + 2\,160}{32.2}\right)\right] = 44\,660 \text{ lb.}$$

With safety factor of 4, the ultimate strength of rope required is 188 600 lb, a smaller figure than obtained from Eq 23. In view of evidence as to increased life of rope with large safety factor formula 23 should be seriously considered.

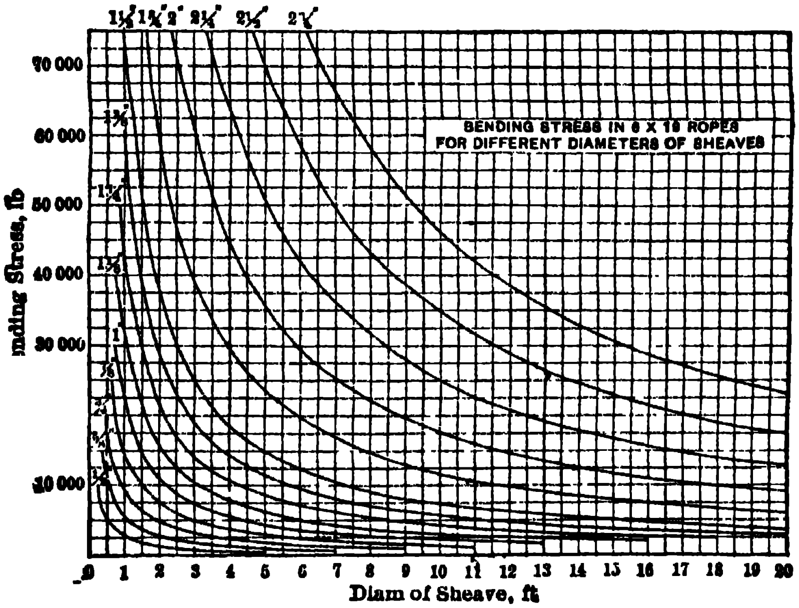

Fig 35. Bending Stresses in Hoisting Ropes

Choice of rope requires knowledge of the working conditions. Steel is always better than wrought iron, and plow or extra crucible steel preferable to ordinary steel. For same strength, a plow-steel rope may be used on smaller sheaves than wrought-iron rope, and on sheaves of same diam as for ordinary steel rope. For the same ultimate strength, plow-steel rope costs 10 to 12% more than cast steel; while, for same wt, plow steel is stronger by from 10% for small sizes to 35% for the larger. Hence, for heavy loads and deep shafts, where rope wt is a large part of total load, plow- or extra plow-steel rope should be used, bending stresses being the same for cast- and plow-steel rope of the same diam.

For slopes, inclines, and rope haulage, 6 × 7 rope wears better than 6 × 19, and Lang lay is preferable for endless-rope haulage where car grips are used. For vertical shafts, 6 × 19 ordinary lay is standard U S practice. In shafts where men are hoisted it is psychologically desirable to use rope not smaller than $^3/_4$ in, regardless of the actual strength required.

Ropes of special construction (Fig 31, 32) are rarely used for mine hoisting in the U S, though present practice seems to tend toward round, preformed rope. Flat rope is obsolescent here, although retained where original reel hoists are in operation. In Butte District, Mont, 9 out of 24 hoists listed (34) use flat rope. Present tendency in the Transvaal is towards ordinary round rope (30). In England the tendency in 1922 was to replace Lang-lay rope by flattened-strand or locked-coil (32).

Wear and durability of rope depend upon diam of sheaves and drums, speed, conditions causing wear or abrasion of the outside wires, and conditions causing corrosion. These qualities are practically independent of the load, so long as it is within elastic limit of the wires. Large diam of drum and sheave increases life of rope; when too small, the rope's outer wires break sooner. High speed causes rapid wear; excessive vibration causes fatigue and crystallization of the steel. If sheaves have rough grooves, and if fleet angle is large, wear on surface wires is severe, due to chafing of the rope on sheave flanges and between the rope coils on ungrooved drums. Internal wear and corrosion depend upon efficiency of lubrication, and whether the mine water is acid. In dry shafts, if rope is well lubricated, and sheaves and drum are of proper size, corrosion and wear of interior wires is negligible. In wet shafts, where water is acid, corrosion of wires determines the rope's life.

Rope life may also be increased (24, 30) by: (*a*) using electric hoisting engines, with Ward-Leonard control (Art 13), to insure smooth acceleration and retardation with consequent small increase in kinetic stress; (*b*) having braking electrically controlled and mechanically governed, to minimize stresses.

Precautions should be taken to prevent abrasion and reverse bends. Plow steel resists abrasion, fatigue and severe shocks better than the lower grades of cast steel, and is always best for heavy service or where great strength is necessary, as in deep shafts. Deflecting sheaves and rollers on slopes and haulage ways should be properly alined, free running and as light in wt as is consistent with strength. Soft rubber makes good wearing surface for rollers. Diam of turn-sheaves and rollers should be at least: 0.8 × deflection angle × diam of rope (19).

Summary of work of 22 hoisting ropes, each 1 $^3/_8$-in diam, at Robinson Deep Gold mine, Transvaal; 19 of the 22 ropes were 6 × 19 Lang lay. Diam of wires, from 0.072 to 0.125 in; aggregate area, 0.6897 to 0.735 sq in; tensile strength of wires, 235 200 to 280 000 lb per sq in, average 259 500 lb. Average aggregate strength of wires was in all cases greater than makers' guarantee, average excess being 7.2%. Initial safety factors ranged from 6.35 to 11.2, aver 8.15. Ropes were discarded when factor fell below 6. Weights, from 2.84 to 3.16 lb per ft. After 6 months' use reduction in breaking strength, from initial aggregate strength of wires, varied from 9.3 to 33.5%. WORKING LIFE ranged from 139 to 706 days; work in ft-tons, from 341 058 789 to 1 551 805 722; distance run, 13 702 to 80 860 miles. Lowest cost per ft-ton, 0.0000824¢, was with a medium priced rope. The 2 ropes showing SHORTEST LIFE were identical, each Lang lay, 6 × 19; 2 diams of wire were used in the strands, 0.114 and 0.076 in; tensile strength of wires, 257 600 lb per sq in; safety factor, 11.2. Work done by each rope was 479 297 244 ft-tons; distance run, 21 790 miles; cost per ft-ton, 0.0001708¢. BEST PERFORMANCE was by a rope not included in the above. This was a 6 × 19 Lang lay, all wires being 0.094 in diam, with total area of 0.7912 sq in. Tensile strength of wires, 274 000 lb per sq in; reduction of initial strength after 6 months was 35%. Initial safety factor, 7.08. At end of 357 days the work done was 1 669 935 634 ft-tons; distance traveled, 57 488 miles; cost per ft-ton, 0.000073¢. Lowest cost per ft-ton is apparently obtained from a high-class heavy rope, carrying a heavy load and working steadily (25).

Hoisting rope practice and care. Much information regarding care and use of ropes is given by Kudlich, Hood, and others (17, 19, 25). Avoid kinking or nicking the wires during installation and use. Frequent inspection is essential. Where men are hoisted, a brief inspection should be made daily, and a thorough inspection weekly. If the rope socket or capping is attached directly to cage, and landing chairs are used, the rope close to the socket will often first show wear or broken wires, because slack rope may cause sharp bends at that point. When this occurs, a few feet of rope should be cut off at regular periods, and a new socket joint made. If there is enough headroom, a few feet of chain between rope socket and cage draw-bar is advantageous, and in some cases required by law. Changing the rope end for end, at the expiration of half its useful life, is also recommended, so that if wear occurs at any particular point, it will be distributed over a greater length of rope.

Lubrication must be efficient, to prevent wear and corrosion of wires and to minimize surface abrasion. In severe service proper lubrication will lengthen a rope life's 75 to 100% (26, 27, 28, 29). The core should never be allowed to become dry enough to absorb moisture. A good lubricant should be chemically neutral, and of such character and consistency that it will penetrate the strands to the core; it should not run nor drip off, nor be so thick and sticky as to form lumps on the rope or in sheave grooves. Some lubricants, apparently good at first, soon harden and flake off, especially in cold climates. Raw linseed oil is good, but runs off easily. More body is given by adding lampblack or fine flake graphite. Mixtures of pine tar and tallow, or coal tar with slaked lime to neutralize acid, are sometimes used. But all tar mixtures are objectionable, because in cold climates they do not penetrate the rope for lubricating interior wires, and tend to form a hard, gummy coating, likely to strip off. Petroleum jelly or vaseline mixed with fine flake graphite and applied hot is good. Rope makers have rope dressings for different conditions. Lubricant should be applied at intervals of say 1 to 3 weeks, depending on conditions; the rope being first cleaned of dirt and gummed lubricant, by passing it through a bath of hot kerosene and scrubbing with stiff-wire brushes (Fig 35a).

Fig 35a. Lubricating Devices for Wire Rope (37)

Splices are not permitted in hoisting ropes used for raising or lowering men; but for haulage, aerial tramway, and power transmission rope, splices may be made practically as strong as the rest of the rope (Fig 36).

For running rope, the splice should be at least 20 ft long for 0.5-in rope, increasing to 30 or 40 ft for 1.25 and 1.5-in rope. Tools required are: hammer and sharp cold-chisel, pair of strong nippers, steel marlin spike, 2 rope clamps (or small hemp rope slings with sticks, Fig 36, *e*), a knife and a pair of 2-lb copper or lead mallets. A bench vise is convenient. To splice (Fig 36): 1. Overlap the rope 20 ft or more, and mark center of lap on each end with string or chalk (*a*). 2. Unlay each end to center mark, and cut off hemp core (*b*). 3. Interlock the 6 unlaid strands of each end alternately, and draw together until center marks meet (*c*). 4. Unlay a strand *A* from one end, and follow it closely with opposite strand 1 of other end, laying it into the groove left open by *A*, and proceeding thus until all but 12 in of strand 1 are laid in (*c*); then cut off *A* an equal length and tie the strands temporarily in place. 5. Treat similarly strands 4 and *D*, and so on for each pair of opposite strands, stopping each pair about 1/5 of the length of splice short of the preceding pair (*d*). 6. Bend the rope back and forth until all strands are set in place and have equal tension. 7. Wrap ends of strands with friction tape, or strips of sheet lead, and straighten them. 8. With the vise and clamps, untwist and open the rope at one strand of the end pair; cut the hemp core at the center, draw it out slowly and follow it up with the strand until the latter occupies the center (*f*). Cut off core at end of this strand. Tuck in the other strand of the pair, being careful that their ends do not cross each other. 9. Twist the clamps back to close up the rope, and hammer the strands with the mallet to fix them firmly in place. 10. Shift the clamps and repeat operation at the other 5 pairs of ends, and the splice is complete.

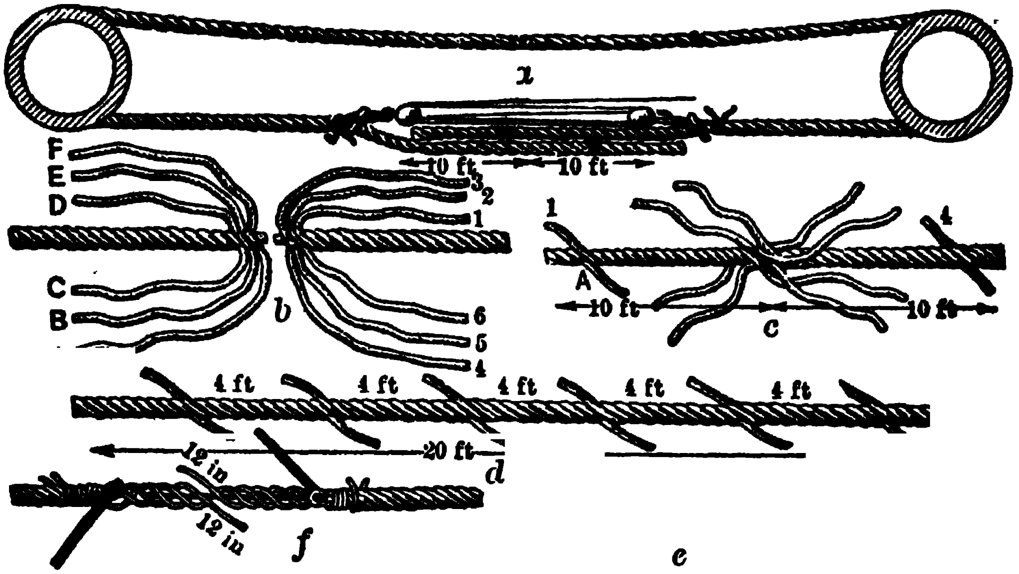

Fig 36. Splicing Wire Rope

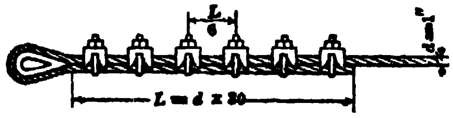
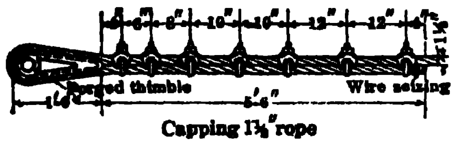
Rope fastenings to cage or skip should develop as nearly as possible the rope's full strength. The attachment is by means of a coned socket (Fig 38, 39), or the rope may be bent back on itself to form an eye containing a thimble, the loose end being fastened by clips or clamps (Fig 37). The coned socket, when properly made, develops full strength of rope, but has 4 disadvantages: considerable skill is required, poor workmanship is concealed, condition of wires in socket can not be inspected, and bending due to slack rope is concentrated just above the socket.



Capping 1" rope



Capping 1⅛" rope

Fig 37. Correct Method of Capping Wire Ropes (*Trans* A I M E)

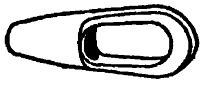


Fig 38. Closed Coned Socket

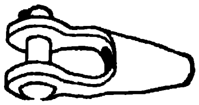

Fig 39. Open Coned Socket

Fastening by clips can always be inspected and requires little skill in making, but gives at most only 85% of strength of rope, and often damages rope at points where clips are applied. Rope makers recommend socket fastening; if properly made it never fails. Special forged or cast-steel thimbles or eyes, instead of usual pressed steel, should always be used for clip attachment of hoisting ropes.

Coned socket is of 2 types, closed (Fig 38) and open (Fig 39). They should be of best W-I or steel forgings, without welds, and accurately bored.

Details of attaching ropes. Bureau of Mines recommends following methods (23). CONED SOCKET: The rope is securely seized at end with soft iron wire, before end of rope is cut square; with another seizing a distance back equal to length of socket from the end. After rope is trimmed off, the end seizing is removed, the rope opened down to second seizing, hemp center cut out and wires broomed out; that is, they should be untwisted but not straightened. Then the wires are thoroughly cleaned in benzene or gasolene, as far as they are to be inserted in socket, and dipped in commercial H_2SO_4 for 30–60 sec, to clean the wires. Next, the rope end is dipped in boiling water, containing a little soda to neutralize the acid. Rope end is then inserted in socket and warmed, if temp is below 65° F, to prevent cooling the zinc-filling too rapidly. Finally, the socket is placed with its axis vert and coinciding with axis of rope, the bottom is sealed with clay or putty, and molten zinc or spelter, heated to a temp that will just char wood, is

Diam of rope, in	No of clips	Length of wrench, in	Effic, %
3/4	5	18	77.39
7/8	5	18	79.13
1	5	24	77.89
1 1/8	5	24	80.00
1 1/4	6	24	82.15

poured into the socket until full. CLAMP ATTACHMENT: The rope is bent back over the thimble, and loose end clamped with proper number of clips. Crosby type of U-bolt-and-drop-forging clip is most satisfactory. Clips are spaced a distance equal to 6 times the rope diam, the forging being against long end and the U-bolt against loose end of rope. Number of clips to develop approx 80% effic of the rope, and proper length of wrench to tighten bolts, are given in above table. Clips must be carefully inspected each day, and tightened if they show signs of loosening by stretching of the rope.

Wire rope clamps, for attaching bridle or safety chains to rope, above socket, are more commonly used at coal than at metal mines; laws of most coal districts require them. Vulcan Iron Works makes the clamps shown in Fig 40. They are usually of cast steel, but forgings are better. They are grooved to fit the rope closely, and the bolts should be finally tightened after the rope is under tension. Tests on such clamps show the ultimate strength against slipping to be about 10 000 lb per sq in of area of the bolts.

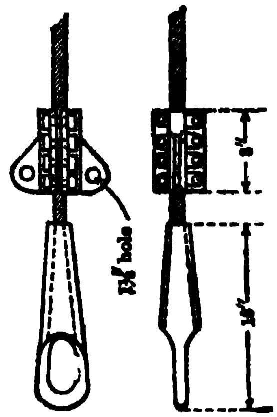

Fig 40. Rope Clamps for Bridle Chains

8. DATA FOR CALCULATING HOISTING-DUTY CYCLE (3, 33, 35)

(1) Weight and kind of material per trip.

(2) Wt. of cage or skip (plus man-cage if used), cars hoisted per trip and weight of car.

(3) Diam and wt of rope (Art 7).

(4) Max tonnage per hr and per shift; number of hr per hoisting shift and number of shifts per day. Approx distribution of tonnage between levels.

(5) To select rope speed, determine the max number of trips per hr required from stated level, also time for loading and dumping. If a cage hoist, state whether the cage is landed at collar and car run off, or car is dumped by a self-dumping platform cage.

(6) Is the "slack-rope system" of hoisting used (Art 1)? If so, give length of slack and working details.

(7) Present and ultimate length of travel from loading levels to the dump or to uncaging position. Estimated time before shaft will be sunk deeper.

(8) Shallowest and deepest levels, that is, length of travel as in (7), from which hoist may be required to operate at full load for an hour or more consecutively.

(9) If shaft is inclined, give angle of inclination with horiz, or per cent grade. If it varies, give inclination and length of each stretch. Per cent grade is generally taken as: vert rise ÷ length along incline.

(10) Is hoist balanced or unbalanced? If normally balanced, when will operation be necessary with cages out of balance? Can rope speed or load, or both, be reduced for unbalanced operation if desirable? Number of unbalanced trips required in succession?

(11) To what extent and for what reasons will partial speed operation be necessary? At what loads and speeds? Duration and frequency of such operation.

(12) Will men be handled? If so, at what speed? Always in balance or sometimes out of balance?

(13) Double or single drum, fixed or clutched?

(14) Diam of drums. Width of face or number of layers of rope? If not cylindrical, furnish sketch of drums, with working diameters and number of active rope turns on each part of drum. If reel, give minimum working diam and thickness of rope.

(15) If an existing hoist, give WR^2 (Fig 16) of drums, or equivalent wt at a stated radius. If a new hoist, state makers' name, or give WR^2.

(16) Is motor or engine geared or direct connected to drum? If geared, how many reductions?

(17) For elec drive, state voltage, frequency and number of phases of supply.

(18) Capacity and character of generating station or system.

(19) Is flywheel equalization required, and for what reason? If power is purchased, obtain a copy of all clauses of proposed contract covering reservation and kw-hr charges.

(20) If hoist is to be installed underground, give dimensions and wt of largest piece that can be lowered in mine shaft and drifts.

(21) Is location dry, damp, or wet?

(22) If above 3 000 ft elev, give altitude of hoist house above sea level.

(23) If an old hoist is to be electrified, give full details; also drawings or sketches of hoist, and photographs if possible.

(24) If overwind protection is contemplated, state max rope travel above top landing or dump before damage can occur.

Table 8. Formulas for Calculating Hoist Load Diagrams. Cylindrical Drum Hoists for Vertical or Inclined Lifts (Gen Elec Co)

Period	Symbols (Fig 40a)	Balanced hoisting	Unbalanced hoisting	Unbalanced lowering (loaded)*
Hp acceleration (max)	(1)	$+\dfrac{Wv^2}{32.2 \times 550 \times t_a}$	$+\dfrac{W'v^2}{32.2 \times 550 \times t_a}$	$+\dfrac{W'v^2}{32.2 \times 550 \times t_a}$

Hp rope friction, inclined only		(7c)	$+\dfrac{w_r \times 0.10\, v \cos\phi}{550}$	$+\dfrac{w_r \times 0.10\, v \cos\phi\ ^{**}}{550}$	$+\dfrac{w_r \times 0.10\, v \cos\phi \times {}^{**}}{550}$

* For lowering empty unbalanced cage, omit w throughout. ** At bottom of incline only. Value is zero at top.
‡ For normally balanced hoists operating out of balance use approx 70% of 7a.

(25) Give full information as to local conditions, and unusual requirements or details not covered by the foregoing.

9. CYLINDRICAL DRUM HOIST

A typical load diagram for hoisting in balance with cylindrical drums is shown in Fig 40a. For the power components, see Table 8, the symbols corresponding with those in Fig 40a. The resultant power values for each point of the diagram are obtained by combining the components listed in Table 8 as follows:

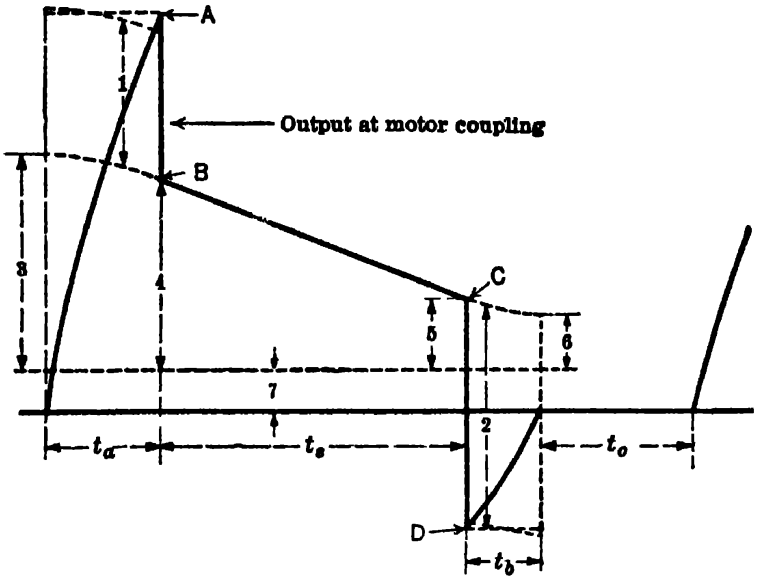

Fig 40a. Load Diagram for Cylindrical Drums and Balanced Hoisting. Horiz broken line at A shows aver motor torque required during acceleration and retardation (Gen Elec Co)

$$\text{Hp at } A = (1) + (7) + \frac{(4) + 2 \times (3)}{3};\ \text{Hp at } B = (4) + (7);\ \text{Hp at } C = (5) + (7);$$

$$\text{Hp at } D = (2) + (7) + \frac{(5) + 2 \times (6)}{3};\quad (2) \text{ is always negative, and } (7) \text{ always positive.}$$

If D is negative, motor or brakes must absorb power during retardation. If D is positive, motor must deliver power during retardation. Power requirements during retardation may be positive, negative, or zero, depending on relative values of dead load, inertia of moving parts, and time assigned for retardation.

The above calculations may be checked as follows:

a. Ratio of net work done during the lift (in hp seconds) to net work represented by the output duty cycle (in hp seconds) should equal the mechanical efficiency.

b. The hp seconds for acceleration and retardation should be equal.

List of Symbols in Table 8:

w = wt of material handled, lb

w_s = wt of one skip (or cage and car), lb

w_r = wt of rope per side, lb

w_a = wt of rope per side wound on during accel = 0.5 − (vt_a × wt per ft)

w_b = wt of rope per side wound on during retard = 0.5 (vt_b × wt per ft)

w_{ro} = w_r + wt dead rope turns + wt rope between drum and skip

W_o = equiv wt of revolving parts (for balanced or unbalanced operation, as case may be), reduced to drum radius, including gears, drums with clutches, headsheaves, but not including motor armature (Fig 40*a*)

$W = w + 2w_s + 2w_{ro} + W_c$ (balanced hoisting)

$W' = w + w_s + w_{ro} + W_o$ (unbalanced hoisting)

v = max rope speed, ft per sec

$$= \frac{L}{t - 0.5(t_a + t_b)}$$

t = time of one-way trip, excluding stops (found from hourly tonnage) $= \frac{L}{v} + 0.5\,(t_a + t_b)$

t_a = accelerating time, seconds

t_s = full speed time, seconds

t_b = time of retardation, seconds

t_o = time at rest

L = total travel of cage or skip, ft

ϕ = angle of slope with horiz

E = mechanism effic, expressed as a decimal, includes drums, gears, sheaves and guides for vert shaft, but not including rolling or rope friction on slope or inclined shaft

Effic of hoisting mechanism, in per cent, is as follows:

$$\begin{array}{cccccc} & \text{First motion} & & \text{Second motion} & & \text{Third motion} \\ E = & \dfrac{w}{w+kW''} & = & \dfrac{0.95\,w}{w+kW''} & = & \dfrac{0.90\,w}{w+kW''} \end{array}$$

where $W'' = (w + 2w_s + w_r)\sin\phi$ (for balanced vert and inclined shaft hoists)

$= (w + w_s + 0.5\,w_r)\sin\phi$ (for unbalanced vertical and inclined shaft hoists)

$= (w + 2w_s + w_r)\sin\phi + (w + 2w_s)\,0.02\cos\phi + 0.10\,w_r\cos\phi$ (for balanced slope hoist)

$= (w + w_s + 0.5\,w_r)\sin\phi + (w + w_s)\,0.02\cos\phi + 0.05\,w_r\cos\phi$ (for unbalanced hoist). See notes under Table 8

$k = 0.05$ for vert and inclined shaft hoists

$k = 0.04$ for slope hoists

Car or rolling friction. Recommended conservative figure for aver conditions is 2% or 40 lb per ton pressure normal to the track = actual wt × $0.02\cos\phi$.

Rope friction is taken as 200 lb (10%) per ton of normal pressure.

10. MOTOR CAPACITY

Rating of the motor, usually determined by the "root mean square" (RMS) of the duty cycle, which represents the max continuous load requirements, is as follows, the letters corresponding to those in Fig 40*a*, except that *A* and *D* include the hp required to accelerate and retard the motor rotor.

For induction motor:
$$\text{RMS hp} = \sqrt{\frac{A^2 \times t_a + \dfrac{B^2 + C^2 + BC}{3} \times t_s + D^2 \times t_b}{\dfrac{t_a}{2} + t_s + \dfrac{t_b}{2} + \dfrac{t_o}{4}}} \tag{24}$$

For direct-current motor:
$$\text{RMS hp} = \sqrt{\frac{A^2 \times t_a + \dfrac{B^2 + C^2 + BC}{3} \times t_s + D^2 \times t_b}{\dfrac{3t_a}{4} + t_s + \dfrac{3t_b}{4} + \dfrac{t_o}{2}}} \tag{25}$$

Since the RMS of the duty cycle, which together with the overload requirements establishes the rating of the motor, can not be accurately worked out until the inertia of the armature (rotor) is known, it is customary to estimate this after a preliminary determination of the motor rating, either by inspection of the cycle or from the RMS calculated with the armature effect omitted. It is impossible to devise any general rule by which the motor-rotor inertia can be accurately predetermined for every case, but in absence of actual values, the following is offered for estimating.

Max hp required to accelerate motor rotor in 1 second: For induction motors and, geared d-c motors, hp = 150% to 180% of normal rating. For direct coupled d-c motors, hp = 80% to 125% of normal rating. In general, the lower values apply to lower speed motors and vice versa, but in individual cases these values may vary considerably from the actual. When the WR^2 of the armature is known the max hp to accelerate is:

$$\text{hp} = \frac{WR^2 \times \text{rpm}^2 \times 0.62}{1\,000\,000 \times t} \tag{26}$$

t being time of acceleration in seconds.

11. CONICAL DRUMS AND REELS

Factors for computations:

w = wt of material hoisted, lb

w_s = wt of one skip (or cage and car), lb

w_r = wt of rope per side, lb (Art 9)

w_h = wt of one head-sheave, lb (effective)

r_1 = smallest working radius of drum, ft

r_2 = largest working radius of drum, ft

r_{ua} = radius of up side at end of accel = $r_1 + pT_a$

r_{da} = radius of down side at end of accel = $r_2 - pT_a$

r_{ub} = radius of up side at beginning of retard = $r_2 - pT_b$

r_{db} = radius of down side at beginning of retard = $r_1 + pT_b$

p = radial pitch per rev, ft (for reels = thickness of flat rope)
T = total active turns on drum (one side)
T_a = revolutions during accel = $0.5t_a \times rps$
T_b = revolutions during retard = $0.5t_b \times rps$
T_s = revolutions during full speed run = $T - (T_a + T_b)$
w_{ua} = wt of rope wound on during accel = $\pi\, T_a\,(r_1 + r_{ua}) \times$ lb per ft
w_{da} = wt of rope wound off during accel = $\pi\, T_a\,(r_2 + r_{da}) \times$ lb per ft
w_{ub} = wt of rope wound on during retard = $\pi\, T_b\,(r_2 + r_{ub}) \times$ lb per ft
w_{db} = wt of rope wound off during retard = $\pi\, T_b\,(r_1 + r_{db}) \times$ lb per ft
L = total travel of cage and skip, ft
rps = max drum speed in rev per sec = $T + (t - 0.5\,(t_a + t_b)$
WR_2 of drums include gears (if any), but not motor armature
Other symbols have same significance as for cylindrical drums

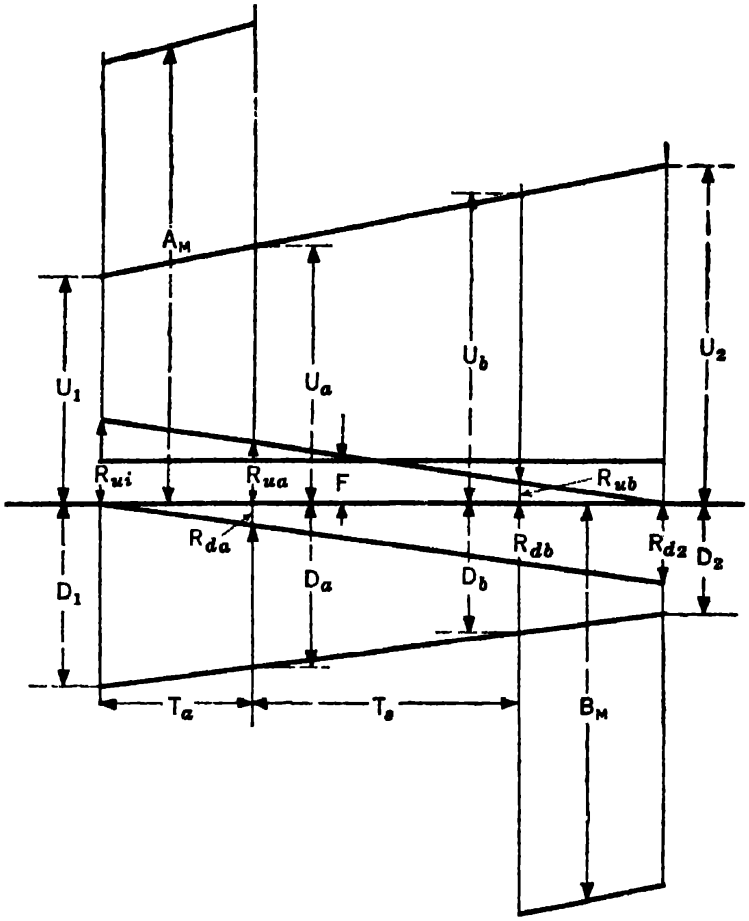

Fig 41. Component Moments, Load Diagram for Conical Drums and Reels, plotted to Revolutions

Load diagrams for conical drums and reels are readily calculated by the moment method. Formulas for component and resultant moments at different points in the cycle are given in Table 9, and moments are shown graphically in Fig 41, 42, 43 (Gen Elec Co). The hp required at motor coupling is derived as follows from Fig 43, the numbers in small parentheses referring to Table 9, column 4:

$$\text{Hp at } A = \left((1) + (7) + \frac{(4) + 2 \times (3)}{3}\right) \times \frac{2\pi \times \text{rps}}{550}$$

$$\text{Hp at } B = ((4) + (7)) \times \frac{2\pi \times \text{rps}}{550}$$

$$\text{Hp at } C = ((5) + (7)) \times \frac{2\pi \times \text{rps}}{550}$$

$$\text{Hp at } D = \left((2) + (7) + \frac{(5) + 2 \times (6)}{3}\right) \times \frac{2\pi \times \text{rps}}{550}$$

Conical-drum hoists are rarely required to operate unbalanced, but from the formulas given unbalanced diagrams may readily be calculated. The large and small working diameters of conical drums are usually known (Art 2), and the number of rope turns is directly obtained from the aver diam. For reels the minimum diam only is usually given. The max diam and number of rope turns is obtained from the equation: $L = 2\pi r_1 T + \pi p T^2$, the letters L, r_1 and p having the significance previously indicated.

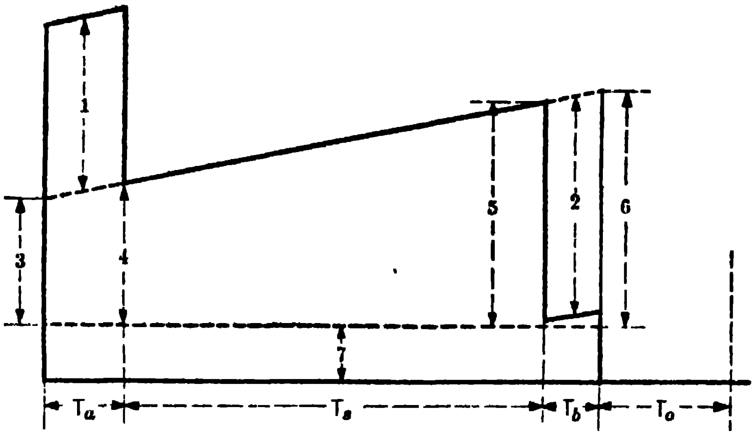

Fig 42 Resultant Moments, Load Diagram for Conical Drums and Reels; Balanced Operation plotted to Revolutions

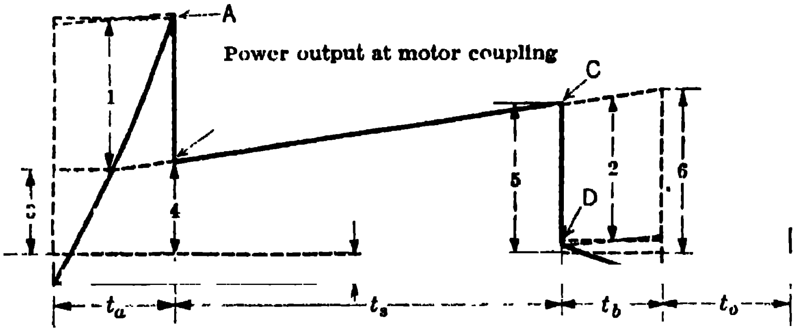

Fig 43. Power Diagram for Conical Drums and Reels; Balanced Operation plotted to Time

General equation for the rope moment at any revolution ψ of conical drums and reels is:

$$\text{Moment} = (w_r - 2\pi r_1 \psi \times \text{wt per ft} - \pi p\, \psi^2 \times \text{wt per ft}) \times (r_1 + p\,\psi)$$

Strict accuracy requires a correction in the results from the formulas in Table 9, to take care of acceleration and retardation due to changing drum radius after the drum itself reaches constant speed. For conical drums this effect is seldom important, because acceleration and retardation effects occur simultaneously and their resultant is of small value. The correction would consist of a slight increase in value of the power required at A and B (Fig 43).

Example of load-cycle calculation for conical-drum hoist (3). Conditions assumed: Coal-mine hoist, vert shaft; output, 2 500 short ton per 8-hr day:

Total lift	410 ft
Wt of self-dumping cage	11 000 lb
Wt of car (one car per cage)	3 000 lb
Wt of coal per car	6 000 lb (3 short ton)
Size of rope	1.5 in diam
Wt of rope per side = (3.55 × 410)	1 420 lb
Working radii of drums, r_1 = 4 ft; r_2 = 5 ft	
WR^2 of drums	700 000 (ft-lb units)
Wt of each head-sheave	3 300 lb
Number active turns of rope = 410 ÷ 9π	14.5
Accelerating time chosen	6 sec
Retarding time chosen	5 sec
Assumed net operating time per shift	7 hr
Dumping and loading time per trip (rest period)	6 sec

Table 9. Formulas for Calculating Load Diagrams, Conical Drums and Reels, Balanced Vert Lifts (Gen Elec Co)

Period	Symbols Fig 41	Component moments	Symbols Fig 42	Resultant moments	Moment of acceleration force, A_M / Moment of retardation force, B_M

Friction	F	$\frac{w(r_1 + r_2)}{2} \times \left(\frac{1 - E}{E}\right)$	(7)	F	

The procedure is as follows (refer to Tables 8 and 9):

$$\text{Trips per min} = \frac{2\,500}{7 \times 3 \times 60} = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad 2$$

$$\text{Time per trip} = {}^{60}/_{2} = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad 30.0\ \text{sec}$$

$$\text{Equivalent full-speed hoisting time} = \left(30 - 6 - \frac{6+5}{2}\right) \ldots \quad 18.5\ \text{sec}$$

$$\text{Max drum speed} = 14.5 \div 18.5 = 0.784\ rps = \ldots\ldots\ldots \quad 47.0\ \text{rpm}$$

$$t_s = 18.5 - \frac{6+5}{2} = 13\ \text{sec} \qquad T_a = \frac{6 \times 0.784}{2} = 2.35\ \text{rope turns}$$

$$p = \text{radial pitch} = \frac{5-4}{14.5} = 0.069\ \text{ft.} \qquad T_b = \frac{5 \times 0.784}{2} = 1.96\ \text{rope turns}$$

$$\begin{aligned}
T_s &= 14.5 - (2.35 + 1.96) = 10.19\ \text{rope turns}\\
r_{ua} &= 4 + 2.35 \times 0.069 = 4.162\ \text{ft}\\
r_{da} &= 5 - 2.35 \times 0.069 = 4.838\ \text{ft}\\
r_{ub} &= 5 - 1.96 \times 0.069 = 4.865\ \text{ft}\\
r_{db} &= 4 + 1.96 \times 0.069 = 4.135\ \text{ft}\\
w_{ua} &= \pi \times 2.35\,(4 + 4.162) \times 3.55 = 214\ \text{lb}\\
w_{da} &= \pi \times 2.35\,(5 + 4.838) \times 3.55 = 258\ \text{lb}\\
w_{ub} &= \pi \times 1.96\,(5 + 4.865) \times 3.55 = 216\ \text{lb}\\
w_{db} &= \pi \times 1.96\,(4 + 4.135) \times 3.55 = 178\ \text{lb}
\end{aligned}$$

$$E = \frac{0.95 \times 6\,000}{6\,000 + 0.04\,(6\,000 + 6\,000 + 22\,000 + 1\,420)} = 76.0\%\ \text{(2nd motion)}$$

Calculation of moments:

$$\begin{aligned}
U &= (6\,000 + 3\,000 + 11\,000) \times 4 &&= 80\,000\ \text{ft-lb}\\
R_{u1} &= 1420 \times 4 &&= 5\,680\ \text{''}\\
D &= (3\,000 + 11\,000) \times 5 &&= 70\,000\ \text{''}\\
U_a &= (6\,000 + 3\,000 + 11\,000) \times 4.162 &&= 83\,240\ \text{''}\\
R_{ua} &= (1420 - 214) \times 4.162 &&= 5\,019\ \text{''}\\
D_a &= (3\,000 + 11\,000) \times 4.838 &&= 67\,732\ \text{''}\\
R_{da} &= 258 \times 4.838 &&= 1\,248\ \text{''}\\
U_b &= (6\,000 + 3\,000 + 11\,000) \times 4.865 &&= 97\,300\ \text{''}\\
r_{ub} &= 216 \times 4.865 &&= 1\,051\ \text{''}\\
d_b &= (3\,000 + 11\,000) \times 4.135 &&= 57\,890\ \text{''}\\
r_{db} &= (1\,420 - 178) \times 4.135 &&= 5\,136\ \text{''}\\
u_2 &= (6\,000 + 3\,000 + 11\,000) \times 5 &&= 100\,000\ \text{''}\\
d_2 &= (3\,000 + 11\,000) \times 4 &&= 56\,000\ \text{''}\\
r_{d2} &= 1\,420 \times 4 &&= 5\,680\ \text{''}
\end{aligned}$$

$$F = 6\,000 \times \frac{(4+5)}{2} \times \frac{(1 - 0.76)}{0.76} = 8\,500\ \text{''}$$

Acceleration moment "A_M":

Up load, up rope, and head sheave =

$$\frac{(6\,000 + 3\,000 + 11\,000 + 1\,420 + 3\,300)2\pi \times \overline{4.162}^{2} \times 0.784}{32.2 \times 6} = 10\,950$$

$$\text{Down rope} = \frac{1\,420 \times \pi(4^2 + 5^2) \times 0.784}{32.2 \times 6} \ldots\ldots\ldots\ldots\ldots\ldots = 743$$

Down load and head sheave =

$$\frac{(11\,000 + 3\,000 + 3\,300)2\pi \times 5^2 \times 0.784}{32.2 \times 6} = 11\,050$$

$$\text{Drums and gears} = \frac{700\,000 \times 2\pi \times 0.784}{32.2 \times 6} \ldots\ldots\ldots\ldots\ldots\ldots = 17\,900$$

$$\text{Total "}A_M\text{"} = 40\,643\ \text{ft-lb}$$

Retardation moment "B_M":

Up load and head sheave =

$$\frac{(6\,000 + 3\,000 + 11\,000 + 3\,300)2\pi 5^2 \times 0.784}{32.2 \times 5} = 17\,850$$

$$\text{Up rope} = \frac{1\,420 \times \pi(4^2 + 5^2) \times 0.784}{32.2 \times 5} \ldots\ldots = 892$$

Down load, rope and head sheave =

$$\frac{(11\,000 + 3\,000 + 1\,420 + 3\,300)2\pi \times \overline{4.135}^2 \times 0.784}{32.2 \times 5} = 9\,800$$

$$\text{Drums and gears} = \frac{700\,000 \times 2\pi \times 0.784}{32.2 \times 5} \ldots\ldots = 21\,500$$

Total "B_M" = 50 042 ft-lb

Resultant moments (see Table 9):

(1) = 40 643 ft-lb
(2) = 50 042 "
(3) = 80 000 + 5 680 − 70 000 = 15 680 "
(4) = 83 240 + 5 019 − 67 732 − 1 248 = 19 279 "
(5) = 97 300 + 1 051 − 57 890 − 5 136 = 35 325 "
(6) = 100 000 − 56 000 − 5 680 = 38 320 "
(7) = 8 500 "

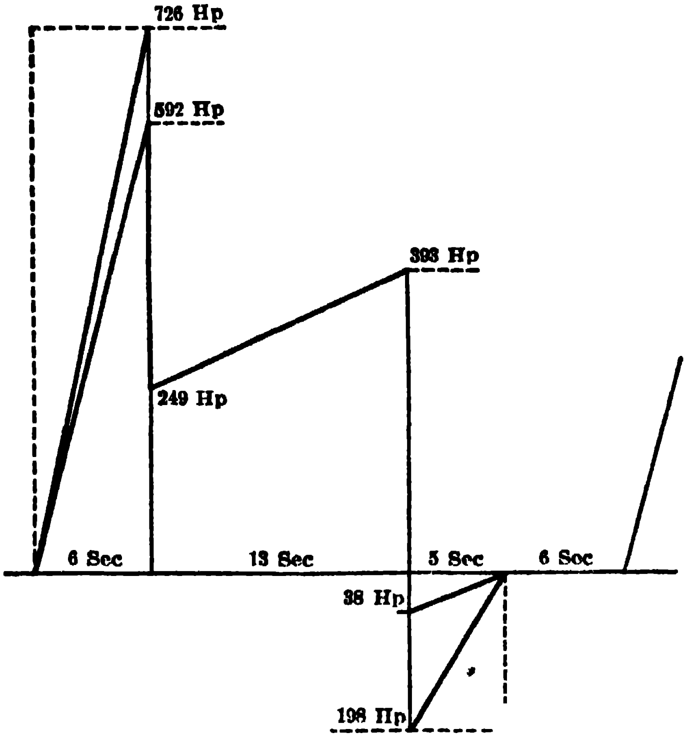

Fig 44. Power Diagram for Conical Drum (Gen Elec Co)

Power diagram (Fig 44):

$$\text{Hp at "}A\text{"} = \left[40\,643 + 8\,500 + \frac{19\,279 + (2 \times 15\,680)}{3}\right] \times \frac{2\pi \times 0.784}{550} = 592 \text{ hp}$$

$$\text{Hp at "}B\text{"} = [19\,279 + 8\,500] \times \frac{2\pi \times 0.784}{550} = 249 \text{ hp}$$

$$\text{Hp at "}C\text{"} = [35\,325 + 8\,500] \times \frac{2\pi \times 0.784}{550} = 393 \text{ hp}$$

$$\text{Hp at "}D\text{"} = \left[-50\,042 + 8\,500 + \frac{35\,325 + (2 \times 38\,320)}{3}\right] \times \frac{2\pi \times 0.784}{550} = -38 \text{ hp}$$

Estimating the *rms* of this cycle by inspection to be 500 hp for induction-motor drive, and assuming the max power to accelerate the armature in one sec to be 1.6 times the assumed rating, the acceleration peak = 592 + 134 = 726 hp, and retardation peak = −38 − 160 = −198 hp.

$$\text{The } rms = \sqrt{\frac{\overline{726}^2 \times 6 + \dfrac{(\overline{249}^2 + \overline{393}^2 + 249 \times 393)}{3} \times 13 + \overline{198}^2 \times 5}{{}^6/_2 + 13 + {}^5/_2 + {}^6/_4}} = 486 \text{ hp}$$

Selecting a standard 500-hp, 450-rpm motor and checking back, using the actual WR^2 of its rotor, to accelerate requires 127 hp, to retard 152 hp, and the *rms* is 482 hp. The motor selected should be capable of operating continuously at the *rms* output, with a temp rise not exceeding 40° C. As full speed of drum is 47 rpm, single-reduction gearing will be suitable, for the motor speed selected.

Applying the checks mentioned:

$$\text{Net work done in shaft} = \frac{6\,000 \times 410}{550} = 4\,473 \text{ hp-sec} \qquad (a)$$

Area under load diagram is computed as follows:

$$\begin{aligned} \frac{592}{2} \times 6 &= 1\,776 \\ \frac{249 + 393}{2} \times 13 &= \underline{4\,173} \\ &\ 5\,949 \text{ (positive)} \\ \frac{-38}{2} \times \ 5 &= \underline{\ -95} \text{ (negative)} \\ &\ 5\,854 \text{ hp-sec (net)} \qquad (b) \end{aligned}$$

Ratio (*a*) to (*b*) $= \dfrac{4\,473}{5\,584} = 0.76$, which checks with the per cent mech effic E, used in the calculations.

12. CYLINDRO-CONICAL DRUMS

The general formulas for conical drums and reels apply here, account being taken of the changing drum radii at different rope turns. The most effective mode of arranging the rope turns is to complete the drum acceleration while the rope is winding on the small-radius cylindrical portion; then climbing the cone in the fewest number of turns (minimum being one turn per ft difference between large and small radii), and winding remainder of rope on the large cylinder (see Fig 8). Both ropes may start on the small cylindrical portion, with only 1 or 2 turns between, and wind over the entire surface, finishing with both ropes on small cylinder at opposite end of drum. This requires a large motor, results in lower hoisting effic and its advantages are questionable.

The force moments are as follows:

Accelerating moments: bottom of cone = $F \times r_1$; top of cone = $F \times r_2$.

Retardation moments: top of cone = $F^1 \times r_2$; bottom of cone = $F^1 \times r_1$

where $F = (w + w_s + w_r + w_h) \times 2\pi\ \overline{\text{rps}}\ (r_2 - r_1) \div 32.2t$

and $F^1 = (w_s + w_r + w_h) \times (2\pi\,\overline{\text{rps}}) \times (r_2 - r_1) \div 32.2t,$

where r_1 = radius small cylinder (ft) r_2 = radius large cylinder;

t = time during winding (or unwinding) on cone, sec;

w_r = wt of rope hanging at bottom of cone + $^1/_2$ wt of rope wound on cone. Other symbols have meanings given at beginning of Art 11.

Example of load-cycle calculations for cylindro-conical drum (3). Following are calculations for a hoist where conditions are the same as for the preceding conical-drum problem:

Small diam..................	8 ft	Time for acceleration.........	6 sec.
Large diam..................	10 ft	Time for retardation..........	5 sec.
Active turns on conical portion.	4	Time at full speed............	13 sec.
WR^2 of drum................	800 000 ft-lb^2		

First determine distribution of rope turns on drum:

Let Z = rps of drum at full speed.

$$8\pi \times \frac{6Z}{2} = \text{rope wound on during acceleration} \qquad (1)$$

$$10\pi \times \frac{5Z}{2} = \text{rope wound on during retardation} \qquad (2)$$

$$\frac{10 + 8}{2} \times \pi \times 4 = \text{rope wound on cone} \qquad (3)$$

$$10\pi(13Z - 4) = \text{rope wound on large cylinder during full speed} \qquad (4)$$

The sum of (1), (2), (3), and (4) is 410 ft of rope, which gives $Z = 0.75$ rps = 45 rpm

$$\text{Turns on small cylinder} = T_a = \frac{6 \times 0.75}{2} = 2.25 \text{ turns}$$

$$\text{Turns during retardation} = T_c = \frac{5 \times 0.75}{2} = 1.88 \text{ turns}$$

$$\text{Turns on large cylinder} = T_b + 13Z - 4 = 7.63 \text{ turns}$$

$$\text{Total turns on drum} = 13.88$$

(Also note 13.88 + 18.5 sec = 0.75 rps)

$$\text{Energy lost in friction} = \frac{4\,475 \times 1 - 0.76}{0.76} = 1\,415 \text{ hp-sec}$$

$$\text{Aver hp friction} = \frac{1\,415}{18.5} = 76.5 \text{ hp}$$

$$\text{Aver hp friction torque} = \frac{76.5}{2\pi \times 0.750 + 550} = 8\,900 \text{ ft-lb}$$

$$\text{Hp load} = \text{moment} \times \frac{2\pi \times 0.750}{550} = 0.00856 \times M$$

Summation of moments:

Time-sec	0	6	6	11 34	11.34	13.19
No turns	0	2.25	2.25	6.25	6.25	7.63
Up load	80 000	80 000	80 000	100 000	100 000	100 000

Fig 45 shows component and resultant moments, plotted against rev of drum, and Fig 46 is the power diagram, plotted from the values of hp and time calculated above. The rms value of this cycle is somewhat less than that for the simple conical drum (Fig 44), and the overall effic of hoisting is greater, due to lower values of power required during acceleration and retardation.

13. ELECTRIC HOISTS

Electric drives (3) now in use are:

(1) Induction motor with: (*a*) master controller, contactors, and grid secondary resistance; (*b*) primary contactors and liquid secondary resistance; (*c*) drum controllers and grid secondary resistance.

(2) Ilgner-Ward Leonard system: Direct-current, separately excited motor operated from motor-generator set with flywheel by Ward Leonard control.

(3) Ward Leonard system. Direct-current, separately excited motor operated from motor-generator set without flywheel by Ward Leonard control.

(4) Direct-current motors with rheostatic control, using either drum controllers or magnetic control.

Induction motors (3, 33) up to 1 800 hp capacity are widely used and comprise 80% or more of motors in use. Advantages: low first cost, simplicity of installation and operation, availability of a-c power at low rates, ruggedness and reliability. Disadvantages: difficulty of accurate control, high gear ratios because of high motor speeds, high inertia effects, excessive peak loads, and uncertain dynamic braking. Bright (8) claims that when rope speeds exceed 1 800 ft per min and the cycle approaches 3 min duration, the desirability of a-c motors becomes doubtful.

Lowering unbalanced loads (3) may be obtained by: (*a*) mechanical brakes; (*b*) induction motor running as a generator at a speed slightly above synchronism; (*c*) counter-torque from the motor. Lowering by mechanical brakes is objectionable because of the wear on brake shoes, necessity of providing brakes with sufficient area to prevent overheating, and danger of failure in operation. In lowering by the second method, the motor is connected to the power supply in the direction tending to drive the hoist down, or the hoist is allowed to accelerate to speed by gravity only, before connecting the motor to the line, the mechanical brakes being used to prevent speeding beyond control until the motor connection is made. The hoist will then run at a speed such that the motor is driven slightly above synchronism, the energy received at the motor coupling being returned to the power system. To stop the hoist the mechanical brakes must be used, or the motor thrown into first or second point of reverse. It is always desirable partially to apply the mechanical brakes, for, while bringing the controller from its running position to the "off" position, the electrical braking effort is being gradually reduced to zero and the hoist will speed up unless checked. This method of braking is economical, but is practicable only for fairly long cycles, in which enough time is allowed for manipulating the control. It is practiced with the greatest safety in case of long slope hoists. The third method involves reversing the motor so that it exerts a torque in opposition to that of the hoist, that is, the motor tends to lift the load. This method is wasteful of energy and a heavy-duty rheostat is necessary.

Dynamic braking (3) with the induction motor, by supplying constant value d-c excitation to the stator windings and obtaining speed control by a secondary rheostat, is sometimes used where heavy unbalanced loads are often lowered, the hoist being operated normally in the usual manner from a separate controller. It is justified under these conditions, where the usual braking methods are unsatisfactory; for instance, due to limited power supply, both the regenerative and counter-torque methods may not be feasible, and entire dependence upon mechanical brakes is objectionable. The system is fairly safe, saves wear on brakes, and is economical in power consumption, the only power necessary being that required for stator excitation and for control.

Ward Leonard system. The voltage applied to the motor, and therefore its speed, is varied by varying the field strength of a generator used exclusively to supply power to the hoist, and which is usually driven by an a-c motor. By reversing the field connections, the polarity of the generator voltage is reversed and consequently the rotation of the hoist motor, which operates always at constant main-field strength. Excitation for motor and generator fields is supplied by an exciter, usually direct-connected to the motor-generator set. Since only the generator field circuit is manipulated in controlling the speed, the currents involved are relatively small, with no difficulty in providing a large number of steps.

Principal factors justifying Ward Leonard control are: (*a*) accuracy of control (desirable for high-speed hoists, rapid rate of hoisting or frequent shifting); (*b*) increased safety in operation; (*c*) higher effic on certain duty cycles; (*d*) equalization of power demands; (*e*) possibility of elimination of gearing.

Ilgner-Ward Leonard system. A flywheel, mounted on the motor-generator shaft, acts as an equalizer, cutting down the peak power demand. It is desirable where high peaks are liable to disturb an electrical system, or a heavy charge is made for peak demands

Comparison of results of different electric drives. See (3) and Tables 10, 10a.

The data for the coal hoist are as given in Art 11; Data for metal-mine hoist (Table 10a) are:

Lift, max	2 000 ft
Skip	6 000 lb
Ore per trip	8 000 lb
Rope speed	1 765 ft per min
Time for acceleration	15 sec
Time for retardation	8 sec
Time at full speed (2 000-ft lift)	56.5 sec
Rest period	15 sec
Rope, round for cylindrical drums	1 3/8 in
Rope, flat for reels, 4 to 11 ft diam	1/2 by 6 in
Cylindrical drums	9 ft diam
Mechanical effic, 2nd motion a-c motor	80%
Mechanical effic, 1st motion d-c motor	85%

For the coal hoist, the conical drum shows some advantage over the cylindrical in effic, peak-power demand, and size of motor. For the ore hoist, reels would show a decided advantage over cylindrical drums if it were unnecessary to hoist from shallower levels. When so operating, reels are disadvantageous both as to effic and peak load, and the driving motor required is therefore as large as for cylindrical drums. The effic for the aver lift is about the same as for cylindrical drums. For the coal hoist, the d-c equipments show higher effic than the induction. In a measure this is also true of the ore hoist without flywheel, there being some advantage in effic of the induction motor over the Ilgner equipment, although the latter very greatly reduces the peak load. The adoption of these d-c systems is most often justified by considering the advantages of control and reduced power demand, rather than the question of increased effic.

above, but with liquid-rheostat secondary control, $31.50 per hp. (*b*) 600-hp, 459 rpm, 2 200-volt, 3-phase, 60-cycle motor, with magnetic control, $15 per hp; with liquid rheostat, $17.50 per hp. (*c*) 1 300-hp, 360 rpm, 2 200-volt, 3-phase, 60-cycle motor, with magnetic control or liquid rheostat, $14.50 per hp.

D-c motor, geared to drum, with motor-generator set and Ward Leonard control: (*a*) 800-hp, 350 rpm, 550-volt d-c motor, 700-kw motor-generator, with 500-kva synchronous motor, $35 per hp; (*b*) same as (*a*), but with 600-hp induction motor and 18 000-lb flywheel, Ilgner control, $48 per hp.

D-c motor, direct-connected to drum, with motor-generator set and Ward Leonard control: (*a*) 950-hp, 93 rpm, 550-volt d-c motor, 700-kw motor generator, with 500-kva synchronous motor, $43.50 per hp; (*b*) same as (*a*), but with 600-hp induction motor and 18 000-lb flywheel, $53.50 per hp. Table 10b gives makers' data and costs of recent installations.

Automatic hoisting (42) at Emma Nevada shaft is obtained by a push button at skip loader's station of either of two mine levels. Pushing the button starts the hoist, automatically controlling acceleration, full-speed running, retardation, final stop at dumping point and the setup for reversing rotation on the next cycle. A third button is used for test purpose. Provision is made for manual operation of the master controller, when changing the drum adjustment for the two levels, or for hoisting men. The hoist is of the balanced cylindrical-drum type, with Ilgner-Ward Leonard drive, and operates at depths of 646 and 826 ft, with a 12-ton load and 10 1/2-ton skip. Similar hoists are used at Miami (43), Inspiration Copper Co, and Butte.

14. HOISTING ENGINE CALCULATIONS

Factors for general case: 1. Daily output required governs number of hoists per day or shift. This, in turn, depends on load per trip, as determined by size of car (or other local conditions), depth of shaft, type of plant, and allowances for delays and handling men and supplies. 2. Gross load = wt of ore + car + cage + rope. 3. Size of rope is determined by wt of ore, car and cage, multiplied by starting factor of 2 to convert dead into live load, plus weight of rope. Rope weight must first be assumed, and one or more approximations made. (For Bending Stresses in hoisting ropes, see Art 7.) 4. Max unbalanced load, when hoisting in 2-compartment shaft, equals wt ore + rope. 5. Total time for a complete hoist. These five factors must be harmonized for selecting type and power of hoist, suitable for conditions; geared hoist for low, direct-acting for high, hoisting speeds.

Total time per load. For SINGLE-COMPARTMENT SHAFT, this covers down trip + up trip + delays at bottom and top, for caging cars; or, with skips, for loading and dumping. This also holds good, in general, for double-compartment shaft, with independent drums operated by clutches. For DOUBLE-COMPARTMENT SHAFT, hoisting in balance with fixed (keyed) drums, or single drum with over and under rope, the total time per load is the elapsed time from the moment cage stops at bottom on down trip until it stops at top on up trip.

Delays. Caging car, with best track arrangements, takes 5 to 10 sec, which may be greatly exceeded when loading facilities are poor. With skips and power-operated loading chutes, loading time may be reduced to 3 to 9 sec (10). When hoisting in balance, delays at top and bottom are coincident and only the longer one needs to be allowed for. If hoisting capacity permits, larger allowances should be made; preceding figures are not obtainable with hand caging or hand loading of skips. If men and supplies are handled with ore hoist (usually requiring 20–40% of each shift), it is best to allow total time for them and compute delays on net time.

Hoisting time and speed. Time per trip includes periods of acceleration, uniform speed, and retardation. Acceleration and its period vary widely. For shafts exceeding say 600 ft depth, acceleration is from 2 to 8 ft per sec per sec (11); for shallow shafts and large tonnages, it may be 6 to 12 ft. At latter rate acceleration period may run into retardation period, with practically no time of uniform speed (as with conical drum or reel). Uniform speed period varies with depth of shaft and hoisting speed. With geared hoists max speed rarely exceeds 1 000 ft per min. With direct-acting hoists, 4 500 to 5 000 ft per min is sometimes attained. Speeds of 2 000 to 3 000 ft are common. Tendency is to obtain increased capacity by increasing load rather than speed, which conduces to safety and less wear and tear.

Let a = accel, ft per sec per sec; v = mean veloc, ft per sec; v_1 = max veloc, ft per sec; t = hoisting time, sec; t_1 = time of accel, sec; t_2 = time of max speed, sec; h = depth of shaft, ft; s = distance passed over during accel, ft. Then, $t_1 = v_1 \div a$, and $s = v_1^2 \div 2a$; and if time and distanse of accel and retardation be assumed equal,

$$t_2 = \frac{h - 2s}{v_1} = \frac{h}{v_1} - \frac{v_1}{a}$$

also,
$$t = 2t_1 + t_2 = \frac{2v_1}{a} + \frac{h}{v_1} - \frac{v_1}{a} = \frac{v_1^2 + ah}{av_1}$$

But
$$v = \frac{h}{t} = \frac{ahv_1}{v_1^2 + ah}, \text{ whence } a = \frac{vv_1^2}{h(v_1 - v)} \tag{27}$$

Examples. Tamarack No 3 shaft, Mich, 4 800 ft in 75 sec, or 3 880 ft per min aver, with max about 5 000 ft per min. Whiting shaft, Calumet & Hecla mine, from 4 900-ft level at aver speed of 3 500 ft. Kimberley diamond mines, South Africa, from 1 560 ft depth, aver speed 2 230 ft, max 3 770 ft; acceleration period 16 sec, retardation 13 sec, constant speed 13 sec, total 42 sec. Hence, acceleration is about 3.5 ft per sec per sec. Loading skip requires 5 sec. Quincy No 2, Mich, 10 000 ft in 250 sec; max speed, 3 200 ft per min; accel, 36 sec; retardation, 26 sec (7). Orient shaft, Ziegler Coal Co, Ill, 600 ft, 5 sec to cage, 5 sec accel and retard; total time for complete hoist, 17.12 sec; max speed, 5 070 ft per min. Dowlais shaft, Cardiff, Wales, 2 220 ft in 52 sec, an aver of 2 562 ft per min. Rosebridge Colliery, England, speed of 5 100 ft per min is on record. Usual speeds are: SMALL GEARED HOISTS, 450 to 500 ft per min; large, 900 to 1 200 ft. SMALL DIRECT-ACTING HOISTS, 1 000 to 1 500 ft per min; large, 2 500 to 3 500 ft.

Table 11. Acceleration in Various Mines (National Safety Council) (46)

With fixed output, speed and load are dependent upon each other. If V = average hoisting speed per min; T = output, tons per hr; W = net load, tons; h = depth of shaft, ft, and t = caging time, min; then,

$$V = \frac{ht}{60W - Tt} \tag{28}$$

15. STEAM HOISTS

Engine details. Minimum diam of drum depends on diam of rope (Art 2 and 7); maximum diam, on hoisting speed required and piston speed of engine. RATIO OF GEARING, from 1 : 3 to 1 : 6. PISTON SPEED rarely exceeds 650 ft per min; for small engines 500 ft. RATIO OF CYL DIAM to length of stroke varies for geared hoists from 1 : 1.2 to 1 : 1.67; ratios of 1 : 1.25 to 1 : 1.33 are common. For direct-acting hoists ratios are usually from 1 : 1.3 to 1 : 2.66.

Friction allowance for engines, sheaves, and shaft guides is generally lumped to cover all these items, including windage. McCulloch and Futers (4) assume starting friction of engine as 25% of wt of one cage + contents + rope; running friction as 0.6 of this or 15%, and shaft friction and windage as 10%. But, since all these items are not effective until after starting, it is customary to take friction allowance at 20% for direct-acting and 25% for geared hoists. Following frictional resistances were measured at three Butte (Mont) shafts, when hoisting from depth of 2 200 ft, at max speeds of 3 000 to 3 500 ft per min (47, p 837):

	In balance	Out of balance
Speculator shaft	21.1%	13.0%
High Ore shaft	23.0	17.5
Diamond shaft	29.0	10.0

These percentages are in terms of indicated work of the engines, the difference between values when hoisting in and out of balance showing that shaft friction at high hoisting speed is much greater than engine friction. In these cases the engine friction alone was probably less than 6% (47).

Effective crank radius is taken at 0.58 of full crank radius for engines cutting off at 87.5% of stroke, which is about as late as is practicable. This enables one cylinder to start the load, when cranks at 90° apart are in their most disadvantageous positions.

Steam pressure. INITIAL PRESS for small hoists is assumed in makers' lists at 80 to 100 lb. For simple, non-condensing hoists, assume 100 lb; for compound, 125 to 150 lb.

(NOTE.—Hoist should be designed to start under a lower pressure, to take care of emergencies.) MEAN EFFECTIVE PRESS (m e p) does not affect size of cylinder necessary to start the load, but must be considered when engine is up to speed and running with shortened cutoff. In absence of indicator cards, approximate m e p may be calculated by:

$$p = 0.9\,[c\,(p_i + 14.7) - b] \qquad (29)$$

in which: p = m e p (gage); p_i = initial steam press (gage); b = absolute back press (for hoisting engines = 17 to 19 lb); c = constant depending on point of cutoff; 14.7 = atmos press at sea level, and 0.9 is the diagram factor.

Table 12. Values of "c" for Engines with 7% Clearance

Point of cutoff, % of stroke	Ratio of expansion	c
100	1.00	1.000
83.3	1.18	0.986
75.3	1.30	0.969
62.5	1.54	0.925
50.0	1.88	0.860
37.6	2.40	0.766
25.0	3.35	0.637

Force required to accelerate load and moving parts can be disregarded for slow hoisting speeds, and in general for geared hoists, but must be determined for rapid hoisting.

Let M = mass of one cage and empty car, and W their weight: M_1 = mass of ore and w its weight; M_2 = mass of one rope and W_r its weight; F_1 = accelerating force in ascending rope; F_2 = accelerating force in descending rope.

Then $F_1 = a\,(M + M_1 + M_2)$, and $F_2 = aM$.

During period of acceleration, load on ascending rope is $W + w + W_r + F_1$, and on descending rope, $W - F_2$, assuming empty cage at surface. Unbalanced load during acceleration, neglecting changing lengths of ropes, is:

$$L = (W + w + W_r + F_1) - (W - F_2) = w + W_r + a\,(2\,M + M_1 + M_2) \qquad (30)$$

Engines must also accelerate the masses of drums, sheaves, and reciprocating parts. Weight of drum is assumed as concentrated at its equivalent radius of gyration, taken at 0.7 r. Then, if M_d is mass of drum, and neglecting sheaves and other parts, the accelerating force required is $F_d = 0.7\,M_d a$, since surface of drum is moving at same velocity as the rope. Weight of drum is calculated, or estimated from known weight of a similar one. A drum 8 ft diam by 8 ft long weighs about 20 000 lb.

Hoisting-engine formulas.

Let P = total press on one piston, due to initial steam press,
p_i = initial steam press, lb per sq in,
l = length of stroke, ft,
d = diam of cylinder, in,
e = starting efficiency or factor, to allow for starting friction of engine, sheaves and cages, assumed at 0.7 to 0.83,
D = diam of drum, ft,
A = area of piston, sq in = $0.7854\,d^2$,
L = unbalanced load, lb,
k = ratio of stroke to diam = $12\,l \div d$,
m_L = moment of unbalanced load about center of drum,
m_P = moment of steam press on one piston about center of crank shaft, in least advantageous position of cranks.

Then $m_L = LD \div 2$, and $m_P = 0.58\,Pl \div 2$

To start the load, em_P must be equal to or greater than m_L, or $0.58\,ePl \div 2 = LD \div 2$, whence

$$d^2 = 2.19\,\frac{LD}{ep_il} \qquad (31)$$

Substituting for l its value in terms of d, $d^3 = 26.3\,\dfrac{LD}{ep_ik}$ (32)

Eq 31 and 32 neglect area of piston rod. For a geared hoist, if q be the gear ratio,

$$d^3 = 26.3\,\frac{LD}{ep_ikq} \qquad (33)$$

These formulas give cylinders amply large unless rapid acceleration and high speed are necessary. Assuming uniform acceleration, the engines develop greatest power just at end of acceleration period.

Let V = maximum rope speed, ft per min; p = m e p, lb per sq in; N = revs of drum per min; L_T = total unbalanced load, lb, including wt of ore and rope, and total force necessary to accelerate load, cages, ropes, and drums. Then the required h p = $L_TV \div 33\,000$, and h p of both cylinders $= 2\,eplAN \div 33\,000$. Equating and reducing to same form as Eq 31,

$$d^2 = \frac{L_TD}{epl} \qquad (34)$$

and

$$d^3 = 12\,\frac{L_TD}{epk} \qquad (35)$$

Table 13. Examples of Hoisting Engines (McCulloch and Futers)

	Case	I	II	III	IV	V and VI	VII	VIII

By substituting for L_T the unbalanced load only, at uniform speed, the m e p for any given engine may be determined, and minimum point of cutoff found for constant speed.

In Eq 34 and 35, e is the factor for running engine friction, shaft friction, and windage, and may be assumed as having same value as in Eq 32, since increase in shaft resistance offsets the reduction from starting engine friction to running engine friction.

Comparison of performance of different types of hoisting engines is given in Table 13. These engines are designed for max depth of 3 000 ft; load of ore, 3 360 lb; skip, 2 240 lb; initial steam press, 150 lb; output, 25 ton per hr; balanced hoisting. (NOTE.—"Shaft horsepower-hour" denotes net load in lb of ore only × total aver depth in ft hoisted per min ÷ 33 000.)

Examples and costs of hoisting engines. Table 14 gives data of large direct-acting hoists, with approx costs in 1914. Present costs (1938) are about double those quoted. Large hoists are all especially designed and costs vary greatly. Table 15 gives approx 1926 costs (in eastern U S) of ordinary geared hoists.

Table 15. Geared Hoists, Single Friction Drum, Reversible Link Motion

Rated hp	Cylinders, in	Drum, in	Wire rope on drum in single coil	Aver hoisting speed, ft per min	Bed-plate, in	Weight hoisted	Shipping wt complete	Approx price, factory

Note.—For double-drum hoists add 50% to weight and 45% to price.

Small geared steam-driven hoists for prospecting, development, or mines of small output and depth, are self contained and of simple design (Table 16). Gear ratios, 1 : 4, to 1 : 6. Lowering is usually by brake, but reversing gear may be had for 10% added cost. Total cost, approx 18¢ per lb.

Table 16. Lidgerwood Portable Hoists, Single Cone-friction Drum

35	9	10	41	40	3 500	350	72	74	9 000

Portable column- or stope-hoists, for handling timber and ore in stopes and winzes, are usually operated by compressed air or electric motor. Air motor is some form of rotary engine, mounted at the end or inside the drum, and has double-reduction gearing. These hoists have 1 or 2 drums, and are especially convenient in narrow workings, as they may be mounted on a column, or temporary timber foundation. Their most useful applications are in operating underground scraper loaders (2) (Sec 27), and in hoisting and erecting heavy timbers in stopes. Capacity, 1 000-2 000 lb, at 50–300 ft rope speed; wt, 450–700 lb; air consumption, 200–250 cu ft per min; over-all dimensions, 14 by 18 by 23 to 15 by 20 by 38 in.

Medium-size geared hoists are suitable for more extensive development work, or mines of small tonnage, to say 500 ft in depth. They are especially adapted for hoisting with buckets, light cages or skips, at speeds of 450 to 700 ft per min (Table 17).

Large geared hoists may be self-contained, or with engines and drums supported on independent bed-frames. They are especially suited to hoisting heavy loads at moderate speeds, up to say 1 500 ft per min; hence, are advantageous for slopes or inclines, where high speeds are not permissible. Under these conditions, geared engines give better steam economy, due to higher piston speed and ability to use drums of large enough diam to prevent undue bending stresses in rope. Geared hoists are useful where economy of floor space and foundation is an object. Their cost is 35 to 50% that of direct-acting hoists for same hoisting load.

Table 17. Single- and Double-drum Geared Hoists, Band Friction Clutches

Rated h p	Cylinders		Engine speed, r p m	Drums			Gear ratio	Unbalanced load, lb, with 100 lb steam	Rope speed, ft per min	Weight		Over-all dimensions

Note.—Specifications of different makers vary. For preliminary estimates, cost may be taken at 25¢ per lb at factory.

First-motion or direct-acting hoists are useful for large output, or for depths requiring high hoisting speeds. Besides the advantage of eliminating gearing, their relatively slow speed of stroke permits use of Corliss or other variable-cutoff valve motion. Though usually designed for greater economy in steam consumption, their first cost is higher, and they should not be used for depths less than 500 ft, unless output is large.

Compound hoisting engines have limited application. Their high cost is justified only where fuel is expensive, and large loads are hoisted in rapid succession from deep shafts. When not operated condensing (condensers often work unsatisfactorily in hoisting service), their economy is but little better than that of simple engines, taking into account the intermittent running. They are either cross-compound or twin tandem-compound. Though more costly, the latter design is preferable, because in the cross-compound the high-press cylinder must be large enough to start the load when low-press cylinder is on center. This prevents an economical ratio of cylinder volumes. Throttle and valve gear must be designed so that, in starting and until full speed is reached, the l-p cyl receives steam at such press as will give a starting effort equal to that of h-p cyl. Cylinder ratios can be proportioned to best advantage in the twin tandem-compound.

Examples of compound cylinder ratios. Old Dominion Copper Co, Ariz, twin tandem condensing, 17 and 31 by 48 in, ratio of areas 1 to 3.4; 20 and 37 by 66 in, ratio 1 to 3.45. Copper Queen Consol Mining Co, Ariz, twin tandem condensing, 16 and 28 by 48 in, ratio 1 to 3.08. Homestake Mining Co, So Dak, duplex cross-compound condensing, 28 and 52 by 42 in, ratio 1 to 3.47. Randfontein, Transvaal, cross-compound condensing, 22 and 40 by 48 in, ratio 1 to 3.3. Village Deep shaft, Transvaal, twin tandem condensing, 17 and 28 by 60 in, ratio 1 to 2.73; duplex cross-compound geared hoist, 14 and 21 by 20 in, ratio 1 to 2.25. Cambria Steel Co, Johnstown, Pa, cross-compound condensing, 28 and 50 by 48 in, ratio 1 to 3.2. Grand Central Mining Co, Mexico, twin tandem, 16 and 24 by 42 in, ratio 1 to 2.25.

Table 18 shows test of a Nordberg twin tandem-compound condensing hoist; cyls 16 and 28 by 48 in, Corliss valve gear; 2 clutched drums, each 7 ft diam, holding 2 100 ft of 1.25-in rope; total rope pull, 19 000 lb.

Valve gear of hoists should be as simple as is compatible with good construction, and economy in steam consumption; with minimum number of parts, and all motions positively controlled when possible.

Three types used in American engines: slide, piston, and Corliss valve. SLIDE VALVES are always used for small and generally for large geared hoists, and for many direct-acting hoists. In small engines, valves are unbalanced; in large, balanced valves should be used. PISTON VALVES are used in the simpler forms of heavy-duty direct-acting hoists; they are balanced as to steam pressure, and are well adapted to high pressure and speed and also to long-stroke engines, because each end of cylinder has its own valve, thus reducing length of ports. But, since the piston valve is not held on seat by steam pressure, it is liable to leakage from wear. High cost of CORLISS GEAR is justifiable when fuel is high, and when saving in this and in decreased maintenance cost exceeds the added first cost within life of mine. It is especially suited to large output from depths of 1 000 ft or more. Its economy results mainly from the automatically controlled variable cutoff, which is more easily applied to Corliss than to other valves. Variable cutoff is operated by ball governor (which also prevents excessive speed), or by an auxiliary lever to throttle, by which cutoff is shortened as throttle is opened. With slide and piston valves, cutoff may be shortened by "linking up," but this interferes with exhaust. Corliss valves with non-detaching gear are now used, having advantage of separate steam and exhaust valves with quick opening and closing. Variable-expansion gear must automatically return to position of latest cutoff with the stopping or slowing down of hoist. As Corliss gear is limited to speed of about 125 rev per min, it is rarely applied to geared hoists.

Reversing gear, when hoisting is in balance, or if lowering is done by steam when not balanced, is commonly of link-motion type, or a modification of it. Both open and crossed eccentric rods are used, but open rods are best as they increase lead of the valve as cutoff is shortened, giving more compression and earlier admission of steam for cushioning when running at full speed. On large Corliss hoists, valve rods are sometimes driven from a crank on an auxiliary shaft inclosed by a hollow shaft geared from main shaft. Inner shaft is driven from hollow shaft, but may be rotated independently by the reverse lever, through an angle sufficient to reverse the engine. Medium size direct-acting and geared hoists are reversed by hand; large hoists by an auxiliary engine (Art 3).

Notes.—Aver load of ore per skip for 232 skips hoisted, 3.81 tons. Wt of empty skip, 5 400 lb. Wt of 1.25-in rope, 2.5 lb per ft. Condensation in pipe line from boilers, 625 lb per hr, with steam on line and hoist not running. Steam for condensing plant charged at 30 lb per kw-hr, an aver of 9 kw being used.

Steam economy of hoisting engines is necessarily poor, due chiefly to intermittent operation. A hoist must start under full load and have rapid acceleration, thus requiring uneconomical admission of steam during nearly full stroke. Also, intermittent work involves loss of stored energy near end of trip if heavy braking is done, and the large variation of load within the short hoisting period prevents economical operation. The frequent stops and periods of idleness allow cylinders to cool and increase condensation loss. Superheating reduces condensation, and is justifiable for large hoists. Hoisting engines cut off at about 0.85 stroke in starting, and with slide or piston valve this is not changed as engine comes up to speed, when hoisting from shallow shafts. Though indicator cards are useful for determining condition of valves and pistons, their results are comparative, rather than absolute, because with varying speed and load no two engine strokes give the same card. Hence, steam consumption as calculated from hoist indicator cards is an approximation at best. Steam consumed per unit of work may be obtained very closely by measuring water supply to boilers, if plant is so arranged that one or more boilers supply the hoist independent of auxiliaries. Such tests should last several hours, useful work being calculated from tonnage hoisted.

Steam consumption varies between wide limits. Small hoists at a distance from boiler require 150 to 175 lb per shaft hp-hr; for large compound condensing hoists, winding from deep shafts, 25 lb per shaft hp-hr is obtainable; for moderate size, simple, non-condensing hoists, with slide or piston valves, 50 to 75 lb.

16. COMPRESSED AIR HOISTS (See also Sec 15)

Compressed-air hoists have same general construction as steam hoists. For small-scale work portable " column " or " stope " hoists (Art 15), or small geared hoists (Table 17) are used. For economy, large expansive-working engines require cylinders of special design. Cutoff is later, clearance volume is reduced to minimum, and larger admission ports are required, since at same pressure the density of air exceeds that of steam. SMALL HOISTS, running intermittently, give no trouble from freezing of moisture in exhaust ports, as cylinder walls and passages have time to regain normal temp. But, for economy, the air should be reheated. For starting and acceleration, air is admitted at practically full stroke, and power controlled by throttle. In LARGER HOISTS, with expansion gear, expansion is only partial, because, since there can be no condenser, the terminal press must be sufficient for proper exhaust. Owing to rapid drop in temp of expanding air, the work done is less than with steam; that is, the adiabatic curve of air is below that of steam, with corresponding decrease in mean effec press. Hence, for same m e p, cutoff must be later (Sec 39). On the other hand, the theoretical final temp of expansion is never reached in practice, because of transmission of heat by cylinder walls, compression in clearance spaces, and presence of moisture in the air. Loss in efficiency due to incomplete expansion can be reduced by two-stage expansion. With cutoff in high-press cyl at 0.9 stroke (minimum practicable starting cutoff), and reheating between cylinders to initial temp, the loss in compound cylinders is about one-half that of a simple cylinder, or a saving of 25% of the energy in the air entering high-press cyl.

Work done by compressed air. See Sec 39 for theory, and results of work with partial and complete expansion. Table 19 gives relations between initial and terminal press and temp for different points of cutoff (48). Corrections are necessary for clearance volume, the actual effect of cutoff being found by dividing the sum of cutoff plus clearance, by cylinder volume plus clearance. Thus, if stroke is 5 ft, with cutoff at 0.2 and clearance of 5%, total volume of cylinder plus clearance is $(5 \times 0.05) + 5 = 5.25$; the sum of cutoff plus clearance is $1 + 0.25 = 1.25$, and actual cutoff is $1.25 + 5.25 = 0.23$. Table 20 is thus calculated. As volume of air at cutoff is increased by the clearance, the mean press is greater than if calculated on basis of nominal cutoff.

Table 19. Theoretical Ratios of Pressures and Temperatures Due to Expansion of Compressed Air in a Motor Cylinder

Point of cutoff	Ratio of expansion = 1 + cutoff	Ratio of mean to total abs press, for entire stroke	Ratio of mean to total abs press, during expansion only	Ratio of initial to final temp	Ratio of initial to final abs temp, due to expansion only	Ratio of initial to final abs press for ratio of expansion

(Tables 19 and 20 are adapted from G. D. Hiscock, "Compressed Air, Its Production, Uses and Applications," 1901. Also, see Peele's "Compressed Air Plant," 5th edn, Chap 16.)

Cylinder volume. Work per stroke is calculated from ft-lb of work to be done and revolutions of engine. This, with initial and final pressures is substituted in formula for partial or for complete expansion (Sec 39), which is solved for initial volume of compressed air per stroke = theoretical cylinder volume. This is corrected for clearance, according to type of engine, and the proper ratio of stroke to diam is determined. Initial vol of air ÷ vol at end of expansion = per cent of cutoff.

Volume of compressed air required = volume of air per stroke (calculated above) × number of strokes, remembering that there are 4 strokes per revolution in a duplex hoist. Volume so found is reduced to free air (Sec 39). Table 21 gives volume of free air per min per indicated hp, for different cutoffs, without reheating, and at 60° initial temp. These values do not include the volume corresponding to piston clearance (see above).

Table 20. Actual Cutoffs Due to Clearance, for Nominal Cutoffs in Column 1

Point of nominal cutoff	Percentage of clearance

Table 21. Cubic Feet of Free Air per Minute per Engine I H P (F. C. Weber)

Point of cutoff	Gage pressures, lb									
	30	40	50	60	70	80	90	100	110	125
1	23.3	21.3	20.2	19.4	18.8	18.42	18.10	17.8	17.62	17.4
3/4	18.7	17.1	16.1	15.47	15.0	14.6	14.35	14.15	13.98	13.78
2/3	17.85	16.2	15.2	14.5	14.2	13.75	13.47	13.28	13.08	12.9
1/2	16.4	14.5	13 5	12.8	12.3	11.93	11.7	11.48	11.3	11.1
1/3	17.5	15.2	12.9	11.85	11.26	10.8	10.5	10.21	10.02	9.78
1/4	19.6	15 6	13.4	13.3	11 4	10 72	10.31	10.0	9.75	9.42

Quantities of free air in Table 22 are based on actual running time of geared hoists. As such engines seldom run more than 1/4 to 1/2 the time, a compressor of 1/4 to 1/2 the volume given is sufficient, provided there is ample storage capacity, and the time per trip is short.

Table 22. Volume of Free Air for Duplex Hoists (@ 60 lb gage)

Diam of cyl, in	Stroke, in	Rev per min	Normal hp	Actual hp	Wt lifted, single rope, lb	Free air per min, cu ft
5	6	200	6	11.8	1 000	300

8.50	12	110	40	37.8	8 000	952
10	12	110	50	52.4	10 000	1 320
12.25	15	100	75	89.2	....	2 250
14	18	90	100	125.0	....	3 174

Reheating (theory and results given in Sec 39 and 15) reduces volume of air required proportionately to the ratio $T_2 \div T_3$, where T_2 = absolute normal temp, and T_3 = absolute temp to which the air is reheated. Or, the increase in volume is expressed by:

$$T_2 : T_3 = 1 : V_3 \qquad (36)$$

V_2 being the volume at temp T_2. The added volume is obtained at $1/4$ to $3/8$ of the cost of producing the same volume in the compressor itself (15, 5th edn, Chap 18).

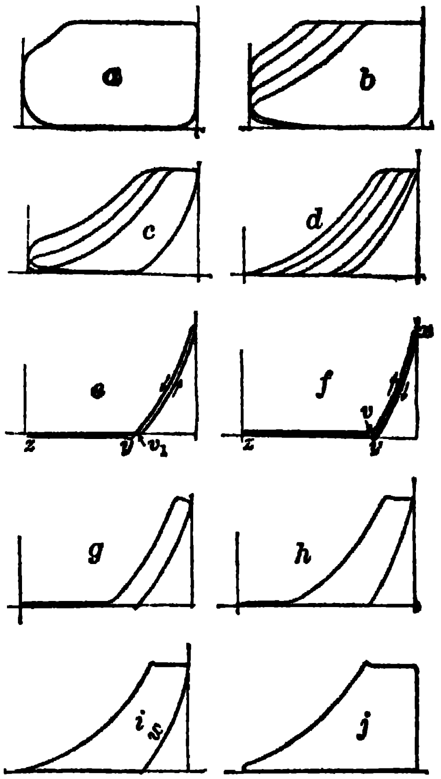

Fig 48. Air-hoist Cards, B. V. Nordberg (47)

Practicable increase of temp is up to 400° F; higher temp makes cylinder lubrication difficult and loss in heat between heater and cylinder becomes excessive. Reheating to 400°, and allowing a transmission drop to 300°, produces theoretical gain of 43%; in practice, say 20 to 30%. Using dry reheaters, a fair average fuel consumption per added hp-hr due to reheating is 0.2 lb coke. Experiments on an 80-hp Corliss engine, with air at 95.5 lb abs, reheated to 338° F, gave a coke consumption of 0.176 lb per added hp-hr. At Anaconda Copper Co's plant, the air is reheated by steam at 200 lb pressure to 250° to 350° F. At Miami, Ariz, the reheating temperature is 350° to 375° F. For hoists, a reheating gain of 20% is generally practicable.

Anaconda valve gear. In modifying the large hoists at the Anaconda mine, and in designing other plants for using compressed air, the aim has been to utilize energy stored in moving parts during retardation to compress air back into the storage system, instead of wasting power in braking. This is done also when lowering instead of hoisting.

Cylinders and valve gear of Anaconda air hoists perform the following functions (47, p 868). In starting, the throttle is opened wide; air is admitted during 0.9 of stroke and exhausted during entire return stroke, giving the card *a*, Fig 48. After making 1 to 3 rev, the governor takes control, cutting off the air at different points as speed increases (card *b*). On reaching about 0.6 full speed the point of closure of exhaust valves is advanced to such point as will cause the clearance air to be compressed to full initial press. As speed increases the cutoff is further shortened by the governor (cards *c*), the last card of series *c* representing the air expanded to atmospheric press, and engine theoretically working at its best efficiency. To maintain this efficiency and eliminate loops in the card (due to expanding below atmos press) free air is admitted to cylinder at all points of cutoff shorter than last card in *c*. This stage is shown in cards *d*. In card *e*, the last of the group, air is cut off practically on center, and expanded to atmos press, which is then maintained to end of stroke. Also, atmos press is maintained on return stroke to the point where recompression begins. This card corresponds to work of ± 0. At this point maximum speed is attained, and the hoist runs by momentum of the moving masses.

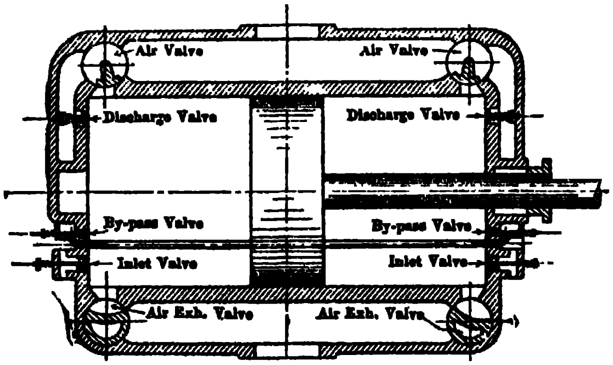

Fig 49. Anaconda Air-hoist Cylinder, B. V. Nordberg (47)

To retard without applying brakes, the regulating lever is moved to retarding position, causing admission valve to remain closed during forward and return strokes, as in card *e*. Exhaust valve now opens, air is ejected during return stroke, and the process of producing cards *e* and *f* is the same. The regulating lever controls point of closure of exhaust valves during the exhaust stroke, resulting in the shaded area of *f*, which represents negative work. By further movement of the lever from its neutral position, cards *g*, *h* and *i* are made successively, *i* representing compression of a full cylinder of air. The effect of the gear is to exhaust all air not to be compressed, and then compress the remainder. By moving the lever to its extreme position, an auxiliary valve opens communication between ends of the cylinder, while the piston passes its center with both exhaust valves closed. The compressed air then flows to other side, which is filled with free air, causing increase of several pounds press in front of piston, the disappearance of the re-expansion line *w* in card *i*, and a much higher mean effec press of compression, which stops the hoist. Card *j* is produced at this time. Fig 49 is a diagrammatic section of the cylinder and valves. The poppet inlet valves prevent air in cylinder from expanding below atmos press. Discharge valves operate automatically when air is compressed back into the system; by-pass valves are opened positively and closed automatically. Fig 50 shows the operation of this gear. For first 5 strokes, cylinders are completely filled; next 5 strokes are made with gradually shortened cutoff, after which the clearance compression gear comes into action.

No air is admitted during last 6 strokes, air being compressed back into the system. Work represented by this compressed air is shown by the area below atmospheric line.

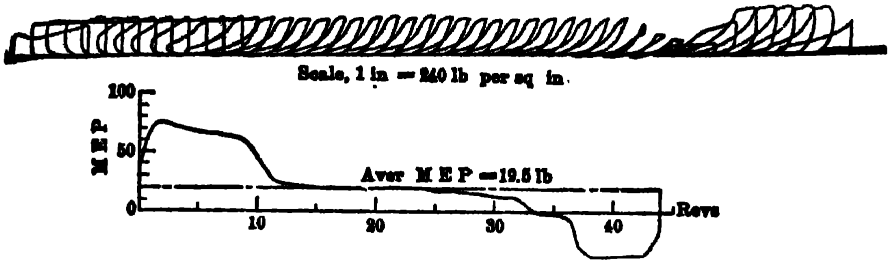

Fig 50. Hoisting Card (Leonard Shaft, Butte) from Head End of 34 × 72-in Air Hoist, 12-ft Drum; Running Balanced. Hoisting Speed, 1 800 ft in 45 sec (B. V. Nordberg, 47)

17. GAS AND GASOLENE HOISTS

Field of use: where high freight rates make coal expensive, where there is scarcity of water for generating steam, for isolated mines, or for temporary work. Small gas engines are not so well suited to hoisting as steam or air hoists of same capacity. Because of time required to start from rest, the engine must run continuously, the drum being operated by friction clutch. Hence, in intermittent hoisting, economy is low.

Fuel consumption. Producer or city gas, gasolene, distillate, kerosene, or crude oil, may be used. Producer gas, or waste gas from coke ovens, furnishes a cheap fuel. Small hoists require 0.10–0.15 gal gasolene per hp-hr; a standard 4-cyl, 20-hp engine uses about 1 gal gasolene per hr.

Advantages: portability, independence of steam or electric plant, low cost of attendance, economy of fuel, and low first cost, when power plant for steam or electric hoists is considered.

Types. Engines may have 1 or 2 drums, with friction clutches. For the larger hoists there is usually an auxiliary friction clutch on engine shaft. They are usually non-reversible, requiring lowering to be done by brake, but there may be special gearing between engine and drums, similar to an automobile gear-shift, to reverse direction of rotation of drum, thus permitting hoisting in balance. Sometimes designed for 2 speeds. Engine is 4-cycle, and varies from single horiz cyl to vertical 6-cyl, rated as 60–80 hp. Larger multiple-cyl units may have self-starters.

Table 23. Single Friction-drum Gasolene Hoists (Fordson units used on 20-hp sizes)

Horse power	Drum		Hoisting capac, lb	Speed, ft per min	Approx shipping wt, lb		Approx price with motor, f o b factory (1926)
	Diam, in	Length between flanges, in			Without motor, lb	With motor, lb	
5	8	18	1 000	100	1 200	....	$ 700
10	10	18	1 500	150	2 200	....	....
15	10	20	2 500	150	2 800	....	....
20	12	20	4 000	125	3 750	4 900	1 095
20	18	20	2 500	200	3 800	4 950	....
20	24	20	2 000	250	3 850	5 000	....
20	24	20	1 250	400	4 000	5 150	....
35	12	26	6 000	160	4 200	....	1 260
50	14	27	8 500	160	6 200	....	....
60	14	27	10 000	160	6 500	....	2 500

Rating and capacity. Rating is usually on basis of indicated hp. Lifting capac and hoisting speed depend on quality of engine and care in maintenance. Let L = load or lifting capac; HP = rated hp of engine; e = mech effic of hoist; S = hoisting speed, ft per min; then,

$$L = 33\,000\, eHP \div S \qquad (37)$$

Up to 10 hp, e may be assumed as 0.5 to 0.6; for larger engines, 0.6 to 0.7.

Costs vary widely with type and make of motor. A Middle-west manufacturer quoted (1926) on single-cyl hoists: 3 hp, 9 to 12-in drum, $368; 6 hp, 6.5 to 12-in drum, $520; 10 hp, 9 to 16-in drum, $845. For other costs, see Table 23.

18. HAND WINDLASS

Windlass has low efficiency and small capacity; hence, limited to prospecting, sinking winzes, beginning shafts, and small-scale development work. For prospecting, economical limit of depth is, say, 75 to 100 ft.

Principal dimensions for ordinary windlass (Fig 51): Diam of barrel, 6 to 9 in; length, to suit size of shaft; crank arm, 14 to 16 in; length of handles, 15 to 18 in; height, center of barrel above platform, 42 in. Cost, $20 to $35 complete, varying more with cost of labor than of materials.

Capacity and cost of operation. An average man can do 2 500 ft-lb of work per min, applying force of 20 lb at crank. Hence, crank velocity is 125 ft per min; which, with 15-in crank, gives 16 rpm, or a hoisting speed of 33.5 ft per min with 8-in barrel. At 75 lb gross load per man ($125 \times 20 \div 33.5 = 75$, nearly), allowing half the time for filling, dumping, and lowering bucket, 2 men can hoist 7 200 lb from 100 ft in 8 hr. Fig 52 shows cost and capacity, for different depths, with 2 men and 1 bucket, wages 20¢ per hr, 3 min being allowed for filling, dumping, and lowering (1915).

Manila rope, 0.75 to 1 in diam is best for windlass; wire rope tends to kink and is not suited to small diam of barrel.

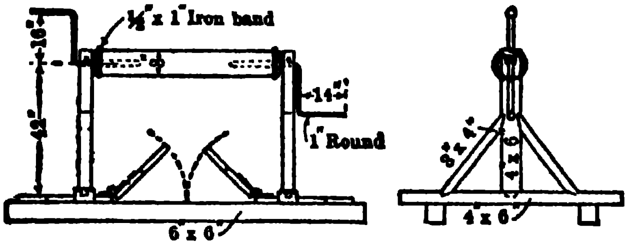

Fig 51. Hand Windla

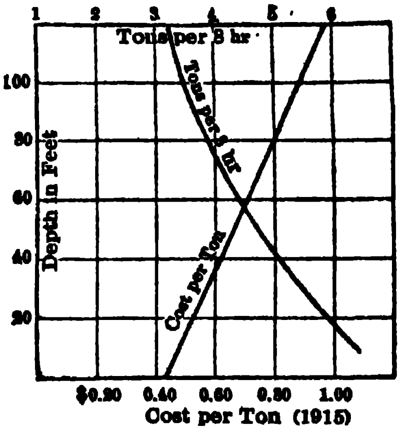

Fig 52. Hoisting with Windlass

Buckets may be of heavy sheet iron, or made from half of an oil barrel, with iron bands top and bottom. Bail, 0.75-in round iron, with eye at center; ears for bail are the ends of a 0.25 by 1.25-in strap, passing down each side and under bottom of bucket, with 3 or 4 rivets on a side. Wt of bucket, 60 to 75 lb (Art 28).

19. HORSE WHIM

Uses. For sinking when depth and capacity required are too great for a windlass; for preliminary or small-scale development work, not warranting a power hoist; or for beginning a shaft while installing steam or electric hoist.

Construction. When made at the mine, whim is entirely of wood except bolts and small quantity of bar iron (Fig 53) (49). This design is called "malacate" in Spanish-American countries. Axis of drum is vertical, and arm or sweep is attached at top or bottom of drum. If at bottom, the horse passes under rope leading to head sheave; if at top he steps over rope, which is then led off in a covered trench. Details of Fig 53: Foundation *a* of rough logs, drift bolted and filled with stone. Footstep bearing for drum is of two 10 by 12-in by 8-ft timbers *b*. Spindle *e*, 12 by 12 in, cut down at ends *c* to 6 in diam and capped with 6-in pipe couplings. Drum, 3 ft 6 in diam by 2 ft 6 in high, of 3-in plank bolted together and lagged with hardwood strips. Sweep *i*, 6 by 12 in, is mortised to spindle and reinforced with 3 by 6 in by 5-ft pieces *j*. Crosspiece *f*, 10 by 10 in by 30 ft, is reinforced at center with 3 by 10 in by 5-ft pieces *g*, and supported by 12 by 12-in posts, braced to suit direction of pull of hoisting rope. Yoke *k* is of 3 by 0.75 in by 6-ft steel, swedged to 2 in diam at top and swiveled in end of sweep, so that horse can turn sharply and travel in either direction. Brake ring *h*, of 3-in planks, may be added for safety. With this whim a 1 100-lb horse raised a gross load of 2.5 tons at 27 ft per min. Instead of a timber crib base, the bottom bearing may be made by a socket in a large stone or in a timber imbedded in the ground. Cost of whim (1915), $70; (1926), $125–$150.

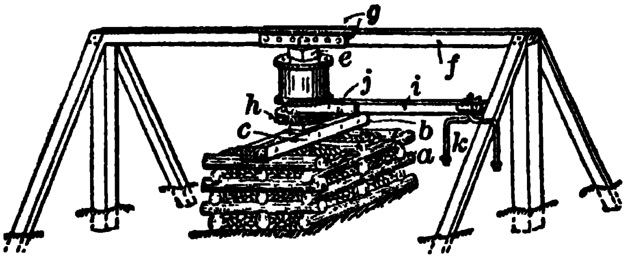

Fig 53. Whim for Sinking Shaft at Mineville, N Y

Length of sweep should not be less than 12–14 ft, as a horse does not work well when traveling a circle of less than 24–28 ft diam. Decrease in hoisting speed due to a long sweep is counteracted by increasing drum diam; and this increases life of rope. Length of sweep should be 5–7 1 radius of drum, when gearing is not used.

Ready-made whims are obtainable in a number of forms. They are occasionally used, but have been largely displaced by small gasolene hoists (17).

Capacity and cost of whim hoisting, for a given depth, depends on power of horse (21 000 to 25 000 ft-lb per min), time required for filling, dumping, and lowering bucket and rate of wages. Fig 54 shows cost per ton and capacity for whim hoisting from depths of 50 to 300 ft, under following conditions: One horse, @ 25 000 ft-lb per min; hoisting speed, 50 ft per min; gross load, 500 lb; wt of bucket, 125 lb; wt of 5/8-in wire rope, 0.62 lb per ft; 2 men and 1 horse at surface, $1.25 per hr; time for dumping and changing buckets, 1 min (requiring good arrangement at shaft mouth); lowering with brake, 200 ft per min. For depths of 50 to 100 ft the duty and cost are constant, because tonnage handled is all that 4 shovelers (maximum number that would be employed under the conditions) could load in time required for each hoist. (**Note.**—Manufacturers' rating of whims is sometimes equivalent to 2 or 3 times the average work of a horse.)

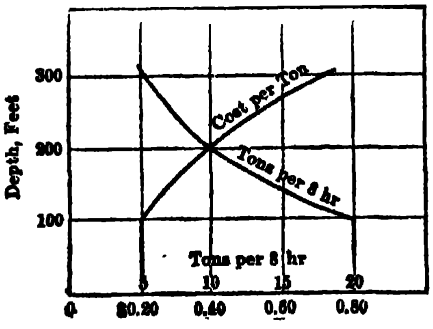

Fig 54. Capacity and Cost of Whim Hoisting

Rope for whims is sometimes hemp, but is better cast steel, of ordinary lay, 1/2 to 5/8 in diam. (For wire rope data, see Art 7.)

Buckets should be light; 1/8-in plate is thick enough, if reinforced at rim. A wide shallow bucket is better than a deep one, as it is easier to fill and dump. Diam is greatest at top, to prevent large stones from wedging fast when dumping; but for inclined shaft, where bucket slides on skids, a barrel-shaped bucket is necessary. Buckets with bail attached at top are safest, but those swinging on trunnions on the sides, below center of gravity, are easier to dump. Proper capacity for 1 horse, 8–9 cu ft. An 8-cu ft bucket, of 1/8-in plate, weighs 130–150 lb and costs 14–20¢ per lb.

20. HOISTING FROM DEEP SHAFTS

Deep hoisting is taken to mean hoisting from depths over 3 000 ft. Because of time required, and increase in ratio of rope wt to net load, both speed and load must be increased to maintain a given tonnage. Long ropes require large drums, presenting special design problems. Best grades of steel rope are requisite and the tendency is towards round rope of constant cross-section. Bi-cylindro-conical drums are used to decrease load on motors, and are of such dimensions that rope does not wind on itself, thus increasing rope life (6, 30). Cylindrical drums are sometimes used, but in each case the choice must be an adjustment of operating cost, effic and capital outlay.

Methods in use and proposed (Art 1) are: (*a*) balanced hoisting in a single lift, with conical drums and ropes of uniform section or tapered; (*b*) Whiting system, with tail rope; (*c*) Koepe system, with tail rope; (*d*) hoisting in tandem with 2 skips on each rope, one suspended at half the depth and one at full depth, for loading and dumping simultaneously, lower skip discharging into bins from which upper skip is filled; (*e*) hoisting in 2 or more stages, with lower stage hoist either on surface or underground.

Types of drive on the Witwatersrand (1923). Out of 72 winding engines serving 39 deep shafts, there were 50 steam, 10 Ward Leonard and 12 induction plants (1). Present practice is towards Ilgner-Ward Leonard drive, in both U S and So Africa (6, 30). A. L. G. Tindley (39) recommends direct-acting steam hoists as economical, when hoisting plant is considered in relation to compressor and haulage capac required. At Randfontein, exhaust steam from hoist is used to give 30 000 cu ft of air per min. Savings of 2 1/2¢ per ton are claimed over Turbo-Ilgner plants. Donk Bros Coal Co, Ill, use exhaust steam from direct-acting hoist to generate electricity for underground haulage and coal cutting; also used by N J Zinc Co and Copper Range Co (37). Stubbs Perry plant (39) resembles the Ilgner-Ward Leonard, but a steam turbine replaces a-c motor, with an eddy-current brake, all on same shaft.

Hoisting in a single lift. Elsdon & Dolan (30), 1935, state that So African practice favors stage hoisting, but that equipment for a single-stage lift of 6 300 ft is being installed at the Simmer & Jack mines. There will be two bi-cylindro-conical drums (Art 2), 13 and 35 ft diam. Ore load, 8 ton; skip wt, 9 000 lb; 2-in rope, with breaking strength of 203 to 210 ton; rope speed, 3 000 ft per min; a Ward Leonard drive, with 2 d-c motors, each of 1 800 hp at 225 rpm. Rope safety factor, 5 for men, 4.7 for ore.

21. EXAMPLES OF HOISTING PRACTICE

Ross shaft, Homestake Mining Co, S Dak (6). Max vert lift, 5 275 ft; wt of skip, 12 500 lb; wt of ore per skip, 14 000 lb; 1 7/8-in rope. Drums, double bi-cylindro-conical, 12 and 25 ft diam, with parallel shafts, cross gear connected, both clutched, Ilgner-Ward Leonard drive. With two 1 500-hp, 300-rpm, 600-volt motors, two 1 250-kw, 720-rpm, 600-volt generators, one 1 750-hp, 720-rpm a-c motor, one 40-kw, 720-rpm, 125-volt exciter, and one 44-ton flywheel, the hoisting capac is 3 225 ton in 15 hr, at 5 275 ft, and 5 475 ton in 15 hr, at 2 200 ft.

Simmer & Jack shaft, So Africa. Stage hoisting (30); vert lift, 6 300 ft; double bi-cylindro-conical drums; wt of ore, 16 000 lb; wt of skip, 9 000 lb; 2-in rope. Rope speed, 3 000 ft per min Ward Leonard drive, 2 d-c motors, one for each drum, rated at 1 810 hp, at 225 rpm.

No 4 shaft, City Deep mine, So Africa (41). Stage hoisting; max vert lift, 4 500 ft; $2\frac{1}{4}$-in rope; rope speed, 3 100 ft per min; wt of ore per trip, 8 ton; capac 250 ton per hr, Ward Leonard drive; 2 cylindrical shafts, $50\frac{1}{2}$ ft between centers.

New Orient coal mine (45, 46), Ill, normally hoists 10 000 ton in 8 hr from 500-ft depth. It has hoisted 15 000 ton and equipment was designed for 12 000 ton per 8 hr. Ilgner-Ward Leonard drive, with a 2 200-hp, 2 200-volt a-c motor; two 1 650-kw, 600-volt d-c generators; one 50-kw, 250-volt d-c exciter; 90 000-lb flywheel at 575 rpm. Hoist motors, d c, are cooled by washed air, each being 2 000 hp, at 75 rpm. Cycle: acceleration, 5 sec; full speed 6 sec; retardation, before entering dumping horns, 3 sec; retardation at dump horns, 3 sec; rest period, 9 sec. Total cycle, 26 sec. Depth of shaft, 607 ft; wt of coal per trip, 22 000 lb; wt of skip, 15 100 lb.

Red Jacket shaft, Calumet, Mich, is equipped with Whiting hoists. Shaft is vert, 4 900 ft deep (91). Two driving sheaves, 19 ft diam, driven by a pair of inverted vert, triple-expansion condensing engines. High-press and intermediate cylinders of each engine act on one crosshead, low-press cylinder on another. The crossheads are attached by connecting rods to opposite ends of a triangular walking beam, pivoted between the crosshead guides. From third point of the beam, a connecting rod goes to crank of first driving sheave. Cranks are 90° apart, connected by parallel rods to cranks of second sheave. Cylinders, 20.5, 31.75, and 50 in, by 72-in stroke. Steam press, 180 lb. Max speed, 50 rev per min. Use of a tail rope greatly reduces swaying and vibration of hoisting rope. Main rope, 1.75 in, tail rope, 1.375 in.

No 5 shaft, Tamarack mine, Mich, is 5 309 ft deep. Hoist has 2 simple, non-condensing Corliss cylinders, each 34 by 60 in (see Table 14, No VI). Cylinders are set at 45° to horiz, so that the two at each end have center lines at right angles, and are connected to a common crank pin. Hence, when one cylinder is on center the others act at 45°, 90° and 135° from this position, giving ease of starting and uniform torque (Fig 12).

Turf shaft, Village Deep mine, So Africa. Vert depth, 6 600 ft. There are 3 stages: upper, about 4 100 ft vert, the two lower stages being inclines (8).

San Juan Del Rey mine, Brazil. Vert depth, 6 726 ft. Hoisting is in 5 stages; in upper stage, 2 264 ft deep, hoist is driven by Pelton water wheel; next 3 stages are each 1 200 ft, with compressed air hoists; lowest stage has an electric hoist.

Quincy No 2 hoist (installed 1920) has probably the greatest single lift: 10 000 ft on the incline; 6 600 ft vert depth. It has a cylindro-conical drum, grooved for $1\frac{5}{8}$-in rope. Skip weighs 10 000 lb; rope, 10 000 ft, 41 500 lb; ore, 20 000 lb.

North and South vert shafts of Randfontein Central Gold Mining Co, So Africa. Two Ward Leonard electric hoists, installed 1922, are designed for 5 000 ft vert depth, at max speed of 4 000 ft per min. The cylindrical drums are 12 ft diam by 6 ft wide; rope, 1.75 in. A steam hoist, designed for same duty, has 39- by 78-in cylinders; cyl drum, 14 ft diam by 5.5 ft wide, to hold 4 layers of 2-in rope; max unbalanced load, 60 000 lb. On the Rand, cyl drums are preferred to cylindro-conical (8). Conical drums can not be constructed for full equalization of rope load, as angle of drum face becomes dangerously steep for deep shafts, or length of drum prohibitive.

For hoisting 50 tons per hr from 5 000 ft, McCulloch and Futers (4, p 142) calculate an engine of following dimensions: small diam of drum, 9 ft; large diam, 24 ft; cyls, 38 by 48 in; max speed, 60 ft per sec; time for loading and dumping skip, 30 sec; net load, 6 100 lb; taper rope in 4 sections, lowest 1 800 ft being 0.9375 in diam, the other 3 of 1 400 ft each being 1.0625, 1.1875 and 1.25 in diam, respectively; total wt of one rope 11 600 lb, with safety factor of 7. If a uniform-section rope were used, diam would be 1.4375 in; total wt, 30 000 lb. Steam press is assumed at 150 lb. For same output, steam consumption is about 4 times that required for 3 000 ft. H. C. Behr (50) shows that hoisting engines more than 3 times as large are required for a given hourly output from 6 000 ft as from 3 000 ft.

23. DESIGN OF HEADFRAMES

Types. Headframes are of the A-type or modifications of it (Fig 56 and 65), or of the 4- or 6-post type (Fig 64 and 59). The A-type is more economical in material, and the stresses are all determinate. The 4- or 6-post type is necessary when the shaft compartments are not in line with engine; that is, when axis of drum is normal to long dimension of shaft. They are common in the Penn coal fields, where the compartments are large and so require considerable overhang of sheave to line up its circumference with center of shaft, and where there are often 4 compartments in a row. Where a rock-house or tipple is combined with the headframe, the 4- or 6-post type lends itself a little more readily to the construction.

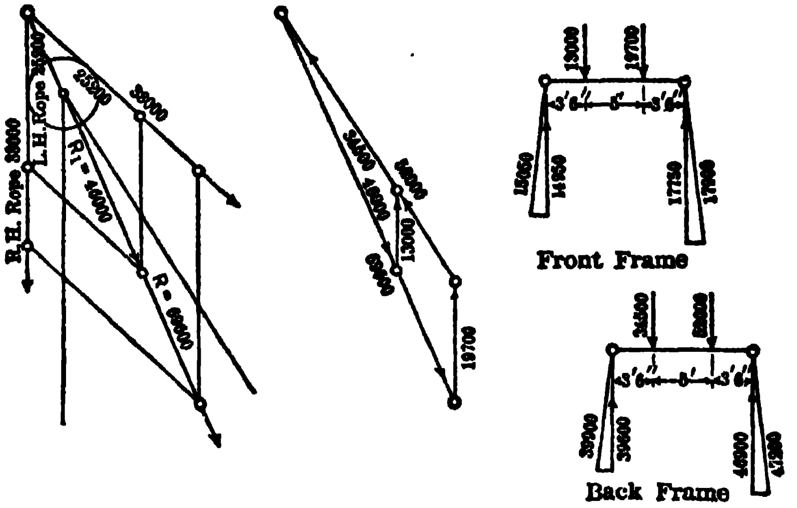

Fig 55. Rope Load Resolution

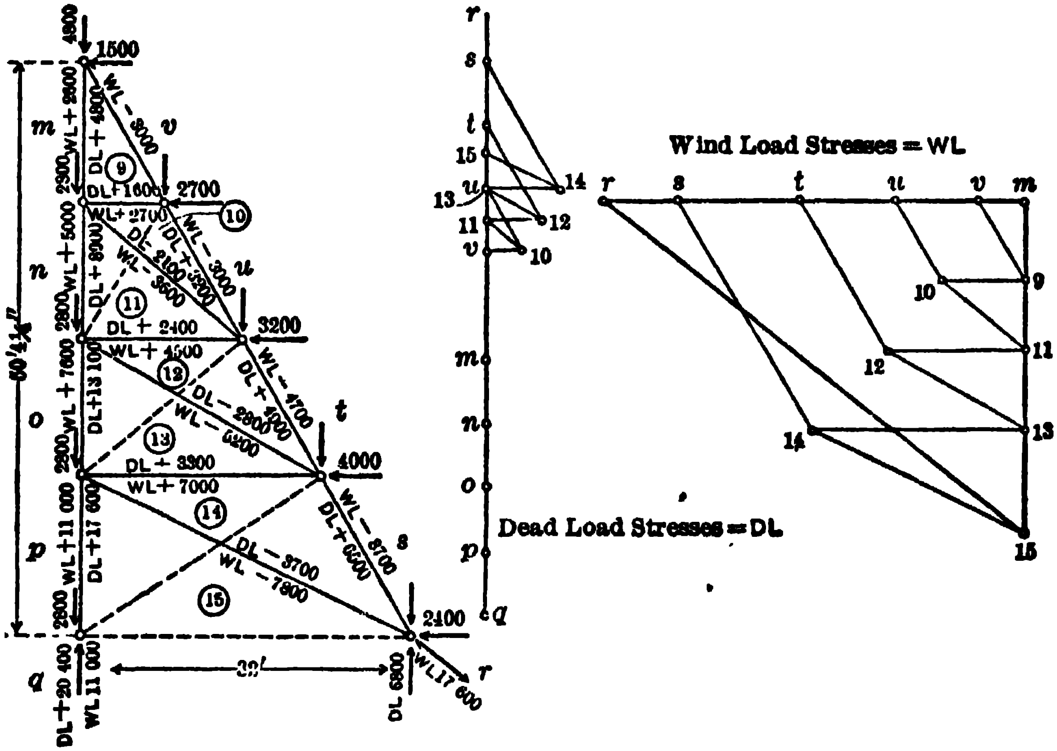

Fig 56. Headframe Stress Sheet, Side Elev

Special structures, falling within the above two classes, are sometimes erected to meet unusual conditions; for example, the concrete headframe (Fig 80), and the rock-houses of the Mich iron

and copper districts (51, 52). Also, frames like those of Allen and Garcia (Fig 74), with single or narrow back-brace, are sometimes advantageous. The main frame may usually be classified as of the A or 4-post type, or combinations of these, as where two or more hoists serve several shaft compartments not symmetrically placed, thus requiring back bracing on more than one side; or where the headframe is built into the tipple or crusher house.

General principles of design are the same as for any framed structure. Severe conditions of mining and great variation of load require larger safety factors than ordinary structures, and ample thickness of section for steel members, because of the exposure to corrosion at mouth of shaft, from mine air. Minimum thickness of section is usually specified as $^1/_4$ in to $^5/_{16}$ in.

Height is fixed by: elevation of cage landing or skip dump above surface; over-all height of cage or skip, when in dumping position; and allowance for overwinding (Art 34). OVERWINDING ALLOWANCE depends chiefly on speed of hoisting, type of engine, and drum diameter. It is usually specified in terms of drum circumference, but with drums of 20 ft or more diam, and where the ore is discharged to bins or crusher at a considerable height above shaft collar, this may give a prohibitive height of frame. For speeds under 500 ft per min, 8 to 10 ft is ample, although it is better to allow more if convenient. For high speeds, a clearance of 25 ft, from rope socket to sheave center, is rarely exceeded, where the landing is above the ground, and 35 ft where the landing is at shaft collar. At the landing portals, bracing is arranged to allow ample room for handling.

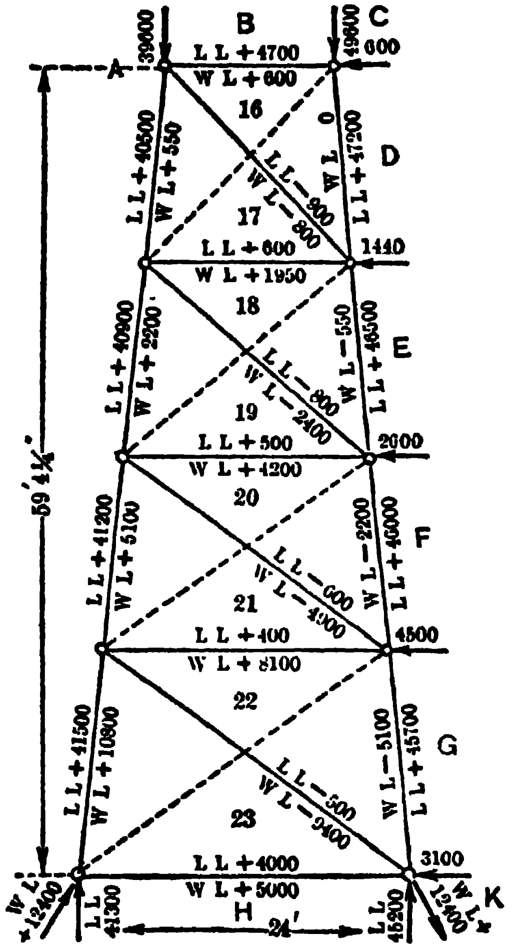

Fig 57. Headframe Stress Sheet, Projection on Plane of Back Stay

Calculation of stresses. For A or 2-post frames, all stresses are determinate and are conveniently found graphically. Total stresses are due to: (*a*) DEAD LOAD, or weight of the structure and sheaves with their bearings (Art 5). Weight of frame is approximated from that of a similar headframe (Table 31, 32), (by a preliminary estimate) and divided equally among panel points. (*b*) WIND LOAD. Wind pressure is taken at 30 lb per sq ft for head-frames which carry a housing, and at 50 lb per sq ft on the vertical projection of the members if not housed. Wind loads are considered as applied at the joints of members. (*c*) LIVE LOAD, assumed as equal to one-half the breaking strength of the rope (see also Art 24 and 25). With 1 rope, each side of frame takes half the live load. With 2 ropes (hoisting in balance), each side of frame takes the full live load of one rope, for 2-and 4-post frames, while with a 6-post frame, having a central set of posts, the middle set takes the full load of one rope, and each side takes half the load, provided the sheaves are equidistant from the center and side posts. In the A or 2-post frame, it is sufficiently accurate to consider the live-load stresses as acting at the intersection of front post and back stays; although, in the structure itself, the resultant of the rope stresses may not pass exactly through this point. Bracing in the side panels takes none of the live-load stresses. Diagonal bracing is assumed as being in tension only, in steel frames, whence the horiz struts are compression members, though under certain conditions they may act in tension. In the 4- or 6-post frame some of the stresses are statically indeterminate, and for accurate design reference may be made to standard works on the subject (53). Fig 60 shows a method meeting ordinary requirements. The frame and its bracing are assumed to carry all the wind and dead load, excepting the wind stresses in transverse bracing of back stays. Since diagonals are considered as tension members only, redundant diagonals are omitted in calculations.

It is to be remembered that the frame as a whole must be sufficiently stable to resist overturning by wind pressure. For this it is usually best to depend on width of base, rather than on anchor bolts, which may be weakened by corrosion. Maximum overturning effect of wind will be in a direction parallel to the shortest dimension of the base area. The total area in sq ft of all members exposed to wind, *on both windward and leeward sides* of frame, multiplied by assumed maximum horiz press per sq ft, gives total press in lb. This may be taken as a concentrated horiz load, acting at the center of figure of the frame. It is resisted by the wt of structure, including sheaves and bearings, multiplied by half the width of base.

The position of the center of figure can be closely approximated in any given case. In proportioning the width of base, sufficient allowance should be made to cause the diagonal resultant of wind press and wt of frame to fall well within the base area. The calculation is similar for a structure with housing attached to the frame.

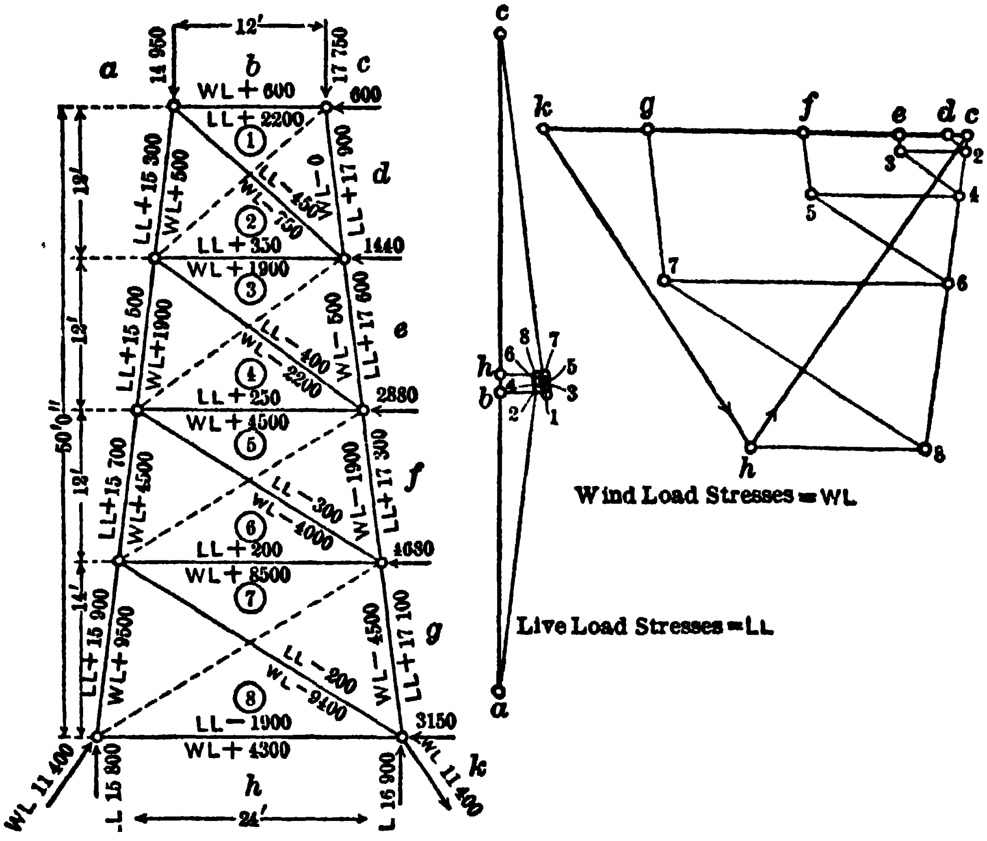

Fig 58. Headframe Stress Sheet, Front Elev

Graphic determination of stresses for an A or 2-post frame is shown in Fig 55, 56, 57, 58, in which the loading on one rope is assumed as half the rope's breaking strength and on

Table 27. Maximum Stresses in Headframe Members

Member	Maximum tension	Maximum compression	Member	Maximum tension	Maximum compression
Front posts	0	+45 700	11–12	0	+ 6 900
Back brace posts	−3 000	+63 000	12–13	− 8 000	0
1–2	−1 200	0	13–14	0	+10 300
2–3	0	+ 2 250	14–15	−11 500	0
3–4	−2 600	0	16–17	− 1 700	0
4–5	0	+ 4 750	17–18	0	+ 2 550
5–6	−5 200	0	18–19	− 3 200	0
6–7	0	+ 8 700	19–20	0	+ 4 700
7–8	−9 600	0	20–21	− 5 500	0
8–9	−1 900	+ 4 300	21–22	0	+ 8 500
9–10	0	+ 4 300	22–23	− 9 900	0
10–11	−5 700	0	23–H	− 4 000	− 5 000

the other double the weight of skip, contents, and rope. Shaft, 1 200 ft deep; skip, 2 500 lb; ore, 4 500 lb; 1-in plow-steel rope, 1 896 lb; breaking strength of rope, 76 000 lb; sheave, 6 ft diam. In Fig 58, the wind load on side of frame, combined with the live load, gives the maximum stresses in front posts and bracing. Bracing in front and back elevations takes none of the dead load. Weight of frame is estimated as 50 400 lb, and stresses due to dead load, and wind pressure from the rear, as shown in Fig 56, give maximum uplift at foot of back brace if the ropes should at any time be removed from the sheaves. Fig 57 shows stresses in back brace due to live load and to wind pressure on one side. Bases of posts are usually made normal to plane of front and back of frame. Combining the reactions at foot of one back post gives maximum uplift normal to the base of 10 500 lb, a maximum pressure of 61 900 lb, and a shear on anchor bolts at right angles to normal pressure (or tension) of 10 000 lb. Similarly for the front posts maximum normal pressure on the base is 48 200 lb and shear 8 900 lb.

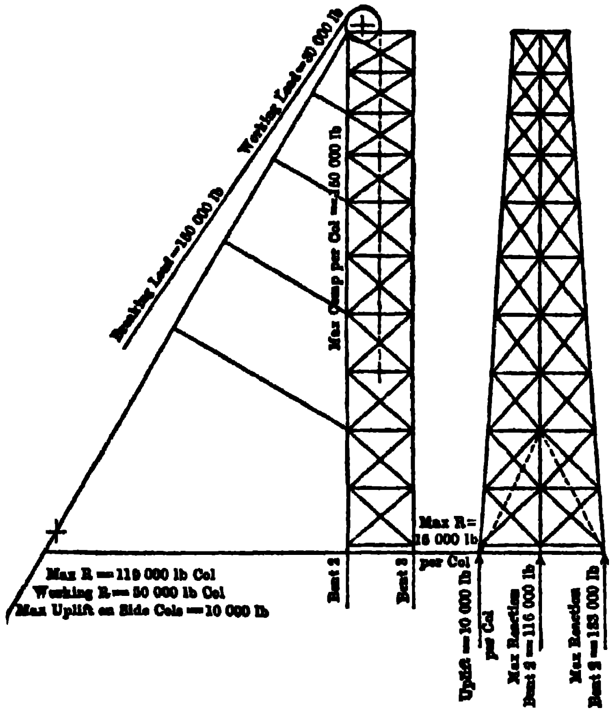

Fig 59. Main Stresses in a 6-post Frame

Four- and six-post headframes. In these, since live and wind-load stresses are indeterminate in some members, either the tower, or the A-frame made by the middle bent and back brace, may be considered as carrying all wind load from front or back. In first case, diagonal bracing between back brace and tower is superfluous, because the struts transmit wind pressure from back brace to tower; in second case, struts between front and middle bents transmit wind pressure from the front. Wind pressure from the side is carried by each bent and its bracing in proportion to the surface supported by each, and the stresses are determinate in a 4-post frame. In a 6-post frame the center post is redundant, and wind stresses may be assumed as transmitted to the outside posts and the bracing between them.

Approximate determination of live-load stresses (Fig 60). 1. Resolve resultant of rope stresses at sheave center into its horizontal and vertical components. 2. Determine equivalent reactions due to total vertical component at front and middle bents. 3. Combine vertical reaction at middle bent with total horizontal component, thus making a new resultant through intersection of middle bent and back brace. 4. In these, determine stresses due to new resultant, as in case of an A-frame.

Fig 60 shows this resolution of stresses in the plane of one rope and sheave. Taking a 6-post frame, and considering both ropes loaded with 100 000 lb, vertical reactions at top of each post are shown in (*b*) and (*c*), and in plane of back brace in (*a*). If back brace is placed near resultant, this method gives less stress due to live load in middle bent than in the front, but in practice the middle bent is usually made of same size members as the front. Dead and wind-load stresses with wind from the side are greatest in middle bent. As exact calculation of stresses in statically indeterminate structures depends on rigidity of the structure, this approximate method may be used to determine the sections of members, and on basis of the sections so found, stresses are exactly calculated. If the section of any member is unsuitable, recalculate by the "method of least work." Stress and design features of Eureka Standard headframe are shown in Fig 61, 61a (37).

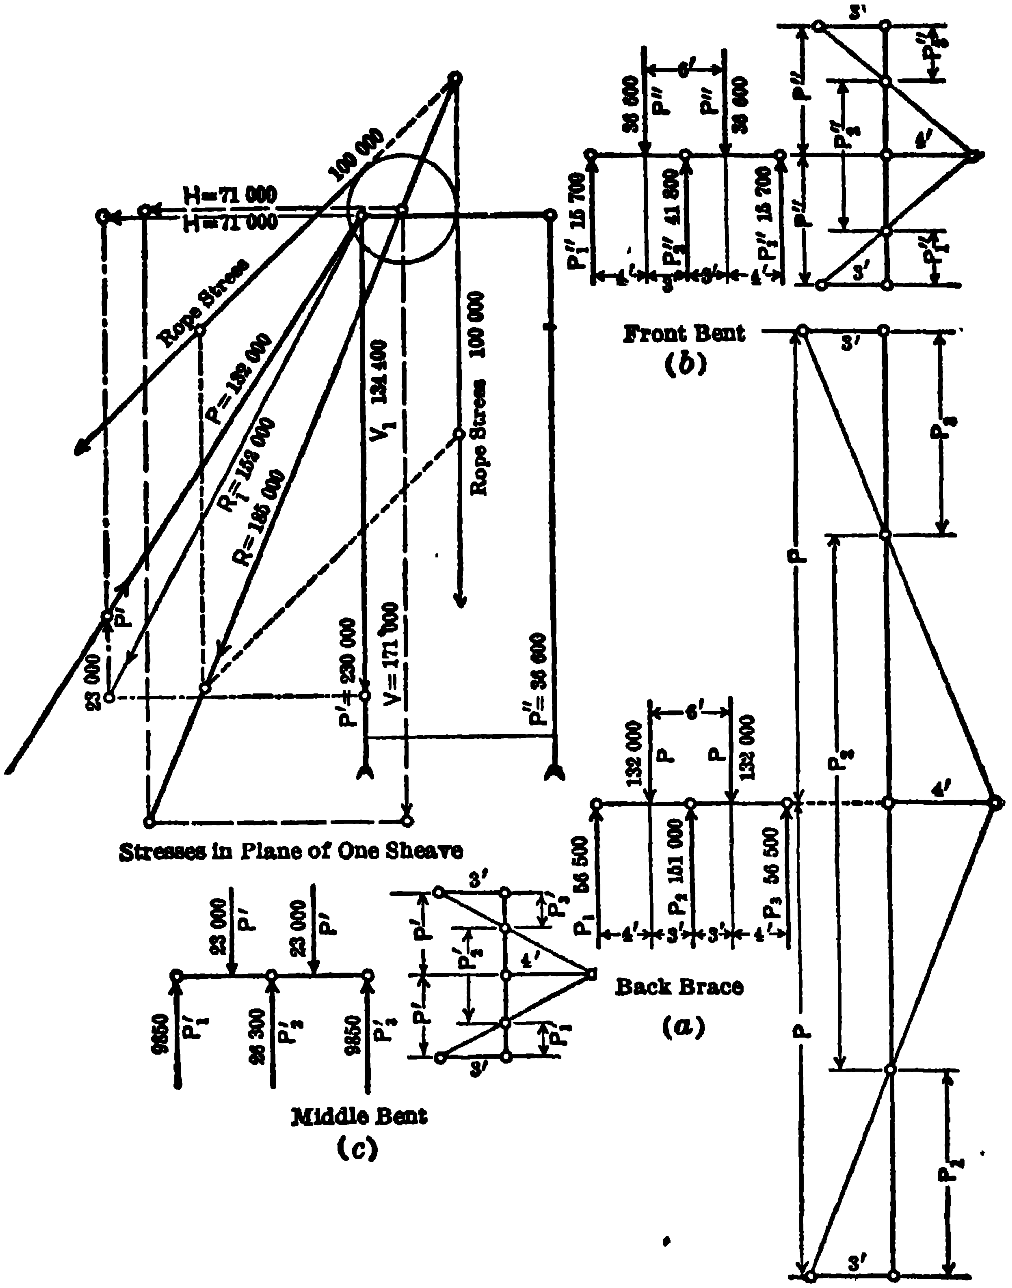

Fig 60. Resolution of Stresses in Plane of One Rope and Sheave

24. WOODEN HEADFRAMES

Temporary headframes for development and shaft sinking are of wood, which costs less, is usually readily obtained and quickly erected. Height depends upon method of disposal of the rock, and size of ore bucket. Simplest form, suitable for a whim in sinking test pits, is a tripod of 3 light posts. A small frame used in Joplin district (Fig 62) has 4 equally inclined posts, without a back brace; the hoist being placed close to shaft mouth, so that the resultant of the rope pull falls well within the base. Fig 63 shows the Montana type, which may be modified for almost any condition; Fig 64, a 4-post and back-brace frame. Fig 65 shows an A-frame, for an inclined shaft at West Dome mine, Porcupine, Ont (54), combined with an ore bin; height, 40 ft; hewed posts,

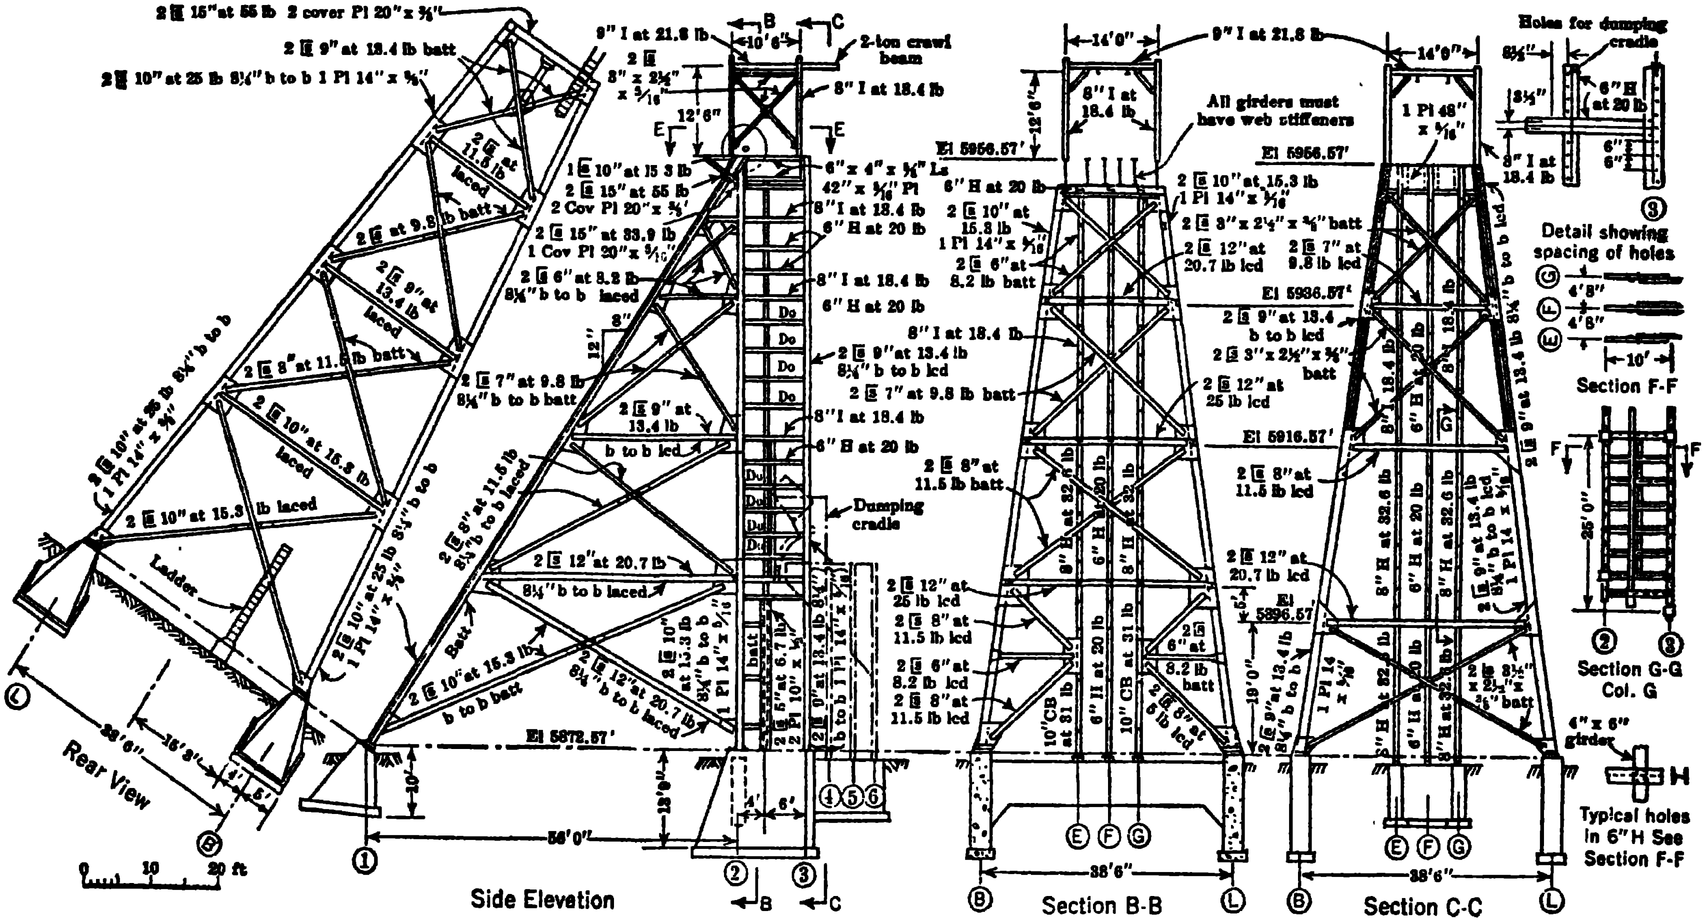

Fig 61. 85-ft Steel Headframe, Eureka Standard Mine, Dividend, Utah (37)

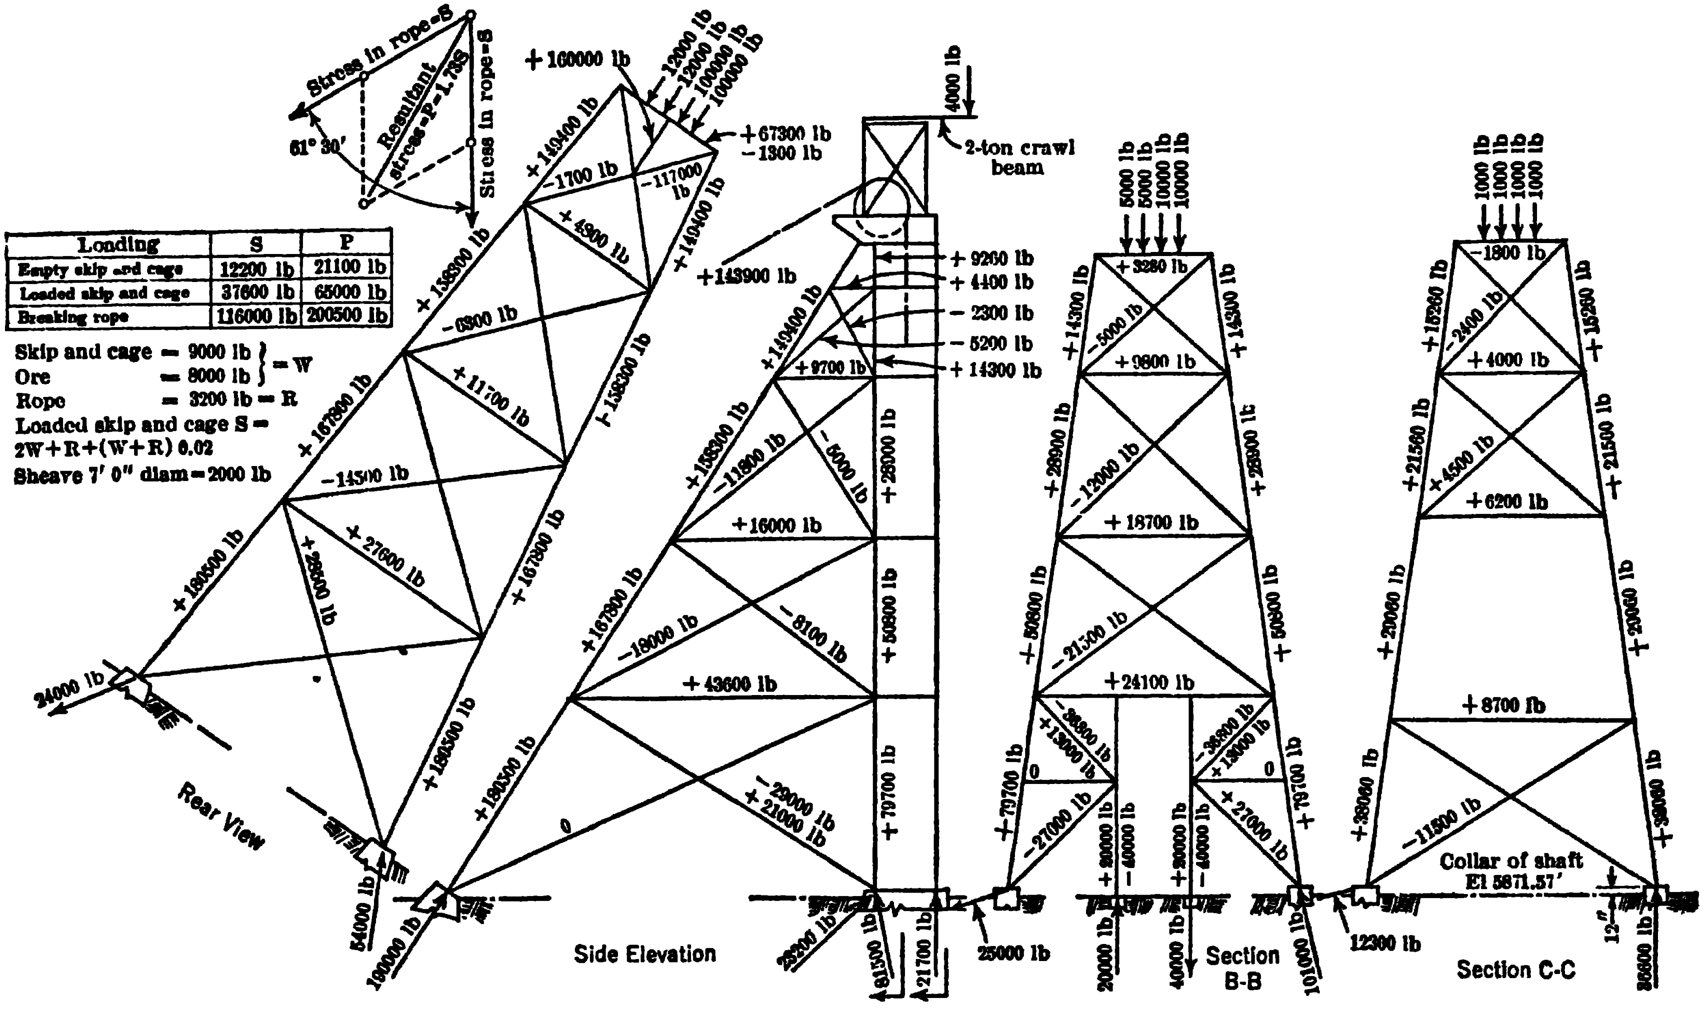

Loading	S	P
Empty skip and cage	12200 lb	21100 lb
Loaded skip and cage	37600 lb	65000 lb
Breaking rope	116000 lb	200500 lb

Skip and cage = 9000 lb } = W
Ore = 8000 lb }
Rope = 3200 lb = R
Loaded skip and cage S = 2W+R+(W+R) 0.02
Sheave 7' 0" diam = 2000 lb

Fig 61a Stress Diagram for 85-ft Steel Headframe, Eureka Standard Mine, Dividend, Utah (37)

10 × 10 in, with a batter of 1 : 8 to 1 : 10. Posts are tied with 3 girts and a cap, back brace with 2 girts, 1-in bolts and tie rods. Front posts are assumed to carry no load, being simply extensions of the bucket skids. This frame costs about $150, exclusive of bin (1913).

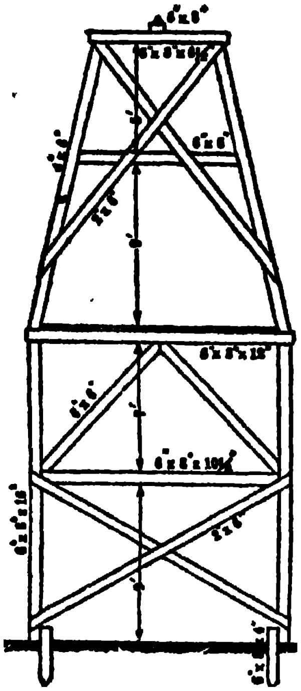

Fig 62. Small Joplin Type Headframe

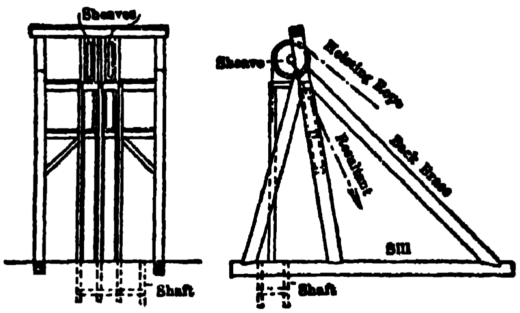

FRONT ELEV SIDE ELEV

Fig 63. Timber Headframe; Montana Type (Ketchum)

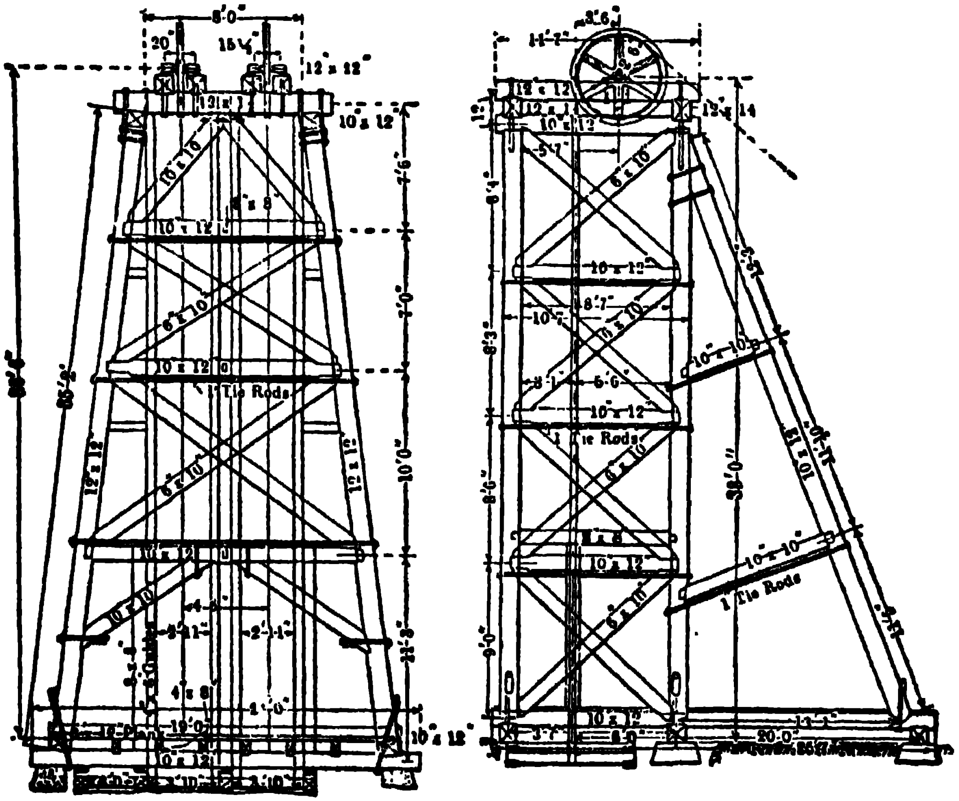

Fig 64. Four-post Frame, with Back Brace

Design of timber headframes. For 4- and 6-post frames the tower is often designed to accommodate the sheaves entirely within the top framing (Fig 64). Otherwise, the sheave girders are carried on short posts set on a girt in plane of middle bent. For 2-post frames the sheaves are supported as in steel frames (Art 25). Fig 67 shows top of 2-post frame, for single-compartment shaft, and working load of 8 000 lb.

Fig 68 shows details of a timber headframe, with tandem sheaves, working load 9 000 lb on each rope. Mortise and tenon trenailed joints, with tie rods, make neat construction, but reduce strength of timbers, and labor cost is greater than for gained joints with bolt connections. For the latter, the braces are gained 1 to 2 in on the posts, with plenty of bolts. Strength of tension members depends more on bearing area of the bolts than sectional area of timber. Malleable or steel castings at joints make strong connections. Steel-plate brackets are not so good as castings. Columns standing directly on the foundation are anchored by angles on opposite sides of the post and bolted through. If resting on sills, columns are similarly anchored to the sill, which in turn is bolted to foundation. A cast pedestal, recessed to receive foot of post, is also recommended. Solid timber is best for main posts, but built-up columns may be used. Allowance for reduction of section by mortises and bolt holes must be made.

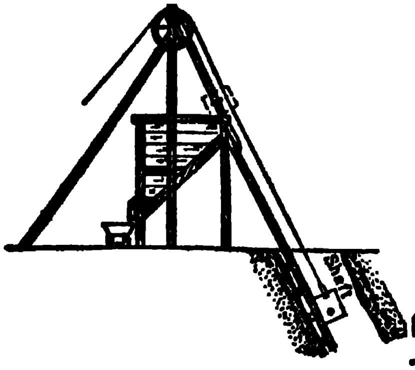

Fig 65. Frame for Inclined Shaft, Porcupine, Ont

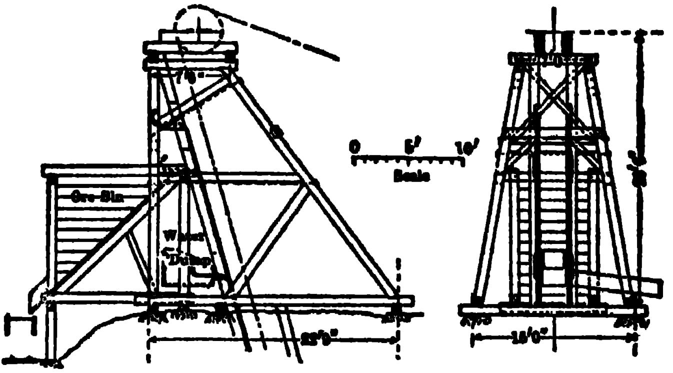

Fig 66. Headframe and Orebin for Development (*Mines & Min*)

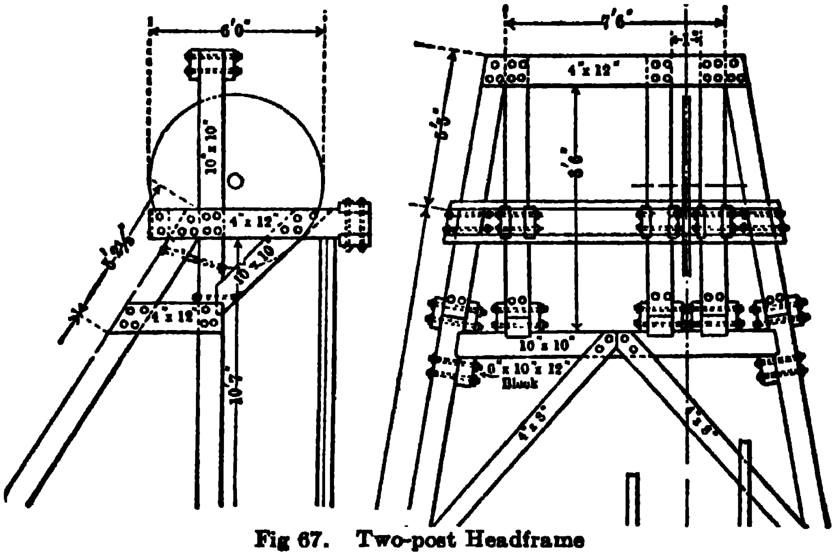

Fig 67. Two-post Headframe

Factor of safety should be double that allowed for ordinary structures, taking into account total rope load from all causes. Or, since headframe should be stronger than the rope, ultimate strength of frame is made twice breaking strength of rope (Art 25).

Allowable unit stresses and strength of members. For timber headframes M. S. Ketchum (53) gives Table 28. Formula 38 gives allowable stresses for dead load, which applies to live load when properly converted to dead load (Art 14). Length of columns should not exceed 45 times least dimension. Unit stress for lengths of more than 10 times least dimension is found by:

$$P = C - (Cl + 100d), \qquad (38)$$

where C = unit stress for short columns (Table 28); P = allowable unit stress, lb per sq in; l = length of column, in; d = least side of column, in. Assoc of R R Superintendents of Bridges & Buildings recommended (1895) the safe unit stresses in Table 29.

Formula 39, for wooden columns, is based on that of the Division of Forestry, U S Dept of Agriculture:

$$P = F \times \frac{700 + 15\,C}{700 + 15\,C + C^2} \qquad (39)$$

in which P = ultimate strength, lb per sq in; F = ultimate crushing strength of timber; $C = l + d$; l = length of column, in; d = least diam, in; F = 5 000 lb for white oak and long-leaf yellow pine, 4 500 lb for Douglas fir and short-leaf pine, 4 000 lb for red pine, spruce, hemlock, California redwood, and 3 500 lb for white pine and cedar.

Table 28. Allowable Working Unit Stresses for Dead Loads, lb per sq in

Kind of timber	Transverse loading, S	End bearing	Columns under 10 diams, C	Bearing across fiber	Shear		Modulus of elasticity, E
					Parallel to grain	Longitudinal shear in beams

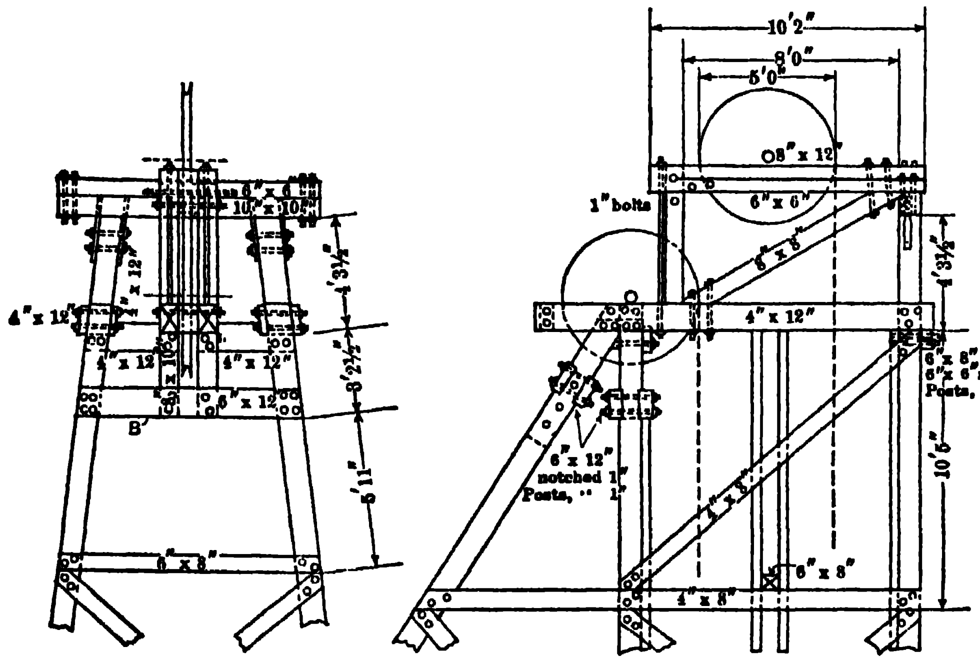

Fig 68. Headframe with Tandem Sheaves

Cost of wooden headframes (Table 30) varies more widely than for steel, due to variation in cost of timber, which ranges from $35 to $100 per M bd ft. With carpenters at $6 per day, cost of erection will be from $40 to $50 per M bd ft. Cost of ironwork, bolts and nails, depends on design, averaging say $20 per M bd ft of timber used.

Comparisons between wood and steel headframes can be sharply drawn for special cases only. Wooden frames are cheaper in first cost and total erection time, considering time required to obtain the material, while steel frames are fireproof and much more durable. Unless given preservative

treatment, wooden frames decay rapidly, and are a source of danger in case of fire. They are now seldom built, except for temporary work or short lived mines; for large tonnage, and when life of mine will exceed that of a wooden frame (say 8-20 yr, depending on climatic conditions), the greater first cost of steel is justified. The difference in cost is less than formerly, due to increased cost of timber. As the strength of steel is known within much closer limits than that of wood, the design can be made with more certainty as to safety of the structure. Large allowances must be made for the variable strength of even the same kind of timber. It is difficult to retain full strength of a timber member at joints, without use of special ironwork which may make the cost approximate that of an all-steel structure. Damage to a wooden frame can usually be quickly repaired by materials and tools at hand. Since joints of wooden frames tend to loosen, from the action of moisture, and from seasoning, steel makes a more rigid structure for high frames. A wooden frame can be erected by local carpenters, while a steel frame requires services of expert erectors.

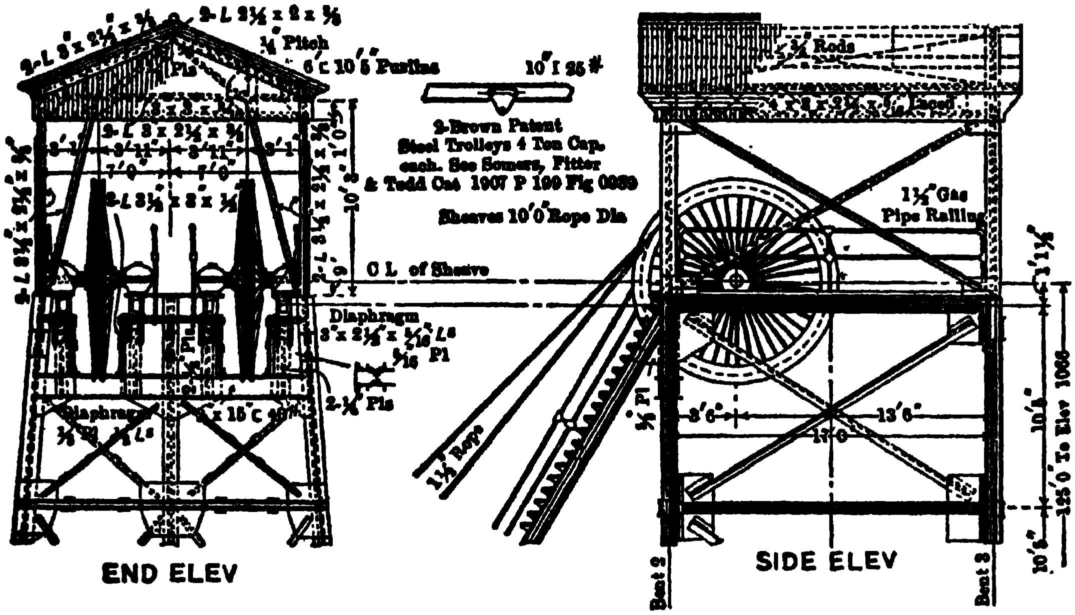

Fig 69. Design of Sheave Supports, Ralph Shaft, H. C. Frick Coke Co

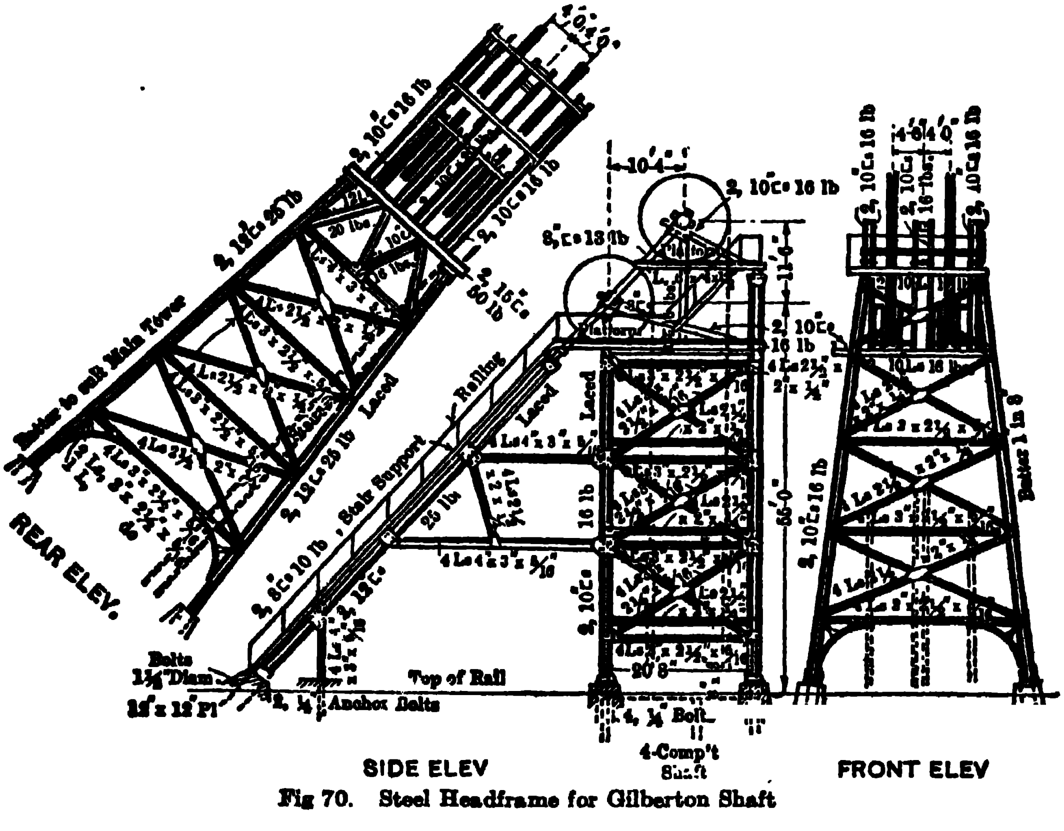

Fig 70. Steel Headframe for Gilberton Shaft

25. STEEL AND CONCRETE HEADFRAMES

Details of design. Cross-sections of posts and main bracing are determined as in Art 23; then sheave girders, post bases and guide supports are designed (see Sec 43). Table 31 gives types of sections of members; angle or H-sections often used for posts of small frames. For 4- and 6-post frames, sheave bearings are usually supported by I-beams. Two shallow beams give a broader and more stable support than one deep beam. They are designed for the bending moment due to vertical component of total rope load on

sheave (Art 14), plus wt of sheave. For the front and back cross girders supporting sheave girders, channels work best into the design. Sheave girders and top of frame are often covered by a steel-plate floor, in which case the horiz component of rope load goes to intersection of back brace and posts, and cross girders on back brace are omitted (Fig 69).

* Hoisting installation, designed for depth of 5 100 ft.

Support of sheaves. With large sheaves, projecting over back of frame, back cross girder must be dropped to clear sheave, and sheave girders then rest on plate diaphragms, with angle stiffeners extending up from cross girder. Fig 69 shows details of this standard design, for Ralph shaft, H. C. Frick Coke Co, by American Bridge Co. Other designs are in use, probably with no increase in wt of material, but at increased cost for shop work. Instead of I-beams, deep plate girders sometimes support sheave bearings, resting directly on the cross girders, but with no special advantage. When sheaves must be in tandem, upper sheave girders are carried at the back by auxiliary posts in plane of back brace (Fig 70); or, upper sheave is supported on an auxiliary tower on main frame. Fig 74 shows an A-frame, designed by Allen & Garcia, with tandem sheaves, the back brace being extended to bearings of upper sheave, and the lower one carried on brackets on back brace. This frame is built into the tipple, and lower half is concreted. As upper half is braced by tipple frame, its width (5 ft) is much less than would otherwise be possible for stability.

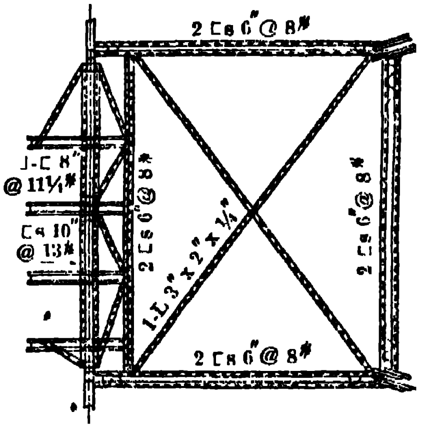

Fig 75. Horiz Sec of Frame, showing Guide Supports

For A- or 2-post frames, sheaves may be supported by plate-girder diaphragms, carried on cross girders on front posts and back brace. If diam of sheave permits, its bearings are bolted to front of diaphragms; if not, they are placed on top. In first case, diaphragms may be braced to the posts by front and back plates. Another cross girder connects front posts above the sheaves, and the diaphragms are extended to it. In second case (Fig 71 and 72), the front posts need not extend above sheave bearings, unless they are to carry brackets for crab rail for changing sheaves. Fig 71, 72 refer to headframes No 7, 12, and 11, Table 31. Fig 73 shows a typical A-frame, Butte, Mont.

Guides for 2-post frames are generally bolted to flanges of I-beams, or other sections, running from shaft collar to top of frame; supported in line by braces of I-beam, channels or angles, from horizontal struts of front bent; they are more rigid if carried back to an auxiliary girt across the frame between 2 side struts (Fig 75). In 4- and 6-post frames, wooden guides are not commonly backed by steel sections, but supported at each panel point by I-beams or channels, between the bents; and, if support is needed at intermediate points, by angle braces from corner posts (Fig 76). Fig 77 shows details of fastening the guides to steel supports.

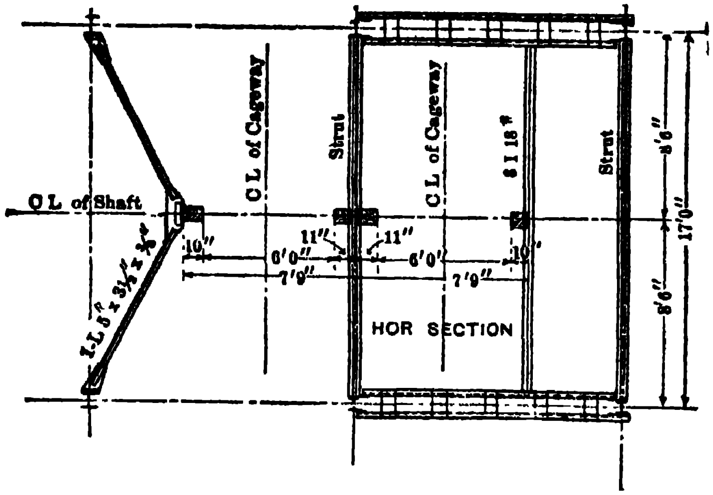

Fig 76. Guide Supports

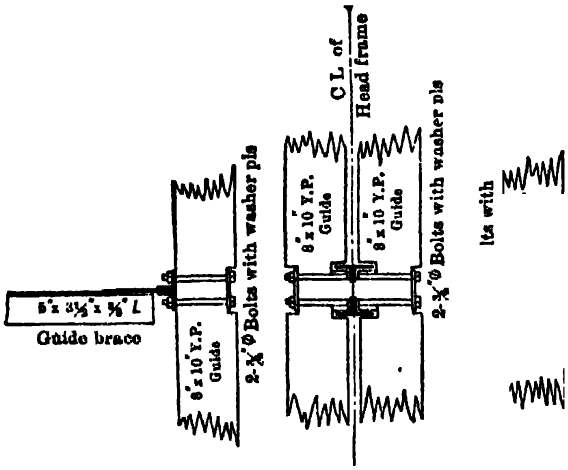

Fig 77. Details of Fastening Guides to Steel Supports

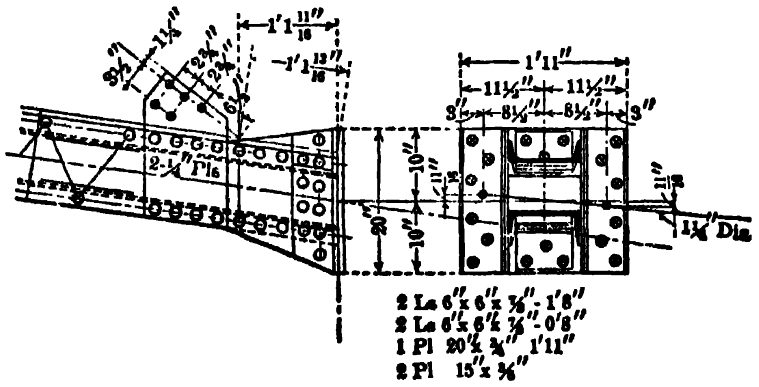

Fig 78. Base of Headframe Post

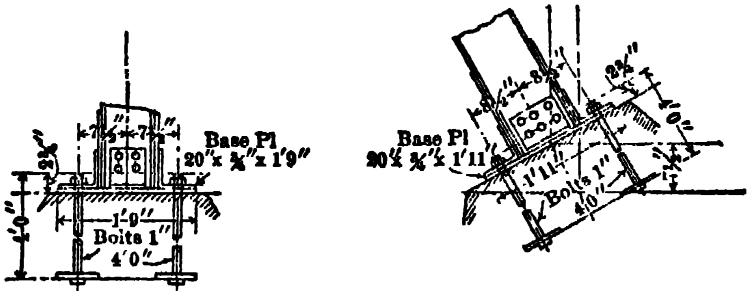
Bases of posts must transmit load to the foundation within the allowable safe unit stress for the type of foundation. This, for best Portland-cement concrete, is 500 lb per sq in; for sandstone or limestone masonry, 400 lb per sq in. There should be at least 2 anchor bolts at foot of each post. Fig 78 shows details of base for a column of two 10-in latticed channels, for a back brace, and Fig 79 an anchorage for front post and back brace. Sometimes a C-I footing is placed between base and foundation, but without advantage for steel frames.

Safety factor must be larger than for ordinary structures, because of varying load and indeterminate stresses (Art 23). Ketchum (53) recommends a factor of 4 for dead and wind load, and 8 for live load (live load being taken as twice the wt of cage and contents, plus wt of rope, plus load due to cage and rope friction); or, a factor of 2.66, if breaking strength of rope or ropes be used instead of live load. If unit stresses for wind, dead and live loads, are added the total unit stress should not exceed the allowable unit stress for dead load by more than 25%; that is, the combined safety factor should not be less than 3.2. If the basis of breaking strength of the rope be used, wind-load stresses may be neglected, except as regards overturning of the frame.



Foot of Post

Foot of Back Brace

Fig 79. Anchorage for Headframe

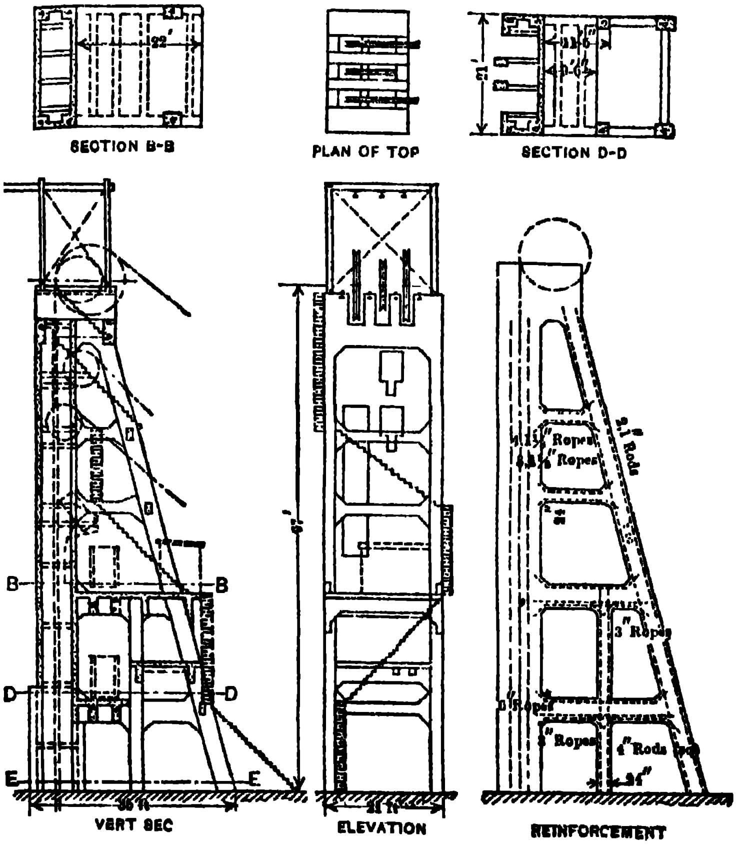


Fig 80. Concrete Headframe, Curry Shaft, Penn Iron Mining Co, Vulcan, Mich *(E & M Jour)*

A rational method is to design for an ultimate strength equivalent to twice breaking strength of rope. Then, by assuming the live load as half the rope's breaking strength, with a safety factor of 4 for all stresses, the live, dead, and wind loads may be combined. This is convenient in selecting proper size of member from structural steel handbooks, the tables of which are usually calculated with a safety factor of 4.

Allowable unit stresses, with a safety factor of 4 (live load being converted to equiv dead load) are: for tension, 16 000, and for compression, 16 000 − 70 (l ÷ r), both in lb per sq in; where l = length of member, in, and r = least radius of gyration, in. Length of compression members should not exceed 100 r for main members, nor 140 r for secondary members. Following values recommended:

Rivets and pins, bearing	22 000 lb per sq in
Rivets and pins, shear	11 000 " " " "
Pins, bending, on extreme fiber	24 000 " " " "
Plate girder webs, shear on net section	10 000 " " " "

In designing the Ralph headframe (Fig 69), the American Bridge Co used following unit stresses for transferring breaking load of the ropes from sheave supports to headframe posts: tension and compression, 25 000; rivets, single shear, 15 000; rivets, bearing, 35 000; all in lb per sq in.

Examples and costs of steel headframes are given in Table 31. Costs apply to the year erected. A firm specializing in design and construction of steel mine structures recently quoted: Per net ton fabricated steel, $100; erection, including tools and insurance, $45; shop drawings, $30; painting (materials and labor), $10; engineering, $15; total, $200 per ton.

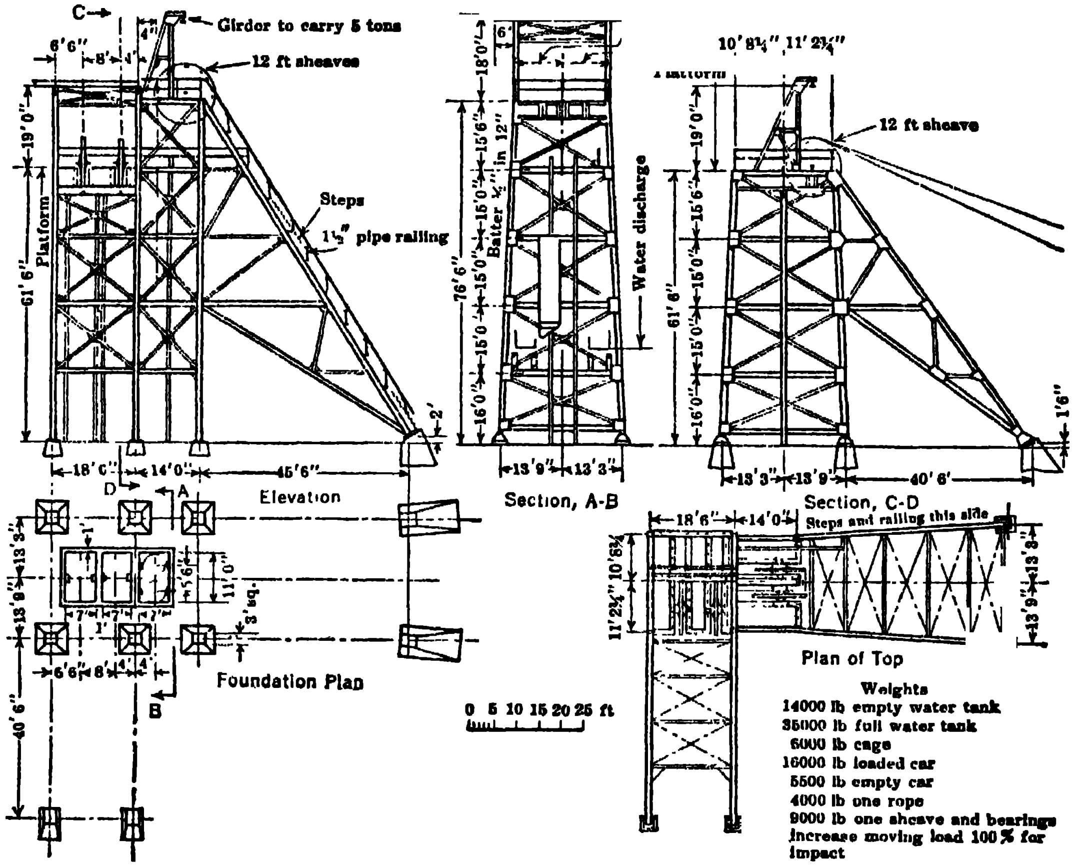

Fig 81. Steel Headframe, No 6 Shaft, Lansford Colliery, Lehigh Nav Coal Co (37)

Concrete headframes, with members reinforced by steel bars or wire rope, have had some application in recent years (52). In general they conform to the lines of steel and wooden frames, except that diagonal bracing is usually omitted, the dead wt and massive structure providing for stability. MATERIALS for the concrete should be of the best; use of mill tailings for aggregate is not permissible unless tests determine their fitness. Old hoisting rope is suitable for reinforcing, if thoroughly cleaned of rust and lubricant. Standard reinforcing bars, however, lend themselves to the different forms and their properties are fully known. DESIGN, as in steel and wood, depends on local conditions. After computation of stresses in usual way, taking into account that dead load usually exceeds rope load, the members are designed as for reinforced concrete structures. ADVANTAGES are permanence, non-combustibility and resistance to atmospheric conditions or corrosive gases from the shaft. Absence of diagonal bracing (Fig 80) leaves more room for portals, and permits most desirable arrangement of bins and tracks. Rigidity and mass of the structure prevent vibration from dumping skips or cars, or swaying from wind and

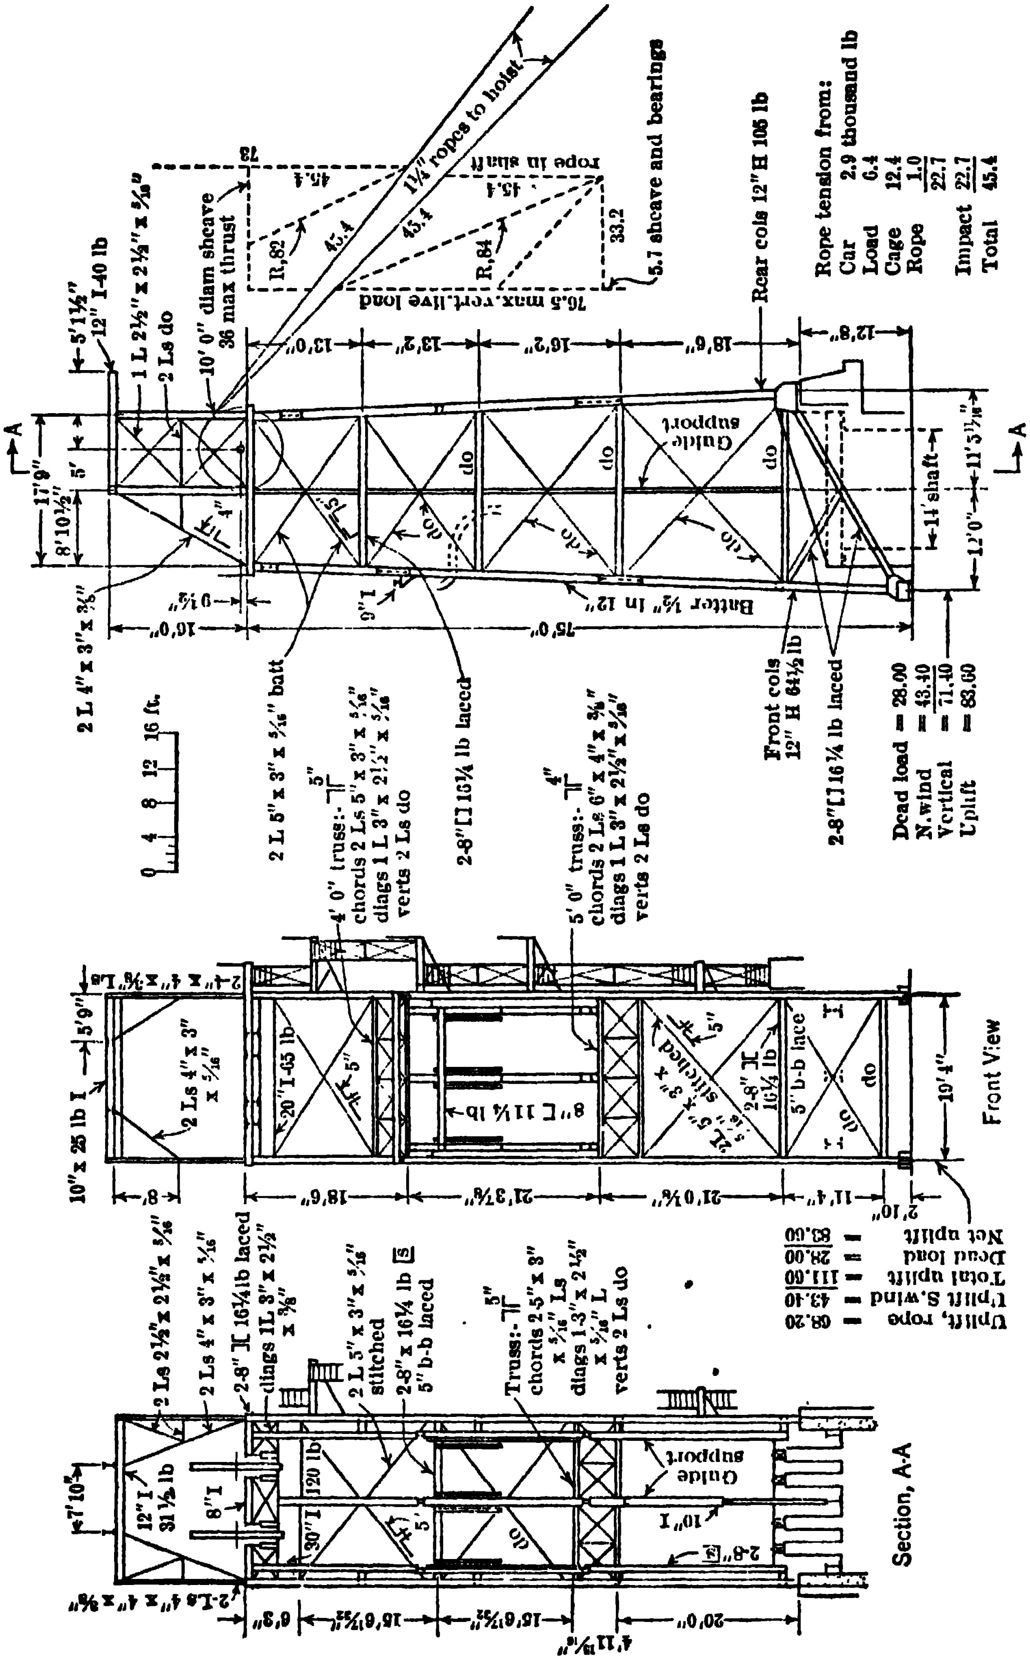

Fig 82. Steel Headframe without Back Legs, Bellevue Breaker, Glen Alden Coal Co, Scranton, Pa (37)

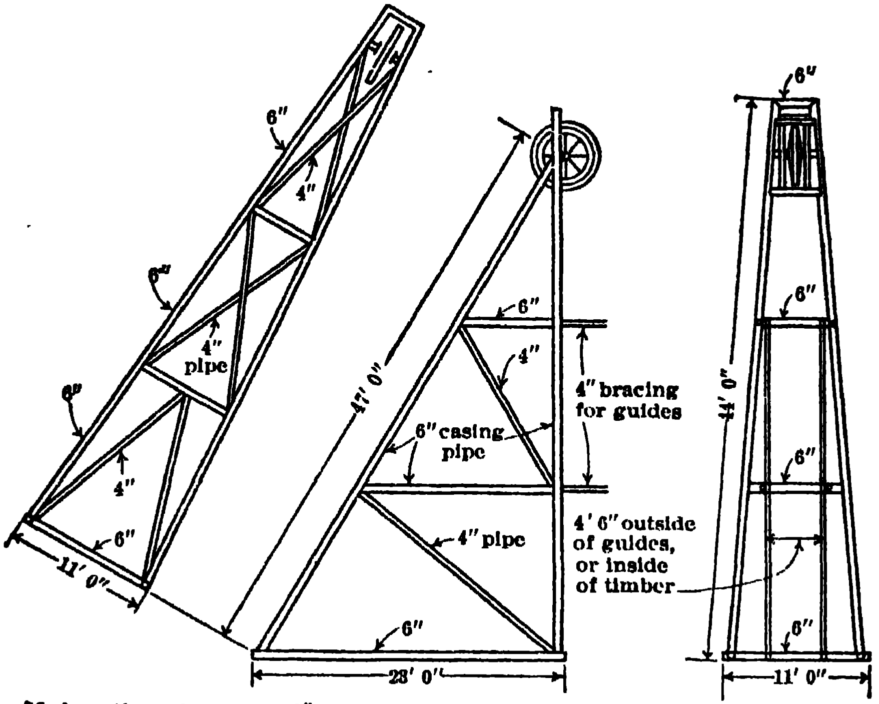
rope stresses. Comparing unfabricated steel and the raw materials for concrete, the latter can be erected more quickly, especially if fast-setting cement is used. DISADVANTAGES. As concrete is not a homogeneous material, design can not be made with the same definiteness and as small a factor of safety as for steel; also, alterations are less easily made than in a steel frame, which can readily be strengthened to carry a heavier load than as originally designed.



Made entirely from used 6" churn drill casing and second hand 4" pipe. All joints welded. Total length of 6" casing = 325 ft. Total length of 4" pipe = 175 ft. Approx wt = 6 ton

Fig 83. Steel-pipe Headframe (37), Metals Reduction Co, Pioche, Nev

Unusual headframes. Fig 81 shows an unusual installation (37) at the Lansford Colliery, Lehigh Navigation Coal Co, where two frames at right angles to each other serve a common shaft; Fig 82, a headframe without back legs, and Fig 83 an ingenious headframe for 2-ton loads, built of scrap pipe, at cost of $150.

26. CAGE GUIDES AND SKIP TRACKS

Wooden guides for vertical shafts are common in American mines, where output is not large nor hoisting speeds excessive. Long-leaf yellow pine is the best wood, because of strength, hardness, and straight grain. Oregon pine is also good. Oak may splinter, warp, and twist out of line in seasoning. Red or Norway pine is best of the soft woods. SIZE of guide depends on wt of cage and hoisting speed. For small cages and slow speed, 4 by 4 in is sufficient, 6 by 8 in being about the max for heavy hoisting. Guides must be dressed to uniform size, thus reducing actual dimensions about 0.25 in from the rough. LENGTH should be such that splices come at the shaft sets; though if the splice be long, this is not so essential, provided shaft sets are not more than say 4 ft apart. CLEARANCE between guide and cage shoe depends upon care with which shaft sets and guides are alined. Greater clearance is needed on face than edges, as gage of guides is difficult to maintain if timbers bend in heavy ground; 0.25 in clearance on edges and 0.5 in on face is usually sufficient. FASTENING to SHAFT SETS is

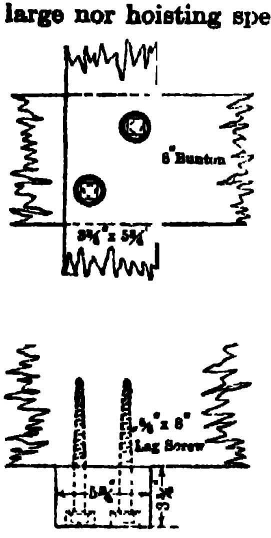


Fig 84. Fastening of Wood Guides

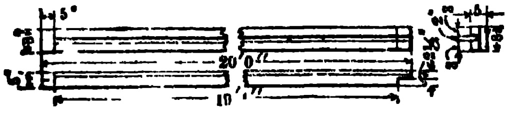

Fig 85. Slotted Guides

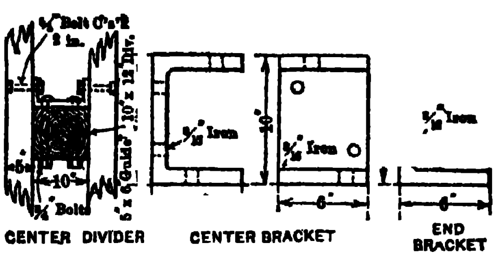
commonly by 1 or 2 lag screws, with countersunk heads (Fig 84). The penetration of lag screw into bunton should be at least equal to thickness of guide. Use of galvanized lag screws facilitates removal and replacement of guides. Iron angles may be used for fastenings, bolted to both guide and shaft timber (Fig 87).



CENTER DIVIDER CENTER BRACKET END BRACKET

Fig 86

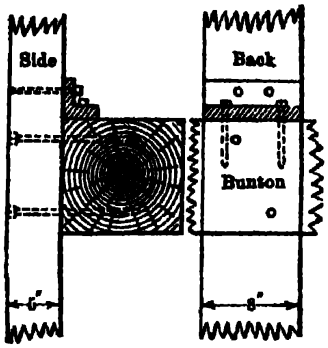


Fig 87

Examples of wooden guides. At No 2 shaft, Hancock Consol Mining Co, Mich, guide face is slotted with lag screw heads countersunk in slot (Fig 85); if a screw becomes loose it will work down this slot, instead of sticking between guide and shoe. These guides are backed by studdles between the dividers. Fig 87 shows fastening for guides at Tobin & Dunn mines, Mich. Lag screws are 5/8 in. The 3 by 3-in angle is placed every 10 to 15 ft, bolted to guide by 0.5 by 6-in bolts, and to divider by 0.5-in lag screws. Fig 86 shows method at Indiana mine, Mich. Guides are 5 by 6 in, in 32-ft lengths, with butt joints; brackets, 3/16 by 5 in. On the Rand, So Africa, the standard wooden guide is 4 by 8 in (1).

Guide joints. Fig 89 shows joints used on the Rand and elsewhere, for 4 by 8, 5 by 6, 4 by 6. and 4 by 5-in guides. At Butte, Mont, guides are usually 4 by 9 and 5 by 9 in, fastened by two 7/8 by 8 or 7/8 by 9-in lag screws at each shaft set.

Steel guides are rapidly coming into use for heavy hoisting, especially in concrete-lined shafts. They wear better than wood, have better alinement, and are non-combustible; safety catches, if of correct design, work satisfactorily. As steel guide dimensions are not changed by moisture, clearance between cage shoe and guide may be smaller.

Different forms of rolled sections are used, but standard T-rail is common. Rails are bolted to buntons and connected by standard splice bars, since only the rail head serves as a guide. Wt of rail, 60–100 lb per yd. In a concreted shaft, Rosedale mine, Cambria Steel Co, Pa, 100-lb T-rail guides are carried by 8-in channels (57). Fig 88 shows bracket support for 80-lb rail guides, in No 4 shaft (cylindrical), of City Deep mine, Rand (1).

Wire-rope guides, preferably of locked-coil type, are often used in Europe for shafts of circular section. At Dalton collieries, Rotherham, England, the shaft is 21 ft diam and 2 238 ft deep. Cages are 3-decked, 18 ft high, and carry 7 tons of coal. At each corner of the cage is a locked-coil rope guide, under 14 tons tension; and between the cages, to prevent collision at passing point, hang 2 rubbing guide ropes under similar tension.

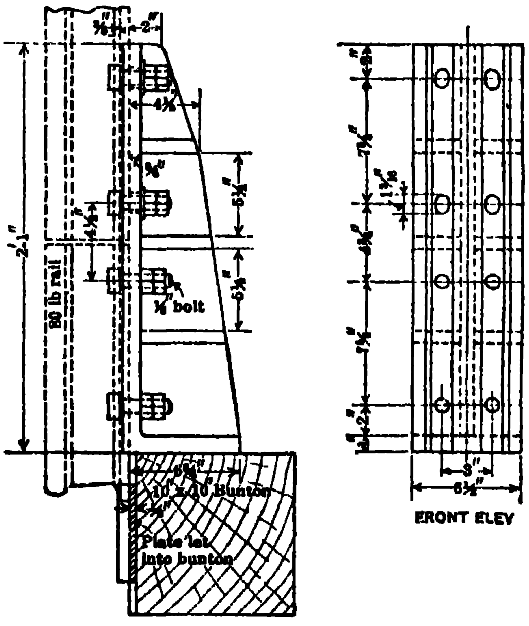

Fig 88. Bracket Support for Steel Rail Guides, Rand (Vaughan)

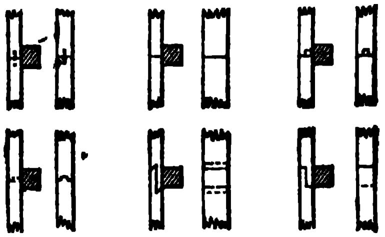

Fig 89. Joints for Wooden Guides

Skip tracks for inclined shafts, if at a pitch not exceeding 30°, are built like surface tracks, except for measures to prevent downward creep of the rails. Notching rail flanges for spikes at 2 or 3 places in a rail length is generally sufficient. If shaft timbering includes sills, rails rest on these with 1 or 2 intermediate ties, and are lined up with wedges. In absence of timbering, every third or fourth tie must be "hitched" into side walls of the

shaft. Rails not lighter than 30-lb should be used, even for light skips and slow speeds; 45 and 50-lb rails for heavier work. Concrete stringers for skip tracks are replacing sills and ties, for heavy service and when the life of the mine warrants added cost.

Fig 90 shows stringers and mode of fastening rails at Mohawk and Wolverine mines. Upper ends of the diagonal bolts are not exposed to injury by derailment of skip. Bolt holes are made by inserting rods 1/8 in larger than the bolt, and withdrawing them when concrete is partly set. Fig 90 also shows the form for molding upper part of stringer, with blocks attached for forming the recesses for nuts and washers. 2 by 4-in creosoted blocks are set in the concrete, 1 in deep and 18 in apart, to cushion the rail. Concrete of 1 : 2 : 5 is mixed on the level above, and poured down troughs to desired point. In 24 hr 6 or 8 men can build 100 ft of double-track stringer. On steep slopes it is difficult to hold the rail. At Copper Range shafts, pitching 70°, the method shown in Fig 91 and 91*a* was devised. The rail rests on a 6 by 10-in longitudinal stringer, set in the concrete base.

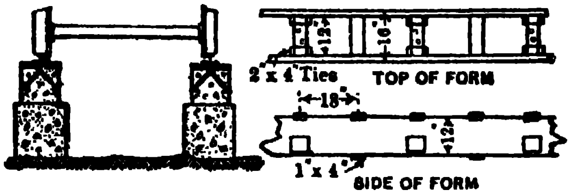

Fig 90. Skip-track Concrete Stringer and Form (*E & M Jour*)

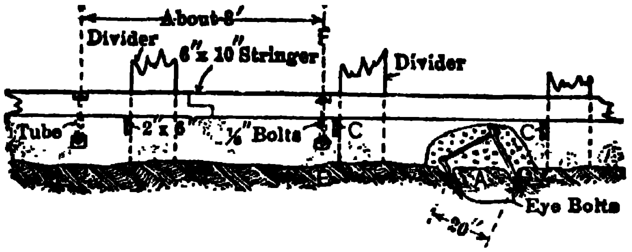

Fig 91. Copper Range Skip Track (Longit Sec)

Three notches on each side of rail receive the spikes, and C-I chairs *B* (Fig 91*a*) prevent spreading of rails. The wooden stringers are bolted to the concrete at 8 ft-intervals. Access to nut end of bolts is through 3 by 4-in iron boxes, set in the concrete. Bolt heads are countersunk in the stringer and covered by the rail, so that they can not be broken off. The concrete is anchored to footwall

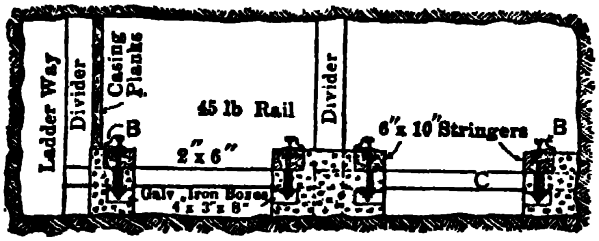

Fig 91a. Copper Range Skip Track (Cross-sec on E–F, Fig 91)

25 ft, by eyebolts set in holes in foot wall (Fig 91). In building the forms 2 by 6-in crosspieces set to grade, on which the wooden stringers are laid. Concrete mixture is 1 : 2 : 6. For r illustrations, see Bib 37, Chap 21.

27. HOISTING SIGNAL SYSTEMS

Signals in use and recommended for metal mines (58) are shown in Table 33; signals in use and recommended for coal mines (59), Table 34. Modifications to provide for hoisting or lowering from and to different levels are generally made by the local management or by telephonic communication with hoistman.

Bell wire and gong operated by hand is cheap and positive for a few levels, or depths not exceeding 400 or 500 ft. Beyond this the springs or weights to counterbalance wt of bell wire require a heavy pull; and the man giving the signal is not sure it has been properly received or understood by the engineer. Light galvanized guy strand, 0.156 to 0.25 in diam makes the best bell wire, though it is quite stiff, and changes of direction should be

made by bell cranks, not by sheaves. Wooden cleats are better than iron staples to hold the bell wire to shaft timbers. Fig 92 shows usual arrangement.

Table 34. Standard Signals for Hoisting and Lowering in Coal Mines (59)

Signal from shaft to engineer:

1 Bell—Hoist; or stop if hoist is in motion.
2 Bells—Lower.
3 Bells—Men to be hoisted. If men can be hoisted, the engineer signals to cager with one bell, who then admits men to the cage, and gives signal to hoist, one bell.
4 Bells—Hoist slowly—danger.
5 Bells—Accident in mine; send in stretcher.

Signals from engineer to shaft:

1 Bell—Men can get on cage.
2 Bells—Send up empty cage.

Other signals as needed may be arranged by mine officials with approval of mine inspector. They must be added to the list posted at landings and in engine room.

Pneumatic signals are largely used in collieries in eastern and middle states. Ordinary pipe and fittings are used between stations. A stroke of the hand plunger in cylinder *A* (Fig 93) slightly compresses air in the pipe, causing all the gongs of the system to ring, and the whistles to blow. The pipe may also be used as a speaking tube.

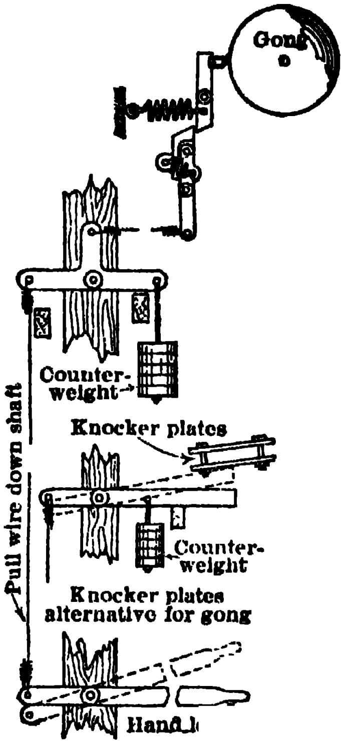

Fig 92. Bell Wire and Gong (37)

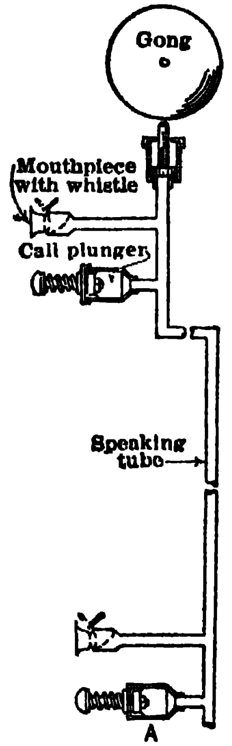

Fig 93. Pneumatic Bell and Speaking Tube Systems (37)

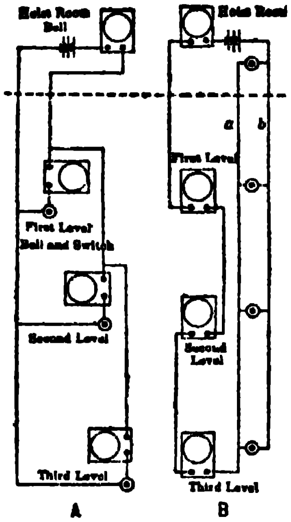

Fig 94. Low-voltage Electrical Signal Layouts

This method is reliable, with practically no maintenance expense; not affected by water, and accidental signals can not be given as in some electrical systems. No indicator can be used, as in electrical systems, to supplement bell signal. Cost for each station outfit (Fig 93), not including piping between stations, is approx: 300 ft signaling distance, $30; 800 ft, $35; 1 500 ft, $45; 2 000 ft, $60. In Missouri lead district, a small whistle is often placed on the air line at top of shaft, and blown by a hand wire from the shaft stations; a bell in engine room is sounded from the shaft mouth.

Electric signal systems are of general application, but for reliability require careful installation and maintenance. There are 3 classes:

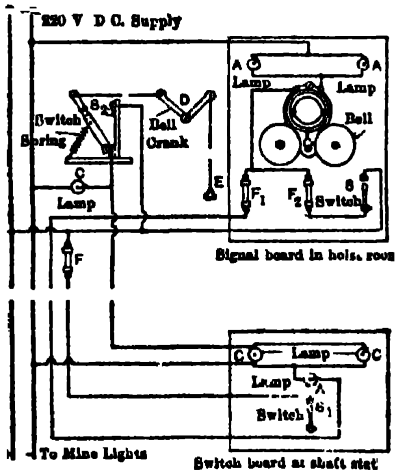

Fig 95. Shaft Signal System, Rosiclare, Ill

A. Low-voltage direct current, operated by wet, dry or storage batteries. Annunciator bells should be iron clad and waterproof, and heavier and more durable than house bells. Only the best rubber-covered double-braided wire should be used, and all wiring carried down the shaft in metal conduit. Double-conductor twisted wire is good. Small single-throw knife switches are better than push-buttons; or specially designed contacts, protected from dirt and water, may be used.

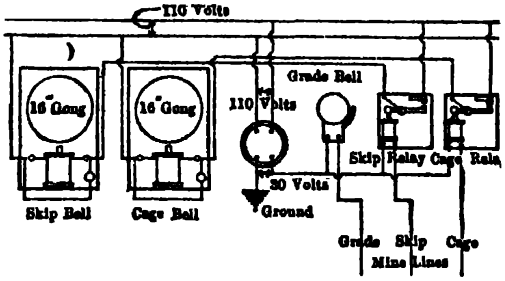

Fig 96. Signal System, Penn & Republic Mine, Mich

All the bells should be on one circuit (Fig 94, *B*), so that the signal sounds at all stations and in the engine room. If only the sending station and engine room bells ring (Fig 94, *A*), confusion may be caused by two stations attempting to signal simultaneously. Engine room and station bells are in series, so that the signal may be repeated from engine room. If necessary to signal from the cage at any point in the shaft, wires *a* and *b* (Fig 94, *B*) may be bare and carried on insulators on shaft timbers, the signal being made by making contact with a piece of iron or by pressing the wires together. In wet shafts this plan gives trouble, and the batteries are rapidly exhausted.

B. Bell-ringing magnetos are excellent, as they do not become exhausted like batteries; though the cost of installation is much higher. Loud-ringing weatherproof bells should be used. Equipment for one installation, consisting of one station outfit of 1 magneto and 1 bell with two 6-in gongs, with a similar engine room outfit so that engineer can return signal, 1 extra bell at shaft mouth, and 200 ft of double-braid rubber-covered No 16 conductor wire, cost $35. Besides this, 150 ft of 0.75-in pipe was used for conduit, the shaft being very wet; also a few insulators on the surface. Labor cost of installation, about $17 (1912). The 3 gongs and 2 magnetos were connected in series.

C. Power or lighting circuits (direct current) not exceeding 220 volts, where fairly constant power is assured, may be utilized for arranging signal systems, both bells and visual signals being used. Alternating current, of 220 volts, is dangerously high, and should be stepped down to 55 volts.

Fig 95 shows a layout at Rosiclare, Ill. All wiring is double braid, rubber covered, and carried down shaft in metal conduit. For signaling, S_1 is closed, ringing engine room bell and lighting lamps *A*. Signal is returned by pulling *E*, thus closing switch S_2, which lights lamps *C* until switch is opened. One lamp is at the engineer's stand. *F* and F_1 are 5-ampere fuses. To test or adjust the bells, F_1 is removed and placed at F_2, and switch *S* is closed. This rings the bell and lights lamps *A*, but not *C*. Lamps are 50-watt, on 220-volt direct current. Bells are weatherproof ironclad, having a resistance of 30 ohms and consuming 0.3 ampere.

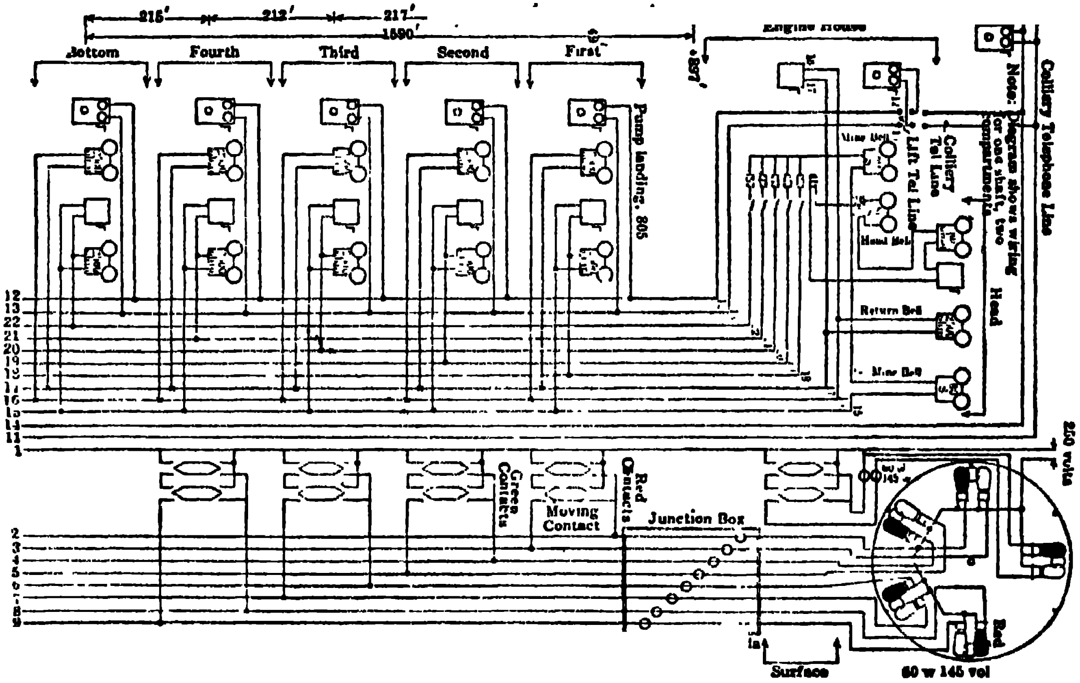

Fig 97. Electrical Signal System, Lykens, Pa

At the Penn and Republic iron mines, Mich, 110-volt alternating current is used (90), stepped down to 30 volts (Fig 96). It is grounded on one side, the other leading to a relay for each bell in engine house, and skip, cage and one side of a grade bell, in shaft house. The other side of each relay and the grade bell are connected to one of 3 No 4 bare copper wires, supported on insulators in the shaft. By grounding any one of these wires a current will flow through the grade bell or the relays in engine room. The relay then rings the 16-in gong, through the 110-volt circuit. A heavy single blow is struck by the a-c solenoid, an indicator registers number of bells, and a lamp is lighted. The signal wires may be grounded from the cage at any point in shaft.

D. Combined magneto and power circuits are sometimes used where both bell and lights are desired. At No 1 shaft, Lykens, Pa (Susquehanna Coal Co), is a magneto circuit for bells and power circuit, to indicate by lights the position of cage chairs at shaft stations. Fig 97 shows wiring for 4 intermediate levels and bottom of this shaft. Five-bar, open-circuit magnetos and 6-in bells are used throughout. Each station has a magneto, two 2 500-ohm extension bells and a phone. One bell is for return signal from engine room; the other is connected across the magneto, so that the man giving signal can hear it. A signal from a station rings the bell there, at top of shaft and in engine house, and records the ring on an a-c operated annunciator. Then topman signals, ringing bell at top and in engine house, the signal being recorded on annunciator. The station bells have different tone from that at top. Telephones connect to a common line between engine room and stations. If necessary, shaft phones may be connected to outside lines. Annunciator has a battery reset (not shown), wired to a brush contact on the dial indicator and is automatically cleared after

each hoist. The system is so arranged that the engineer has full control of signals from stations by operating a series of switches, which are all kept open except the one at station from which hoisting is being done. Each station has landing chairs; attached to each is a switch in a C-I box, wired to light a green lamp on indicator in engine room, if both chairs are free of the shaft, and a red lamp if one or both chairs are thrown in. This facilitates handling the cage when stopping or starting. In the indicator, 1.25-in holes are drilled at points corresponding to the levels and covered by frosted glass. Back of these holes are 1 red and 1 green bulb, to indicate position of chairs at landings.

Fig 98. Cage-pull, Shaft-conductor Signal System, Park Utah Cons Mines Co, Keetley, Utah (60, 37)

Desirable features of a hoisting signalling system: 1. In the hoistroom visual or sound devices should indicate: (*a*) cage or skip position; (*b*) landing chair position; (*c*) station where signal originates; (*d*) also provision for hoistman to repeat signals to sender, or signal all levels. 2. Each signalling station should have (*a*) devices for signalling hoistman, and visual or sound devices to indicate whether (*b*) cage or skip is in motion, (*c*) hoistman is being signalled, or (*d*) hoistman is signalling. 3. A communication system between all signalling stations and engine room on an independent circuit, to be used in case of failure of signalling system, and for general communication. 4. A signalling and/or communicating system between man-cage and hoistman, to operate while in motion or at rest, is desirable for shaft repair work and when hoisting men.

Special signalling systems (60). Fig 98 shows detail of signalling between cage and hoistman. At Park Utah Consol Mines, source of power for signals is a battery on the cage. Essentials: (1) a sensitive telegraph relay in engine-room, connected to the hoisting rope and a bare copper wire in the shaft; (2) an Edison battery on the cage, one terminal being permanently connected to the hoisting rope; (3) a contact-maker, operated by pulling a chain which completes contact between the battery on cage and bare copper wire in the shaft. With this device a man on cage has full control of its operation, a desirable feature when hoisting men or doing shaft work.

The signalling system (61) of Oglebay Norton Co, Gogebic range mines (Fig 99), provides for giving signals from cage whether at rest or in motion, and makes conversation possible between cage tender and hoistman at all times. These features are particularly desirable for shaft work. An interesting feature is a safety switch connected with the rope in cage bonnet and normally open. Slack on the cable, due to cage sticking when lowering, closes the switch and signals hoistman to stop. Cost of equipment, 1931, was $250.

Ross shaft, Homestake, S D, signalling system (62), designed for a deep shaft (5 200 ft) and in operation since 1934, has distinct modes of wiring for each of two skip compts.

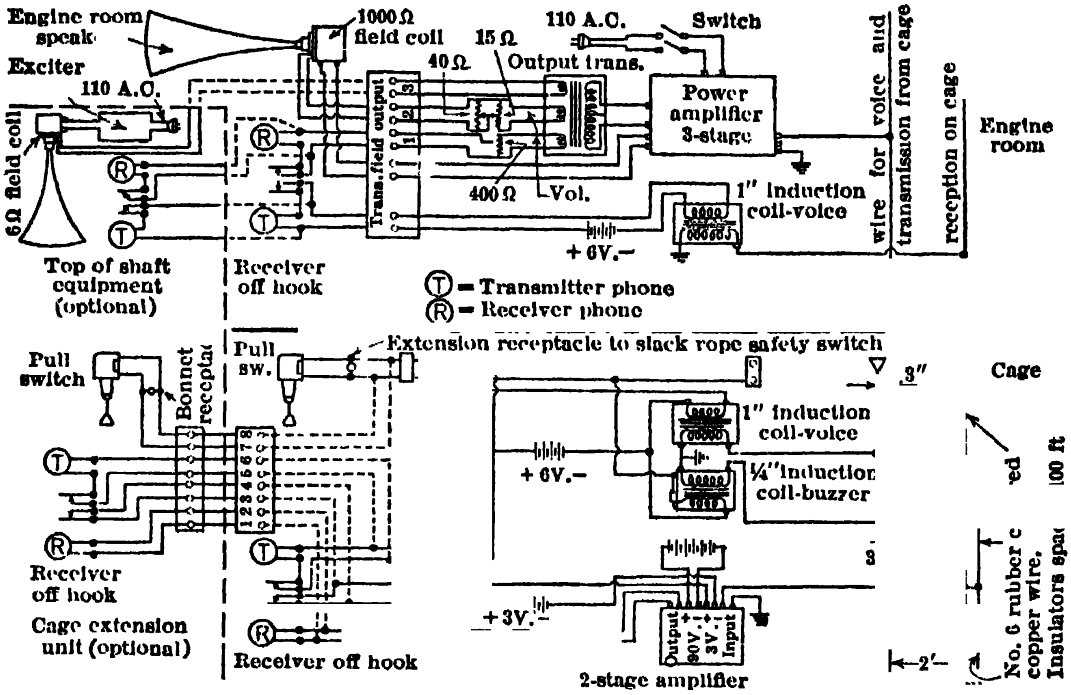

Fig 99. Wiring Diagram of Radio Cage-signalling System, Oglebay, Norton & Co, Ironwood, Mich (37, 61)

When hoisting men, skips are removed and cages substituted. Fig 100 is the diagram for one compartment, showing only 4 of the numerous stations. The annunciator is part of the skip or cage position-indicator. Receptacles for holding indicating lamps are placed radially outside the station numbers or names, and correspond to respective switches. The shaft part operates with a ground return; ropes and conduits have a return circuit wire, so that if the ground return causes too much induction the entire circuit may be made metallic and carried in the same sheath. The return wire is indicated by the broken line. Operation. When the pull switch is operated, a circuit is closed in the ground through one winding of a relay, then through one of two wires to the bell and lamp, and finally through the secondary of the transformer to the ground. The first impulse, caused by closing a switch, closes a connected relay which locks itself in position through a contact and second coil, and lights the indicator lamp through a second contact on the relay. The engineer may extinguish this lamp by a device attached to the hoist control-lever, operating a relay that in turn opens the relay holding circuit, and relay contacts. The bell sides of the relay coils, in series with the pull switches, are connected alternately to one of two wires connected as a single wire to the bell. Signal ropes. Fig 100 shows two pull ropes attached to each switch. One rope is short; the other long enough to reach the next switch. The long rope is a small, galvanized-steel cable, with a chain insert at the switch and chain at lower end. It is used for station and shaft-inspection work only, and is attached to the switch, so that it does not move when the short rope is pulled. The ropes may be reached by the cageman when cage is at the station. They are of light manila and attached to the switches with harness snaps. Pull switches are housed in cast-iron boxes, and ruggedly built. The insulating parts, of bakelite, provide long creeping distances, so that moisture within reason does not cause appreciable leakage. Switch mechanisms, held in the boxes with only one bolt, can easily be replaced. Call horns for signalling cagemen, operated at any station by a convenient pull switch are placed in the shaft at 100-ft intervals down to the 1 100-ft level; below that, at the level stations, 150 apart. They are placed under timbers, for protection from falling rocks. The horn boxes have small heaters to keep the air in them slightly warmer than the surrounding air, because high humidity damages the coil. Each heater consumes 6 watts. Fig 101 shows connections for the horns. At present, power is received at the top end, but, when the shaft reaches its ultimate depth of 5 200 ft, it may be necessary to supply power to the system at its midpoint, to prevent excessive voltage drop. Wiring is rubber-covered, in a galvanised-steel conduit. A fourth wire (dotted in the diagram) was installed as a precaution, so that if the number of horns became too great for one circuit they could be sounded on several circuits by relays operated by this fourth wire. Probably this wire will not be required for the shaft depth contemplated. The third wire is a ground connection, so that men will not receive shock when handling the cover and attached mechanism while changing units, if a wire is grounded to a live part.

28. BUCKETS AND CROSSHEADS

Ore buckets, unless made at the mine, are of steel (see also Art 18, 19). Fig 102*a* shows a bucket made from three-quarters of an oil barrel; capac, 4.5 cu ft. Band *B* is 0.25 by 2.5 in, riveted to bottom and sides, and forged into bail pins *C*. Rings *A* and lugs *D* prevent accidental overturning. This bucket is too large for a windlass; it requires a horse whim, or power hoist. Fig 102, *b* to *e*, shows light steel windlass buckets, as made by mining

supply houses (Table 35). Stock sizes of large buckets for heavy work, with capacities of 1 ton or more, are listed by makers. Large mines often have buckets for sinking and winzing made to order. Bail may be attached to ears at top, or to trunnions a little below center of gravity. The bottom is best dished, with a ring at center for attaching the dumping hook. Self-dumping buckets are more convenient to dump and clean themselves better, but with some danger of accidental dumping while being hoisted. Buckets with straight or flaring sides (Fig 102*b*) are more liable to catch on shaft timbers.

Examples. At Joplin, Mo, buckets (locally, "cans") are used commonly for both regular hoisting and development work. Largest size is 34 by 34 in, called a "1 600-lb can," but usually loaded with about 1 200 lb. Other sizes: 30 by 30, 30 by 28, and 28 by 30 in, diam being the first dimension. Smaller sizes: 26 by 28 and 24 by 28 in. Fig 102*c* shows typical Joplin bucket: ears are welded to side straps, which generally hook under bottom flange (72). Fig 102*f* shows a heavy shaft-sinking bucket. At iron mines of Mineville, N Y, a heavy 1-ton bucket was used for sinking. It had flaring sides, with bail pivoted on side trunnions. Fig 103 shows ore bucket and truck as used in many lead and zinc mines in the U S (63, 37) for both hoisting and haulage.

Fig 104. Bucket Hooks

Bucket hooks should be designed to prevent accidental unhooking, due to slack rope spinning, or striking shaft timbers. They are best made of Norway iron.

Ordinary snap hook (Fig 104*a*) is safe, but, with a spring strong enough to be safe, it is difficult to unhook. Serpentine hook *b* is safe and convenient for rope up to 0.5 in diam, but difficult to unfasten if rope is heavy and stiff. Chain hook *c*, in which only one part of the last link will pass through the hook opening, is safe, but inconvenient. Sister hooks are both safe and convenient (Fig 104*d*, *e*). Any liability to accidental unhooking is prevented by a ring around both hook shanks, which must be raised before hooks will separate. Fig 104*d* shows use of 2 pairs of sister hooks and chains, instead of a bail, for a sinking bucket at Hancock No 2 shaft, Mich. Two forms used in Canadian mines are shown in Fig 104*e*. Fig 104*f* shows a simple safety hook. Gap *C*, large enough to pass the bucket bail, is closed by thimble *D*, made of heavy pipe, or a piece of shafting bored out. COMBINED HOOK AND SWIVEL, used at the Rand Collieries, Ltd, So Africa, is shown in Fig 104*g*. Dimensions given are for a 2-ton bucket. Locking nut *a* has a large-pitch thread, so

that 3 or 4 turns by hand will allow bucket bail to pass. Threaded portion of shank of hook must be upset, so that the nut will pass over its end. All types of hooks should be swiveled to rope socket; this decreases spinning of the bucket, and facilitates detaching the hook.

Devices for dumping buckets at shaft mouth should be simple and positive. Safety from rock falling down the shaft is first consideration; then, speed of handling with minimum labor. When bail is attached at rim, bucket is commonly dumped by hooking into the bottom ring the lower end of a chain which is fastened at a point near top of headframe, and over the chute or bin. Then, by lowering, the bucket is swung to one side and dumped (Fig 105). With self-dumping bucket,

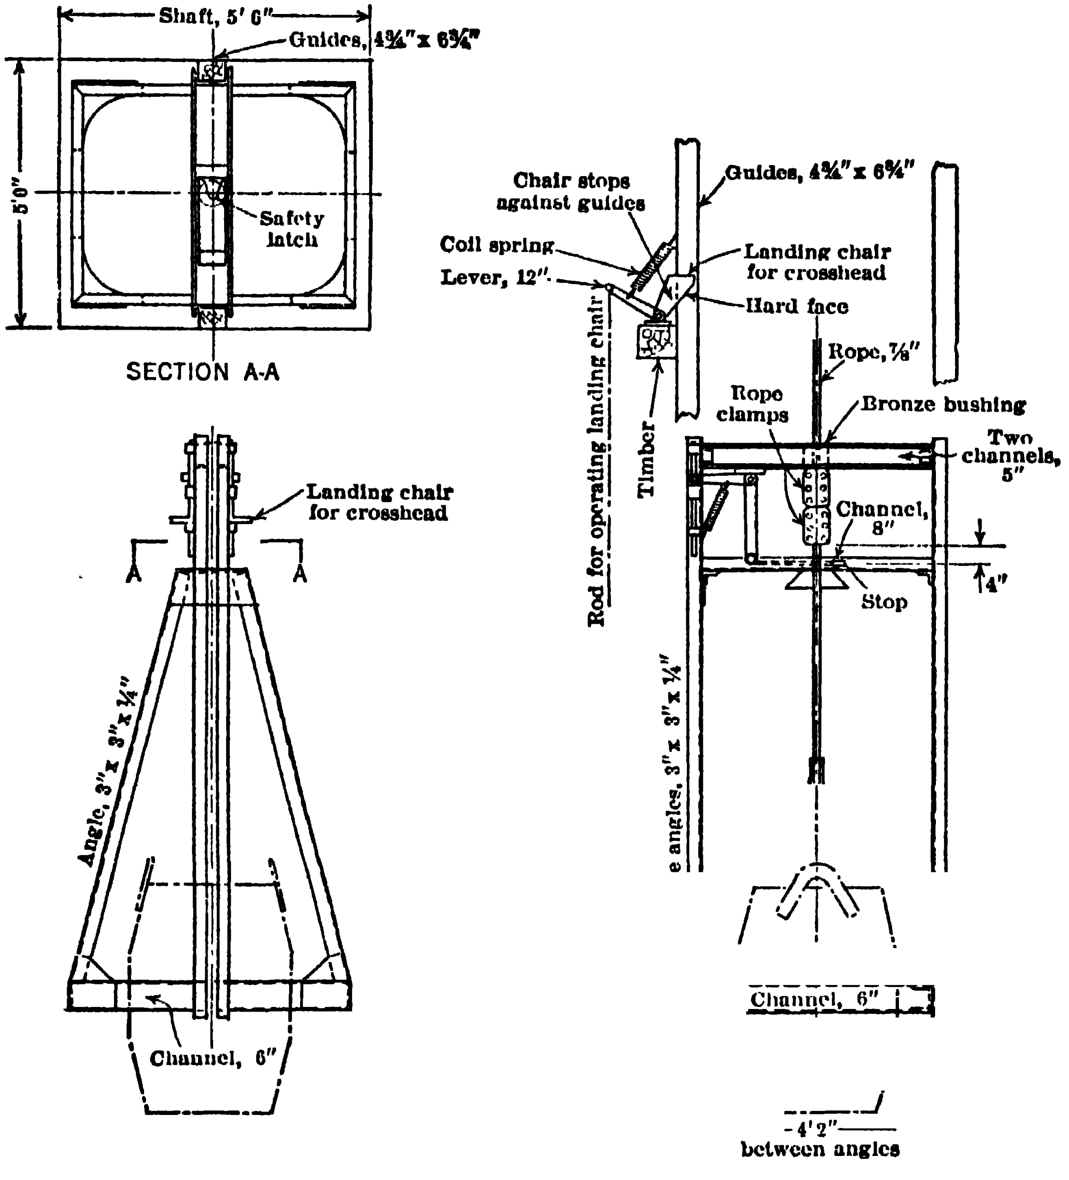

Fig 109. Crosshead for Bucket Sinking, Macassa Mines, Kirkland Lake, Ont (37, 65)

after hoisting to position *C* (Fig 106), the chain is hooked into bail ring; then, by lowering, bucket is swung to position *B*, for dumping and the latches are released. Automatic dump, for inclines with skids (Fig 107), is used at several Ontario mines. Bail is fastened to rim of bucket, and lugs *l* are below center of gravity. Lugs slide on skids until they drop into notches *a* above chute, when, by lowering, bucket is dumped. Bucket is then raised until lugs are above pivoted curved arms *b*; and on lowering again these arms cover the notches and allow bucket to slide down shaft. After bucket has passed the arms, they swing back by gravity to their original position. At the notch, skids should be edged with 0.5 by 2-in iron; curved arms are of 5/8 by 3-in iron, pivoted at *c* on a 1-in bolt. At dumping point, skids should have a slope not exceeding 72°. Crossheads, to prevent bucket from swinging, are required by law in some states and countries. As there is danger of serious accident if crosshead sticks in its guides, and then falls after bucket has been lowered some distance, the crosshead should be held positively to the rope socket, until it reaches the stops at lower end of guides. To prevent jamming in the guides, the height of crosshead should exceed distance

between guides. *Examples.* Fig 109 shows crosshead for bucket shaft sinking at Macassa Mines, Kirkland Lake, Ont (66). Similar crossheads of this general type made of aluminum have also been used in Ontario (67, 37). Bryant crosshead (73) has safety gear to prevent crosshead and bucket from falling if rope breaks, and to hold the crosshead if it should stick in the guides. It has a bonnet. Crossheads with safety catches are justified in large or deep shafts; they are usually entirely of steel. Fig 110 shows a design recommended by U S Bur of Mines (74); *a* is safety-dog spring; *d*, $1/2$ in less than distance between guides; *g*, not less than distance between guides; *j*, rope button. Frame and connecting angles, all 3- by 3- by $5/16$-in. In the Berry safety crosshead (Fig 110*a*), designed in the Transvaal, springs, instead of gravity, keep the bucket attached to crosshead until guide stops are reached. In descending, levers *a* strike stops *b*; and, through rod *c*, the latches *h* are thrown outward against springs *e*, thus disengaging rope socket and allowing bucket to descend. When crosshead is raised from the stops, springs *e* again cause latches *h* to engage the rope socket. In the headframe is a device to hold crosshead and release the bucket for dumping.

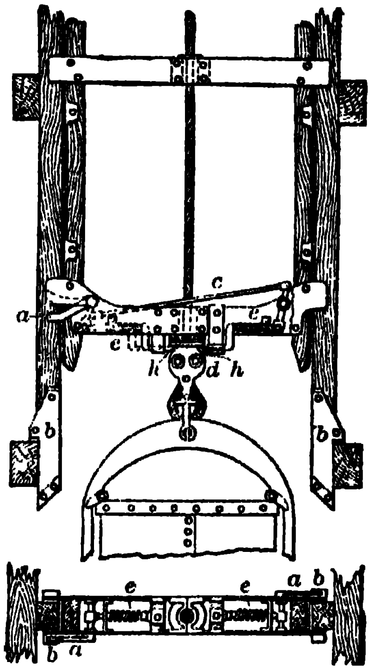

Fig 110a. Berry Safety Crosshead

29. CAGES

General features. Since the cage is a dead load, its weight should be as small in proportion to the useful load as is consistent with safety. Platform frame is of flat bars, or structural shapes (channels or heavy angles for side members and I-beams or channels for crosspieces). For light metal-mine cages (Fig 111) center suspension member *A*, carrying guide shoes *G*, may be a flat, welded to forging *B*, for the jackshaft (*S*) bearings. To *B* is bolted or riveted the triangular forging *C*, with a socket for draw-bar *D*. Inclined members *E*, from *B* to the cage deck, are of light angles, or flat or round bars. If members are narrow bars, bolted joints are best; if wide (structural shapes), rivets are used, with at least 2 rivets for each joint. For heavy colliery cages (Fig 112) the center suspension member on each side is a single channel, or a pair of angles, riveted to a plate carrying jackshaft bearings and pins for bridle chains. In this case, upper cross member is made of structural shapes.

Multiple-deck cages are used more in Europe than in America, although they are employed to some extent in Western U S for increasing hoisting capacity of shafts of small cross-sec, or where skips are not feasible. In Butte, Mont, and in S W Ariz, there are cages of 2 to 4 decks. Their disadvantage is the loss of time in handling cars, as each deck must be shifted to the landing to receive or discharge its load. To save time there may be multiple landings, so that only 1 shift of cage is required for 4 decks; but this adds largely to expense of installation, and complicates car handling arrangements. Multiple-deck cages are sometimes used for handling men, when ore is hoisted in skips. These are usually in separate compartments, or the skip is removed and cage substituted at beginning and end of each shift.

Fig 112. Heavy Cage (wt, 2 500 to 4 000 lb, for 7 000 to 9 000-lb gross load), Vulcan Iron Works

Self-dumping cages (Fig 113, 114) are often used in bituminous and sometimes in anthracite coal districts; rarely elsewhere.

Cage consists of 2 frames (Fig 113). The outer runs in the shaft guides; pivoted to this at bottom is an inner frame and platform, on which car is held fast by a locking device. At dumping point, inner frame is swung outward, by roller *a* engaging in curved guides, thus supporting car at a dumping angle. Meantime, the outer frame runs up on main guides. Catch *b*, to prevent accidental tipping of inner frame before dumping point is reached, is not common. Sometimes, pivot *c* is at one side of center line of cage, while center of gravity of car is on opposite side. Wheel *a* may run in an auxiliary guide, passing out of the guide through a gap at dumping point.

Where utmost capac is necessary, cage is wide enough to take 2 cars side by side; as at Cloverdale mine, Pittsburgh Terminal R R and Coal Co, where each cage carries 2 2.5-ton cars, 4 000 tons being hoisted in 8 hr; total lift, 405 ft (75). In some self-dumping cages the platform and car only are tilted, by rollers mounted near front end of platform and running in dumping guides. When closed-end (no door) cars are used, an overturning cage may be employed; cage platform and car are rotated endwise through 135° (78) by a pair of rollers at top, as in most dumping cages. In this case, special arrangements are necessary, due to greater movement of platform and car. ADVANTAGES of self-dumping cages: (*a*) reduced labor cost and attendance at top landing, and increased capac; (*b*) less wear on car than with most stationary dumps. DISADVANTAGES: (*a*) increased cost and wt; though, when hoisting in balance, extra wt is objectionable only in adding to total rope load, which also must be accelerated each trip; (*b*) larger rope and stronger headframe are required.

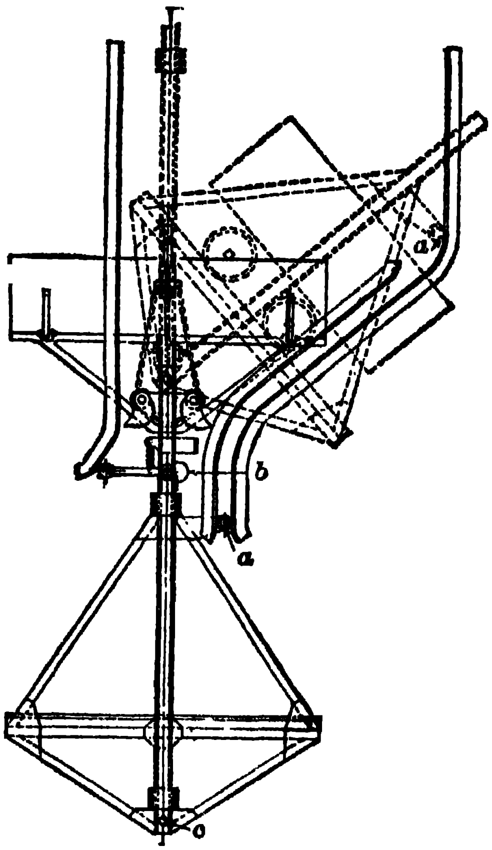

Fig 113. Self-dumping Cage

30. CAGE DETAILS

Structural details. For light cages the platform frame may be one W-I bar, say 0.75 by 4 in or 0.5 by 6 in, bent to a rectangle. Crosspieces, 2 for a small cage, are of same size, their ends being bent at right angles and riveted to frame. Rails may be of bar iron not less than 1 in wide, or T rail. Ends of VERTICAL SIDE MEMBERS should be bent under bottom frame (Fig 111). Opening *F* in side member is for access to guide bolts. SHOES are of short bent plates; or 2 angles back to back, or a channel, extending from platform to bonnet. Edges of shoe are rounded to prevent cutting the guides; rivets are countersunk and their heads chipped flush. Width of shoe is 0.5 in greater than width of guide; length, 2 to 3 times the width. If UPPER MEMBER of frame is a triangular forging (Fig 111), flats are welded to the lower angles, to give rivet or bolt space for attaching suspension members. If a straight horiz member is used, 2 channels back to back are structurally convenient. DRAWBAR is of best Norway iron; of square section, or sometimes round with a spline, to prevent rope from twisting. Area at root of thread determines its strength (Art 31). When VERTICAL SIDE MEMBERS are flat bars, they are widened at the head to receive the cam shafts, as in Fig 111, or riveted to a piece of heavy plate; when of angles or a channel (Fig 112), these serve as shoes; but in any case liners or wearing pieces, of thin plate, should be provided. With the construction shown in Fig 112, cage is usually attached to rope by CHAINS of such length that they take the weight of the cage when the drawbar operating the safety catches is in its highest position. Auxiliary or safety chains (Fig 112) are required by law in some states. These are fastened to a clamp on rope above the socket (see Art 7), and should be just slack when load is on the chains. An incidental advantage of the chain connection is that, when slack rope has been paid out after cage has been landed, the rope is not bent sharply at socket. Large cages are braced at corners with GUSSET PLATES, to keep cage square, and to reinforce connection of horizontal member to side gussets. For small cages, the BONNET is hinged at sides (Fig 111); for large cages the hinge is at center (Fig 114). By raising the bonnet, long timbers, rails, or pipe, can be stood on platform and lashed to hoisting rope. Bonnet is of No 10 or 12 steel for light work, up to $^5/_{16}$ in for heavy work.

Safety catches are required by law where men are hoisted or lowered. Standard form consists of 2 JACKSHAFTS (Fig 112) on which are keyed TOOTHED CAMS or dogs. When rope breaks these are turned against guides by springs, and after they grip the guides, weight of cage tends to tighten them still more. When cage is supported by rope, cams are rotated away from the guides by chains, or link and arm connections, to the drawbar (Fig 111, 112). Ideal safety gear should bring cage to rest gently. If rope breaks when cage is ascending, this condition may be realized, as the cams have time to grip guides during the momentary pause before cage begins to fall. But, if cage is descending, the shock is great; and if moving rapidly it is doubtful whether any safety device could hold, because momentum of cage and load would either break the safety gear, or strip guides from the shaft timbers. Moreover, in a deep shaft, if rope should break near top, with cage near bottom, the springs could not quickly overcome inertia of the rope, and falling cage would attain too high a velocity for the cams to be effective. Also, if hoisting engine fails, the springs could not overcome the drag exerted on the rope by the drum. Fatal accidents from these causes have occurred.

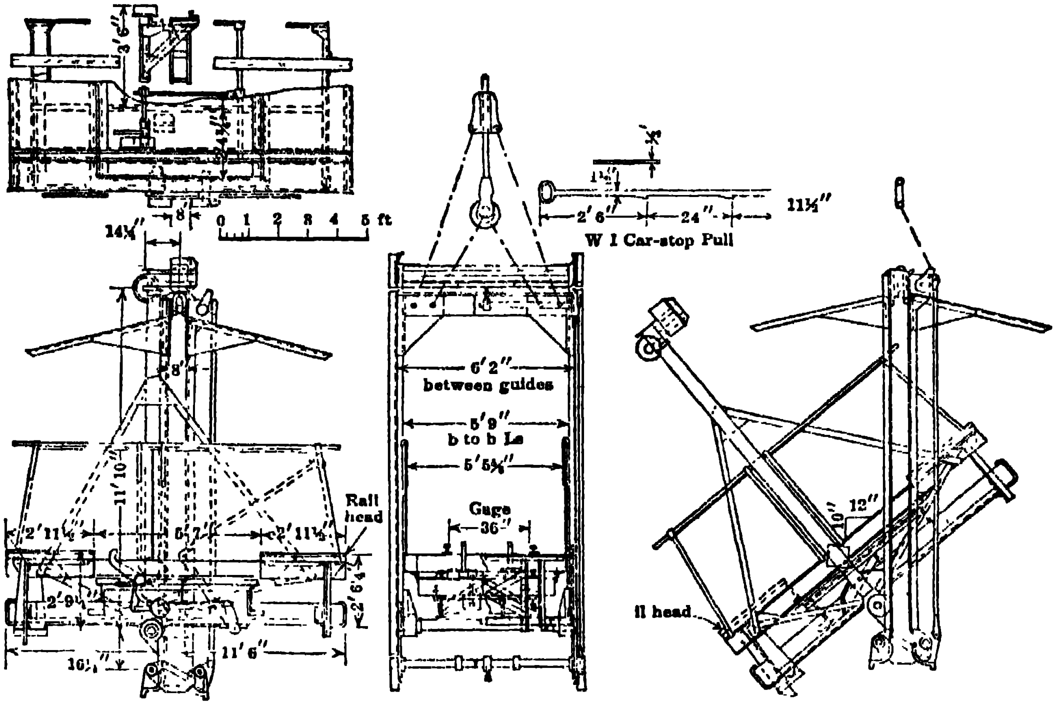

Fig 114. Drop-bottom, Self-dumping Car Cage, Lehigh Valley Coal Co, Wilkes-Barre, Pa (37)

Details of safety gear. All parts are of steel or W I except the cams, which are of C I or cast steel. CAM CURVE is usually involute of a circle, but is often modified. Teeth should be sharp and deep enough to bite well into guide, with an angle at the end of not less than 45°. Width of cam is about 2 in for small, to 3.5 in for large, cages. Chain connection between drawbar and chain wheel on jackshaft (Fig 111) is simplest construction for light cages. In coal districts the cams are sometimes placed at sides of cage, 2 or 3 ft above platform, and connected with jackshafts by levers and long links (Fig 115, *a*). Several designs of flat spiral or helical SPRINGS, encircling the jackshafts or drawbar, are used. When on jackshaft, one end of spring is fast to a collar keyed on shaft, the other end to the side of cage; or, short levers keyed on each shaft are connected across by helical springs. For heavy cages, a powerful spring encircling the drawbar (Fig 112) is effective, and incidentally eases the shock when starting to hoist. An objection to operating both jackshafts by one spring or set of springs is that, if one shaft sticks or the cam happens to act against an unusually hard or smooth place on the guide, the other shaft can not bring it into action. They are best operated by independent springs.

Fig 115 shows designs of typical safety catches: *a*, sometimes used in Penn anthracite mines, has chisel-pointed levers thrown against guides by action of springs (said to be effic); *b* is for a 3- by 4-ft metal mine cage; *c*, for a cage about same size as *b*; *d*, for a light coal mine cage. One type of catch consists of a pair of toothed wedges, working between edges of guide and angles on the side plates, which are set at an angle equal to that of the wedge. They are thrown in by spring-operated levers, as in other forms, and are automatically tightened by wt of cage. It is stated they are difficult to release, sometimes requiring cutting away of guide. For STEEL GUIDES, the cams are either not toothed or have much smaller teeth; because, as the increment of the cam spiral is less, they grip the guide more strongly.

Safety gear should frequently be inspected and tested. Present tendency is to rely more on careful inspection of rope and to use rope of better quality. Many mines have discontinued safety catches on cages and skips which hoist ore only. Where men are not raised or lowered, the law does not require them. For description and tests of other safety devices, see Bib 37, 76, 113.

Weight and cost of cages. Plain steel colliery cages, for a gross load of 6 000 lb, weigh 3 000 to 4 000 lb; for heavier loads, up to 6 000 lb. A combined wood and iron cage, in anthracite district, weighs 5 600 lb, has a deck 6 ft by 11 ft 6 in, carrying a 2 500-lb car and 6 000 lb of coal. Cage at Sugar Notch No 9 colliery, Pa, weighs 5 000 lb, car 2 500 lb, and contents 6 500 lb. Drop-bottom cage in Fig 114 weighs 2 680 lb, car 1 270 lb, contents 2 000 lb. Large colliery drop-bottom cages weigh 6 000 to 8 000 lb. Single-deck cages, with 4 by 5-ft decks, for 1-ton gross load, weigh 900 to 1 400 lb; for 3 000-lb load, 1 400 to 1 800 lb; for heavier loads, up to 2 800 or 3 000 lb. Each additional deck adds 50 to 60% to the weight. Self-dumping cages are 30 to 40% heavier than plain cages. Light cages of standard design cost 16 to 24¢ per lb; heavy cages, 14 to 20¢. If made from special designs requiring new patterns, cost is increased 20 to 25% (1935).

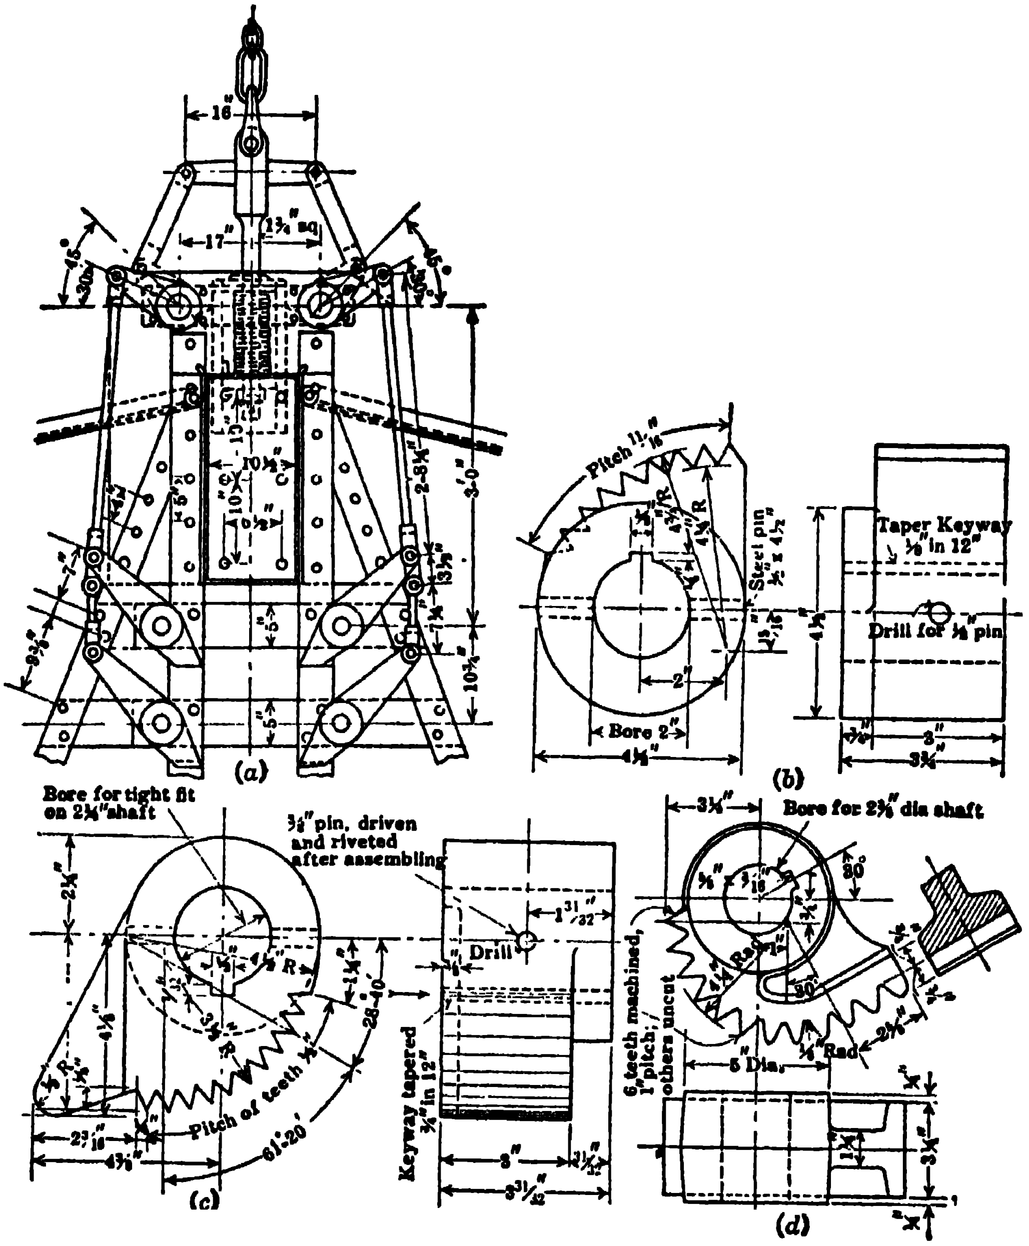

Fig 115. Types of Safety Catches

31. DESIGN OF CAGES

Factor of safety should be 10, whence allowable unit stresses for iron and steel are: tension, 6 000 lb; and for compression, $S = 6\,000 - 70\ (l \div r)$; where l = length of member, and r least radius of gyration, both in inches. Rivets and pins: single shear, 5 000 lb; double shear, 10 000 lb. Bolts, when used in place of rivets or turned pins, single shear, 3 500 lb, double shear, 7 000 lb. If size and gross weight of car and contents, and the dimensions of hoisting compartment, are known, design is a matter of mechanics and knowledge of the general type of main and auxiliary parts, as determined by practice. Clearance between ends of cage deck and shaft timbers is 2 to 4 in. Width is fixed by width of car, or by distance between guides, less thickness of shoes and side members, less clearance between shoes and guides (Art 30).

Details. Lay out dimensions of cage deck, and place crosspieces equidistant. Small cages have 4 crossbars, including the ends; long decks may have 5 to 7 crossbars. Maximum CAR-WHEEL LOAD and its point of application on the deck rail are determined, and the rail and other deck members are then calculated as beams (Sec 43). It is to be noted that in dumping-cars the body is not placed symmetrically on its truck; one pair of wheels carries more than the other. Throughout the calculations the dead load is multiplied by 2, to convert to live load (Art 14). If l = length of rail between crossbars, and W = wheel load, the bending moment $M = 0.25\ Wl$; also, $M = pS$, where p = unit stress = 6 000 lb. If T-rail or structural shape is used, $S = 0.25\ Wl \div 6\,000$, and proper size is selected from table (Sec 43). For a rectangular bar, $M = pbd^2 \div 6$; in which b is width of bar and d its depth. Assume b and solve for d, in $d^2 = (3\ Wl) \div (2 \times 6\,000\ b)$.

Maximum LOADING ON DECK CROSSBARS is determined by relation between their distance apart and wheel base of car, remembering that front wheels may carry more load than the rear (see above). Find maximum bending moment, substitute it in $M = pS$, and select required section. Shear at end of crossbar = P. One rivet may be sufficient, but at least 2 should be used, not less than 0.625-in diam. With light sections it is well to check bearing area of the rivets. Side members of deck are rectangular bars, or channels with the flanges inward. They usually act as beams supported at ends and center by the suspension members. Their cross-sections are found as for the other deck members. INCLINED SUSPENSION MEMBERS carry a load equal to p times *secant* of their angle from vertical. Minimum section should be 1 sq in, proper rivet bearing and shear being provided. If an angle is used it is connected to deck with a gusset plate; if a bar, the end is carried down and bent under edge of deck, and also bolted or riveted. VERTICAL SIDE MEMBERS are of flats, angles or channels; their connections are similar to those of the inclined members. Net head room on the deck should be not less than 7 ft. Load at each end of TOP CROSS MEMBER equals half the weight of car and contents plus half the weight of deck and suspension members. As in Fig 111, a TRIANGULAR TOP FRAME may be made of a single forging (Art 30). If a drawbar is used with a horizontal top member, latter is designed as a beam loaded at center, and ample rivet area and gussets are necessary. Bending moment at center = $Rl \div 4$, in which R is total pull on drawbar. When CHAINS are used (Fig 112), horizontal member acts both as a strut and as a beam loaded at 2 points. Chains are about 30° to vertical; hence, load on each is approx $0.5\ R \times \sec 30°$. Since strength of a chain is 165% of strength of rod from which it is made, area of the rod = $(R \sec 30°) \div (12\,000 \times 1.65)$, and its diam $d = \sqrt{0.0000742\ R}$. Pins for connecting chain to cage are in double shear. DRAWBAR is of best wrought iron, with lock nuts at lower end. Its net section at root of threads = $R \div 6\,000$. The pin to connect it to rope socket is in double shear; hence, its area = $R \div 10\,000$. Net area of metal in drawbar head = 1.5 times area at root of thread.

Safety catches. Two of the SAFETY DOGS or cams should be able to support cage if the others fail; hence, each is designed to carry half the load. Considering as cantilevers the extensions of jackshafts beyond the gusset plates through which they pass and by which they are supported, then, when safety gear comes into action, concentrated load at center of dog is $0.5\ R \sec \alpha$; in which α is angle between the vertical and the line through center of jackshaft to point of contact of dog with guide. This angle may be assumed as 45°; whence $\sec \alpha = 1.41$, and load is $0.705\ R$. Therefore, bending moment in inch-lb is $M = 0.705\ Rf$, in which f is horizontal distance between center lines of dog and jackshaft bearing (usually from 2.5 to 3 in). Substituting in $M = pS$, $S = 0.705\ Rf \div p$. For circular section, $S = 0.098\ d^3$, in which d = diam of shaft; hence $d^3 = 0.0012\ Rf$. Values of d so computed are in excess of practice, and can safely be reduced by 25%.

SPRINGS FOR SAFETY CATCHES must be strong enough to act promptly, and yet be deflected by weight of empty cage, with sufficient margin to prevent lashing of hoisting rope from causing the dogs to grip the guides. Total supporting power of springs is from 0.33 the weight of cage for small cages to 0.10 the weight for large ones. Number of coils in the spring depends upon deflection required, or the angle through which the shaft must turn to engage dogs with guides. Cross section of rod composing spring depends upon load, and radius R of crank arm or chain wheel by which rope pull rotates the jackshafts against spring pressure. For FLAT SPIRAL SPRINGS:

$$P = \frac{S}{6}\,\frac{bh^2}{R}; \qquad f = R\theta = 12\,\frac{PlR^2}{Ebh^3} \tag{40}$$

in which, P = force applied at radius R, or assumed load on chain or link connecting drawbar with chain wheel or arm on cam shaft; θ = angular motion of R, in radians; S = allowable max unit stress = 60 000 lb per sq in; E = modulus of elasticity in tension = 30 000 000; l = developed length of spiral; b = width of spring and h = thickness. For large cages R may be taken as 7 in;

for small cages, 2.5 in. Angle of rotation should be from 60 to 90°. For HELICAL SPRINGS, WRAPPED AROUND SHAFT:

$$P = \frac{S\pi d^3}{32\,R}; \qquad f = R\theta = \frac{64\,PlR^2}{\pi Ed^4}; \qquad \frac{f}{R} = \frac{2\,Sl}{Ed} \tag{41}$$

where, besides the values given above, d = diam of the spring rod. If HELICAL SPRINGS are used IN TENSION OR COMPRESSION (Fig 100) following formulas by J. W. Cloud apply:

$$P = \frac{S\pi d^3}{16\,R}; \qquad f = \frac{32\,PR^2l}{\pi Gd^4} \tag{42}$$

in which, P = load on each spring; S = max unit stress = 80 000 lb; R = radius of center of coil; l = developed length of coil; G = modulus of elasticity in torsion = 12 000 000; d = diam of spring rod; f = deflection of spring in inches under load P. In this case, the pull from drawbar to chain wheel or lever must be converted into component load in direction of axis of the spring. (See also Sec 41, Art 10.)

32. CAGING DEVICES AND LANDING CHAIRS

Caging of small cars is nearly always done by hand. Large cars are also often caged by hand; but mechanical devices are common, especially in collieries, and increase capacity and safety. For hand caging, where station layout permits tracks on both sides of shaft, the track approach to cage is laid with 1.5 to 2% grade, so that cars will run on by gravity, the loaded car pushing off the empty on opposite side. Car checks, placed at a safe distance back from the shaft, are controlled by a lever worked by the station tender. They should be so far automatic that, after a car passes, the check is raised into position to hold the following car. At surface landing, if point of dumping be some distance from cage, loaded car may be pushed off by the empty; but, with hand caging, this is not satisfactory, because more effort is required than at shaft stations.

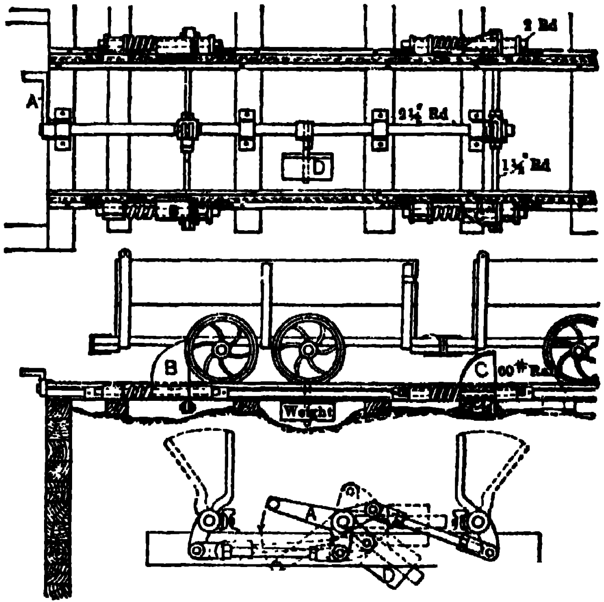

Fig 116. Automatic Cager

Mechanical cagers. Rams, operated by steam or compressed air, are often used at collieries. They act against the empty car, which pushes loaded car off the cage. Throttle for the ram should be operated by levers interlocking with car check and landing chairs, so that it can not be opened unless cage is at landing and car check down.

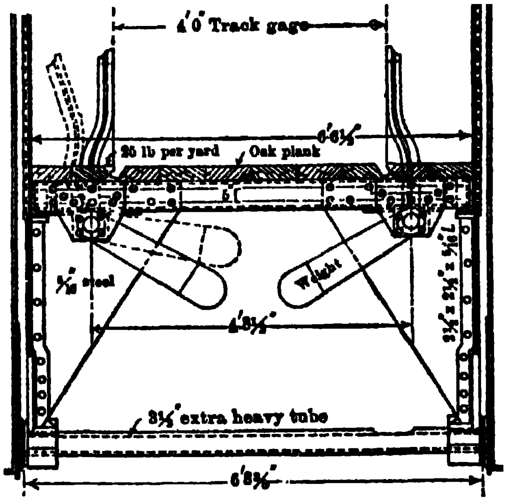

Fig 117. Car Stops for Self-dumping Cages, Jed Coal and Coke Co

Fig 116 shows an apparatus made by the Mining Safety Device Co. When cage reaches station landing, its weight turns crank *A* and opens horns *B*. This allows first car to run onto cage, and at same time closes horns *C*, thus holding back second car. When cage is raised, horns *C* are opened and *B* closed by weight *D*. For intermediate levels, the cage-operated crank is replaced by a hand lever, which is locked in position unless cage is at that level.

Car stops, to hold car on cage, may act on the body, wheels, or axles. Commonest stops are: (*a*) hook attached to side of cage, which drops into an eye on side of car; (*b*) pair of bent bars, 0.375 or 0.5 by 1.5 in, hinged on vertical side members of cage, and resting in brackets on the diagonals. These bars drop with a small clearance over ends of car body.

Automatic stops applied to car wheels or axles, whenever cage is not on the chairs, permit more rapid caging. They are of 2 kinds: (*a*) HORNS raised in front of wheels or between them, and

operated by weight and levers when cage leaves landing. Fig 117 shows stops for a self-dumping cage. For ordinary cages, the horns are often operated by a lever at corner of cage, within reach of cage tender at landing. (*b*) DROP-BOTTOM CAGE. In this an independent transverse section of

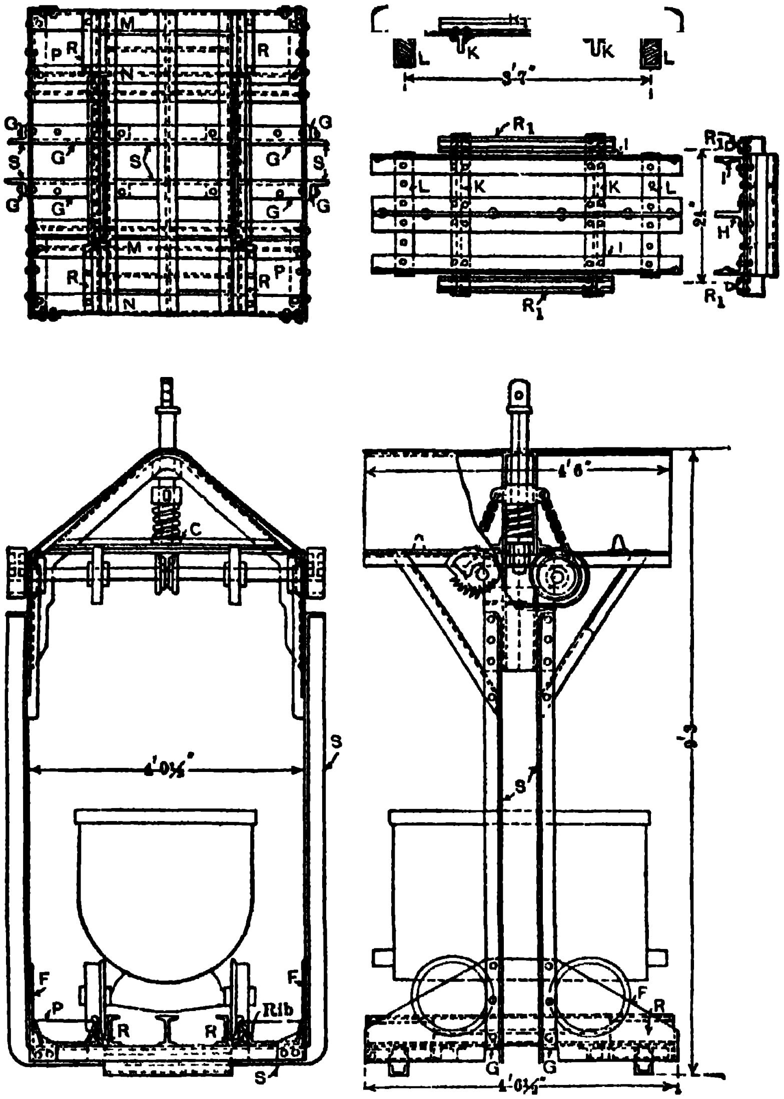

Fig 118. Drop-bottom Cage

deck and rails, on which the car stands, drops a few inches when cage is lifted from chairs. Wheels are thus blocked by the fixed rail ends (Fig 118). In Jeffrey drop-rail cage, rails are pivoted at outer ends and divided in the middle. When cage is lifted from chairs, inner ends of the rails drop, and car axles fall into notches in a pair of rigid skids. Car is thus held in place until cage is landed at another station.

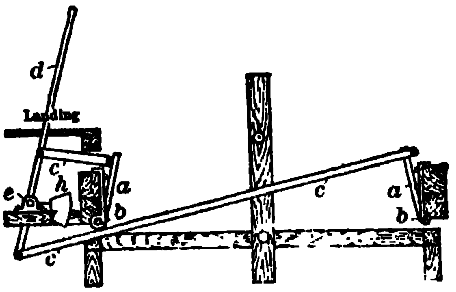

Fig 119. Chairs for Surface Landing

Landing chairs (keeps, keps). Fig 119 shows a common form, installed at each shaft station. Cage is supported at its corners by 4 fingers *a*, pivoted at *b*, and connected by rods *c* to hand lever *d*; which is pivoted at *e*. The cut shows chairs at shaft collar; fingers *a*, which are pushed back by the rising cage, are thrown outwards under the deck by weight *h*. For UNDERGROUND LANDINGS, weight *h* is on opposite side of *e*, thus always holding the chairs back out of the way of a passing cage. To support cage at a given landing, the station tender pushes lever *d* into the position shown A spring may be used instead of a weight. Especially designed chairs, with 8 fingers instead of 4, are required for drop-bottom cages.

Fig 120 shows chair supported by steel construction at mouth of Annabelle shaft, Four States Coal and Coke Co. Fig 121 shows a simple design used by Desloge Consol Lead Co, S E Missouri. Parallel rails are caused to slide in and out by links and levers, serving both compartments. **Chairs attached to cage deck** (Fig 123) have advantages for shafts with many levels, since only one set of chairs is required for each cage. Fig 123 (37) shows method at Horne Copper Mine.

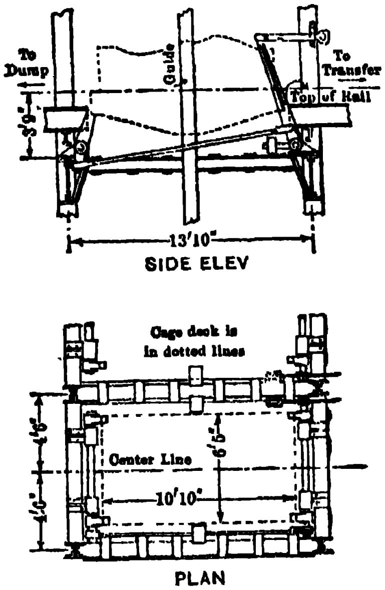

Fig 120. Surface Chairs, Annabelle Shaft, Four States Coal and Coke Co

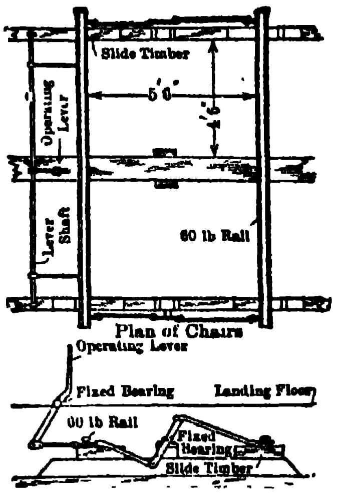

Fig 121. Desloge Landing Chairs (*E & M Jour*)

Man cages should be fitted with gates, about 6 ft high. If same cage is used for ore, the gates are detachable, and removed when not needed. Cages especially for men have hinged gates, opening inward, or of pantograph form as for elevators, and are lined on sides with sheet steel, or strong closely-woven wire mesh. Hand-holds should be provided;

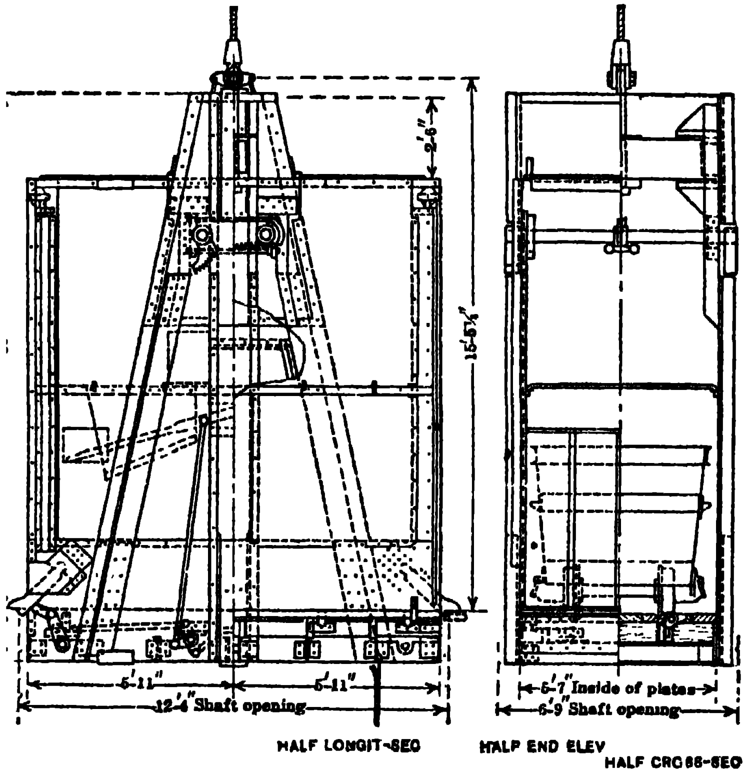

Fig 122. Man and Material Cage, Inspiration Mine, Ariz (*E & M J*)

usually horiz rods attached to cage frame under the bonnet. Fig 122 shows the man and material cage of Inspiration Consol Copper Co (77), with counterweighted gates moving vertically in guides. It carries 55 men. The cage has its own chairs, which are automatically drawn in when cage is lifted.

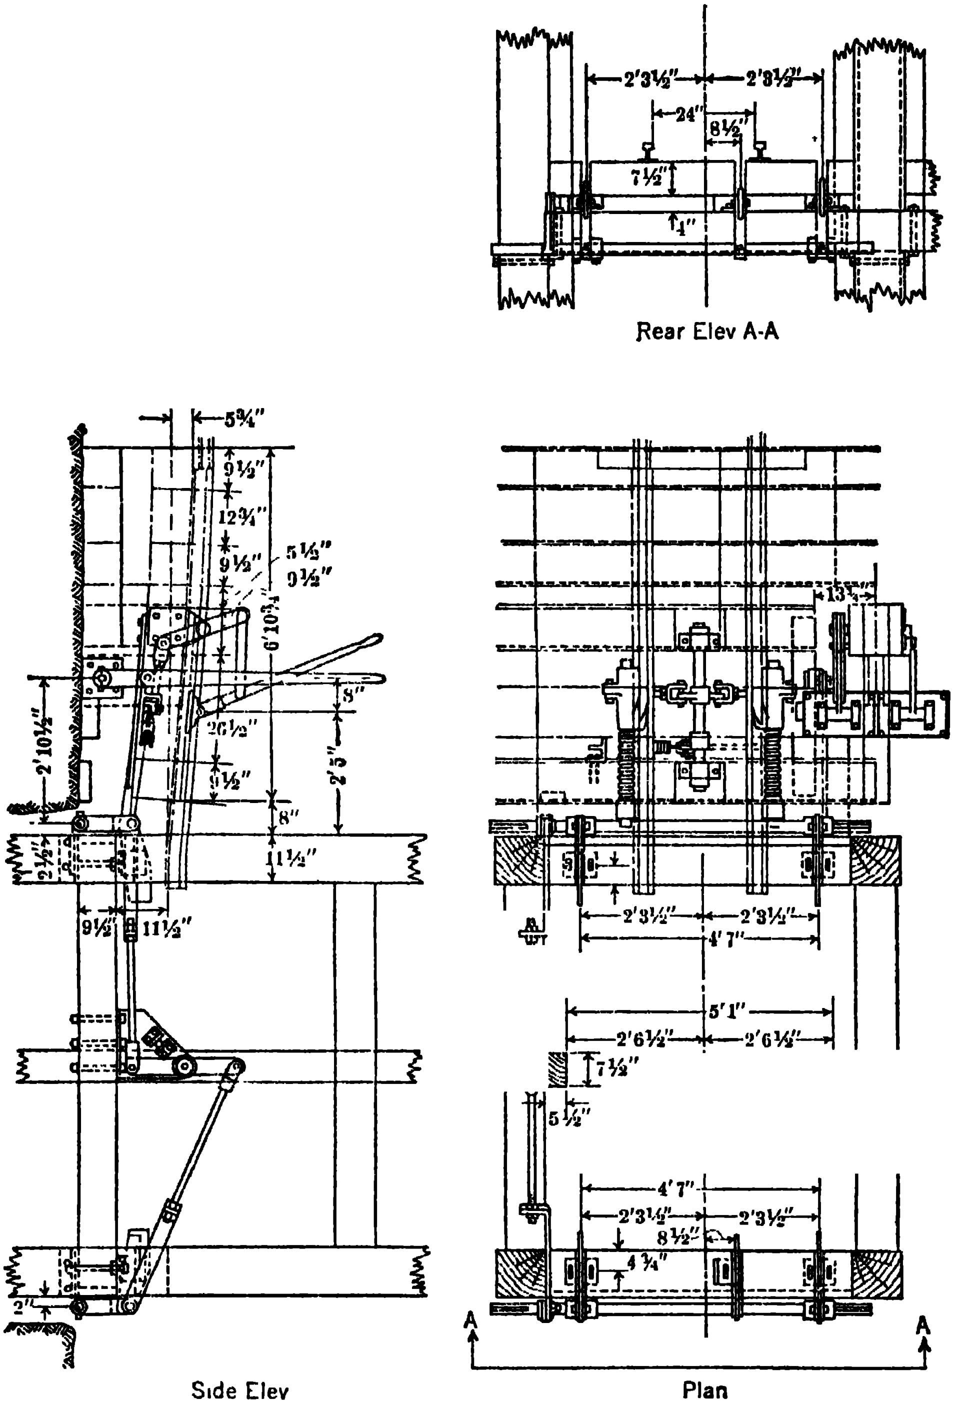

Fig 123. Underground Chairs and Caging Equipment, No 3 Shaft, Horne Copper Mine, Noranda, Quebec (37)

For hoisting men on slopes, mine regulations of some states require safety catches working on a third rail, on a stationary wire rope, or on wooden guides as for cages.

33. SKIPS

Skips may be used in either vertical or inclined shafts (as employed for colliery slopes they are called "gunboats"). Advantages over cages: less time required for loading and dumping; large capacity in shafts of small cross-section; less labor for dumping at shaft top; weigh less than combined cage and car. Less dead wt means smaller rope, drums and engine, or greater useful load. Disadvantages: difficulty in keeping separate different grades of ore, or ore and waste; impossible to distribute output into a long storage bin without additional handling; men can not be so conveniently raised or lowered; while loading or dumping, there is more danger of ore dropping down shaft. With well designed skips, breakage of coal is very little or no greater than with self-dumping cages (78). When skips are used, men are conveyed: (*a*) on a cage permanently fixed above skip; (*b*) on a man car, replacing the skip at end of shifts; (*c*) on a cage in a special shaft compartment. When a skip is hung below a cage, increased height of headframe is necessary.

Inclined-shaft skips. Fig 124 and 126 show skips of heavy construction, for iron and copper mines. Skips similar in design to that of Fig 127 are built for Michigan copper mines up to capacities of 7 and 10 tons. For convenience of loading, the angle at forward end is made approx equal to dip of shaft.

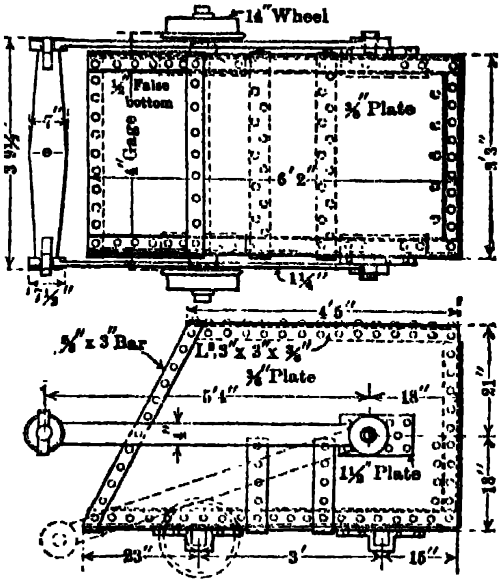

Fig 124. 3.5-ton Skip, Mineville, N Y (*E & M J*)

Where inclination of shaft is low, the skip body has no top and becomes a modified car. Fig 127 shows such a design, of the Tenn Coal, Iron and R R Co, Birmingham, Ala (1925), for hoisting iron ore. Front end is hinged at top, and held closed until the dumping point is reached by the front crossbar of the bail, which is in contact with 1-in plates, faced with angles extending from the door. As skip goes into dumping position the front end drops, while the bail maintains its position, allowing the door to be opened by the wt of ore. For safety, a loop of wire rope passes around the skip body, and through the hoisting rope thimble.

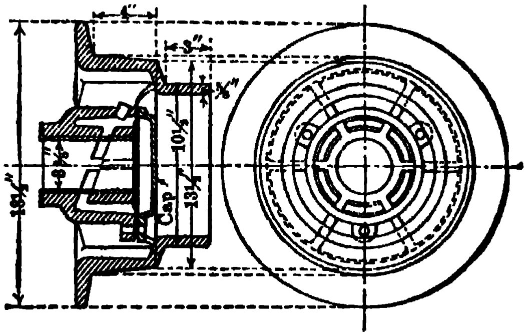

Fig 125. Rear Wheel, Mineville Skip

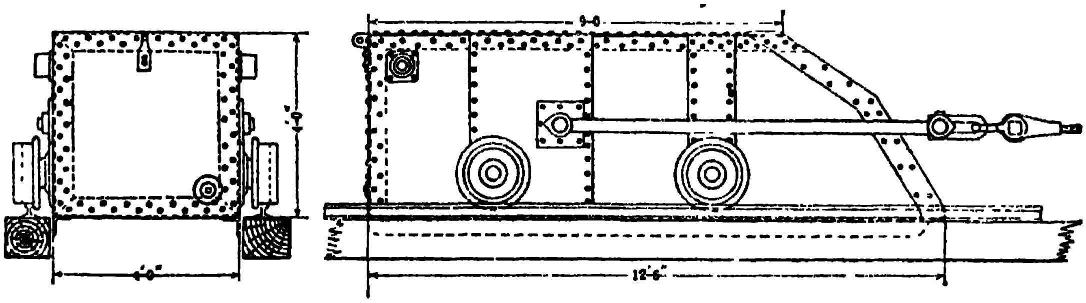

Fig 126. 8-ton Skip, Hancock No 2 Shaft, Quincy Copper Mine, Mich; Weight, 4¾ Tons

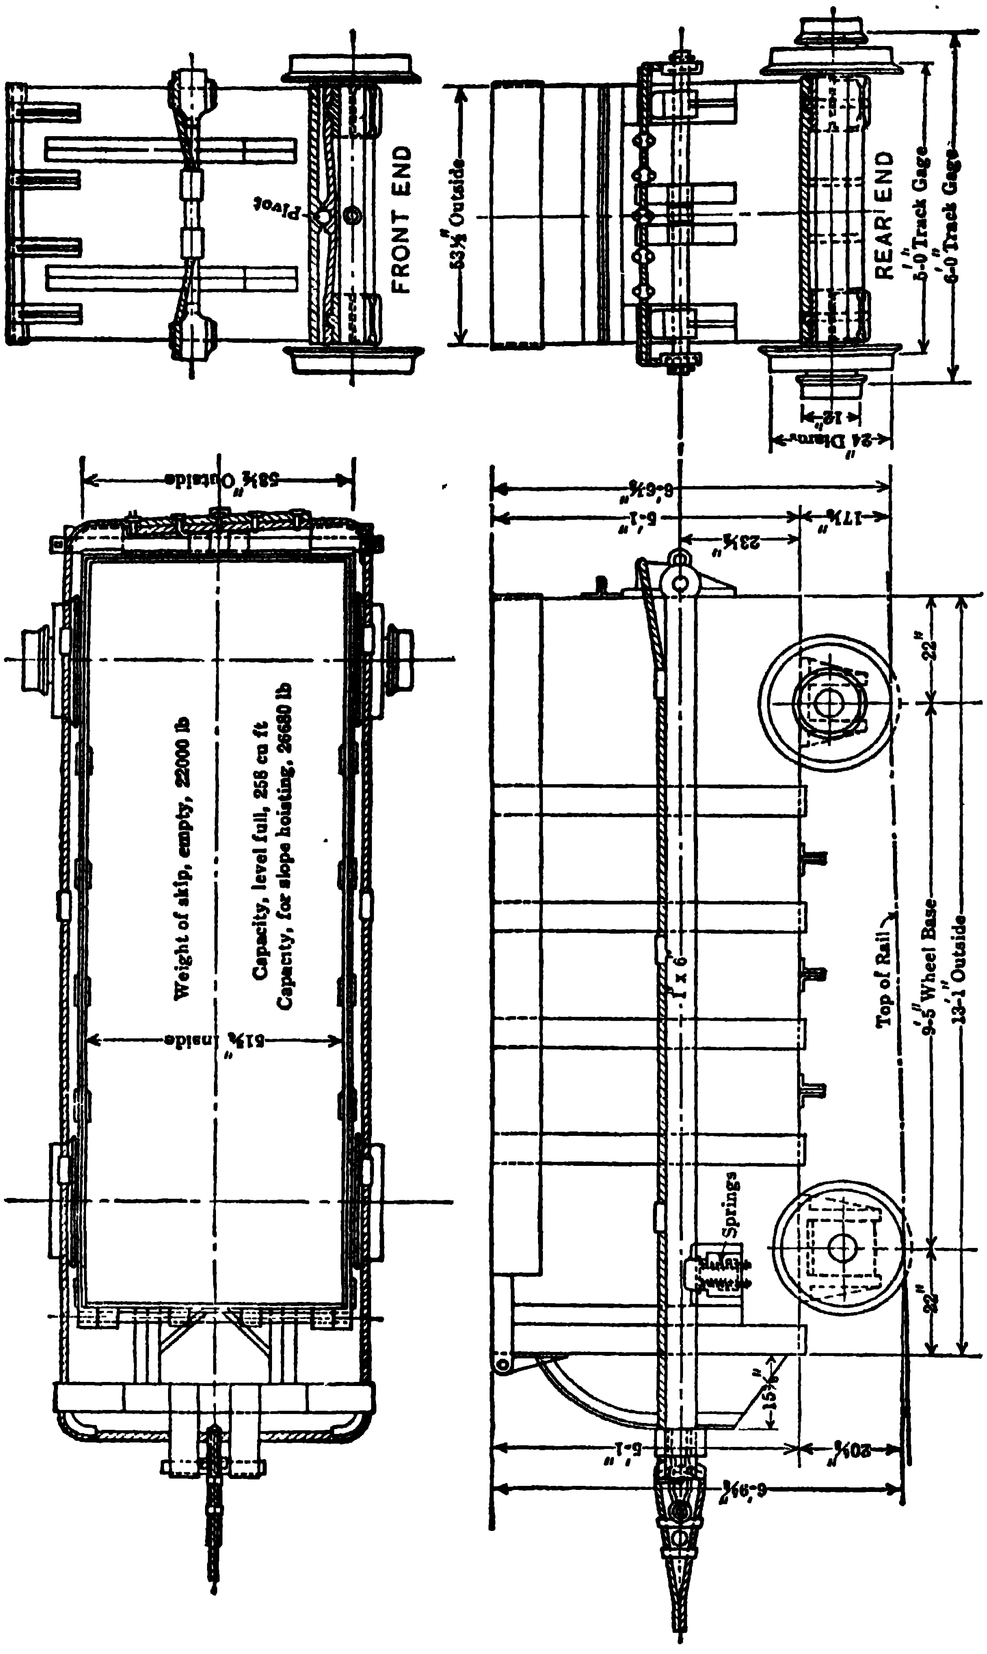

Fig 127. Skip with 3-point Suspension, for a Flat Slope, Tenn Coal, Iron & R R Co, Red Mountain Div (1920)

Details. Wheels are on axles under the body (Fig 124), or on trunnions set in heavy plates or castings bolted to sides (Fig 126). They must be in accurate alinement. Side trunnions cost more, but reduce headroom required in shaft compartment; and if body extends below rail heads, derailment is almost impossible. Axles, when worn, are more readily replaced than trunnions. Wear on wheels and axles is severe, due to grit and frequent presence of acid mine water; hence, end of axle should be capped and liberal lubrication provided for. These features are shown in Fig 126, illustrating rear wheel of skip in Fig 125. Manganese steel wheels are good; or a steel or chilled tread, with soft center bored for a bronze bushing. Front wheels have treads of standard width; rear wheels are extra wide (5 to 6 in) for dumping the skip (see below). Bail side bars are attached

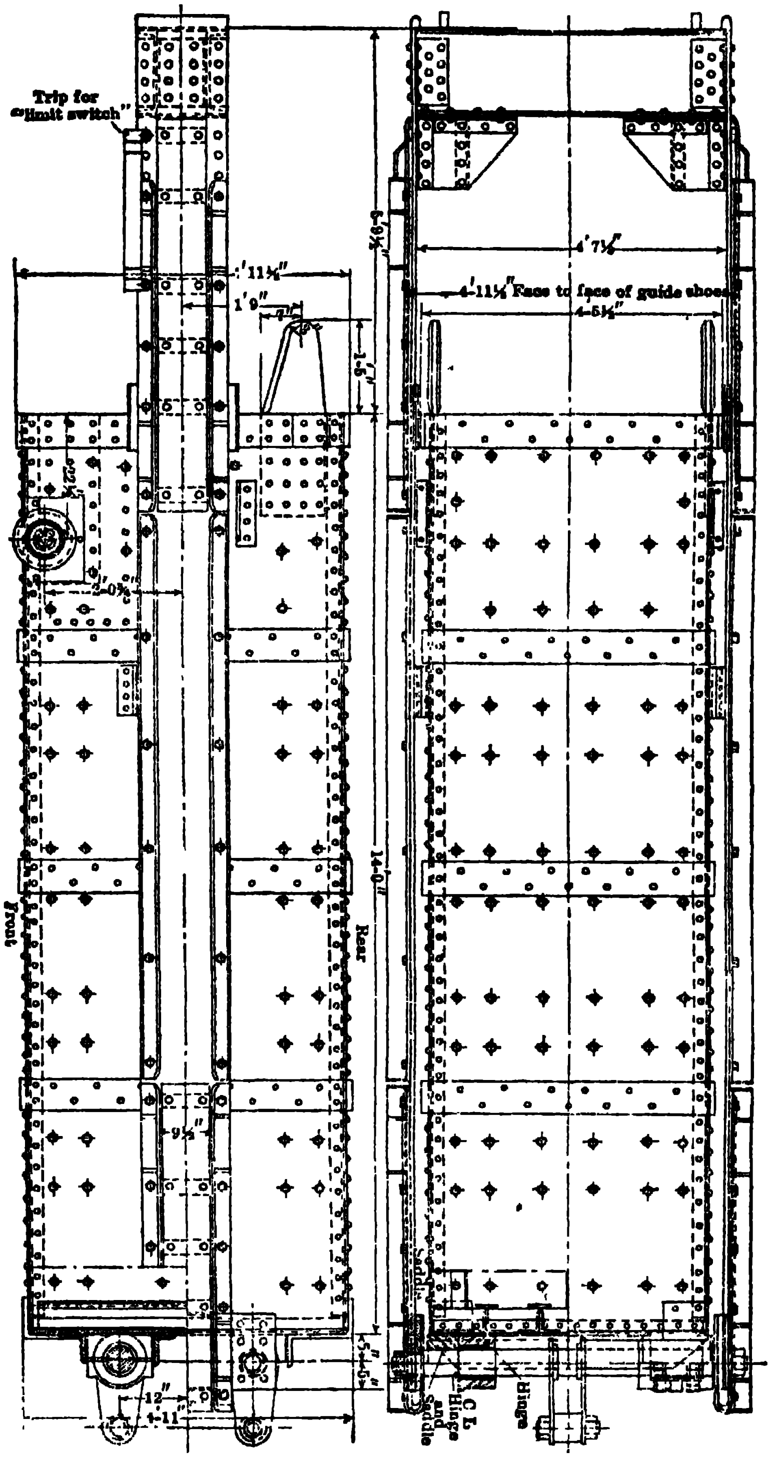

Fig 128. 12-ton Skip, Inspiration Mine, Ariz (77)

to lugs bolted to side plates, as shown; or better, to pins supported in double shear by a flat bar, passing around back of body. Pins should have ample bearing value. Sectional area of metal through center of eyes of bail bars should be 35 to 40% greater than that of the bar. Length of side bars should be such that crossbar will not interfere with loading, as skip hangs on the rope. Crossbar is designed as a beam, supported at ends and loaded at center with total rope load, including starting factor (Art 14); its service is severe, and a large safety factor is necessary. Hole for rope clevis is best in neutral axis of bar. POSITION OF BAIL LUGS depends on dip of shaft. For dips of 30° or less, lugs are placed near the rear and as low as possible without causing interference of side bars with hubs of wheels. For dips exceeding 60°, lugs are only slightly below horizontal center line of skip body; and to secure stability they should be as far forward as satisfactory dumping will allow. LINERS. Most of wear due to loading and dumping is on back and bottom of skip,

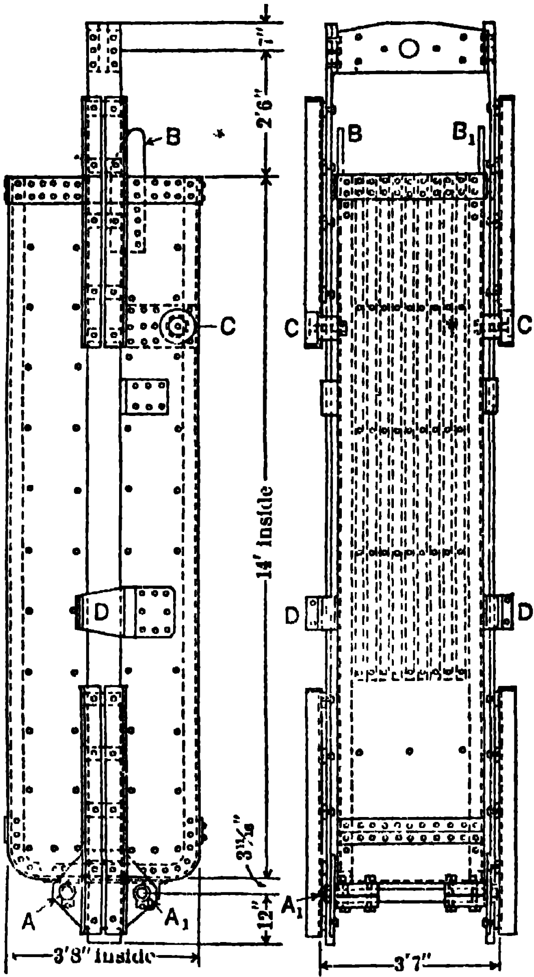

Fig 129. 145-Cu ft (10-ton) Skip, Belmont, Badger State, and Mountain Con Mines, Anaconda C M Co, Butte, Mont (79)

which should be lined with false plates, with wood fillers. For convenience of renewal, these plates are bolted, not riveted, the bolts having countersunk heads. When ore breaks large, the wear is great.

Vertical skips. For large outputs from vert shafts, skips are almost universal, except when different kinds or grades of ore must be run to separate bins on surface. Even then, some separation can be made by especially designed dumping chutes.

Fig 128 shows a skip of Porphyry shaft, Inspiration Copper Co (installed 1924); wt empty 14 000 lb; capac, 280 cu ft or 12 ton. Dumping horns, and side corner liners are of manganese steel; trunnions, forged steel; rollers, cast steel. Fig 129 shows 10-ton skip (79) used at Butte; Fig 130, a Kimberley type skip in Wisconsin (37, 80).

Ore sticking to bottom of steel skips at mines of the Randfontein Gold Mining Co, So Africa, resulted in decreased skip load and increased spillage. See Fig 131 (37). It was found that tendency to expand of a rubber (linatex) bottom caused skip to empty itself completely. Rubber lining may be applied to mine cars used in rotary dumps, where bottom pounding is used to clear muck.

Design of vert skips is largely a matter of experience and good practice, load stresses being usually more than taken care of by proper allowance for heavy wear and tear of operation. Unless required capac cannot otherwise be obtained, LENGTH of body should not exceed twice the least cross-sectional dimensions; otherwise the skip is slow in dumping, especially if the ore is sticky. Safety gear, if employed, must be high enough above body to be out of danger of injury, and not to obstruct loading from chute or car.

Combined cage and skip are useful in providing transit for men and supplies; also, for sinking operations when the shaft is to be deepened, provided height of skip body is small. Fig 132 shows a design for règular hoisting, Federal Lead Co, Flat River, Mo; capac, 125 cu ft, or about 6 ton,

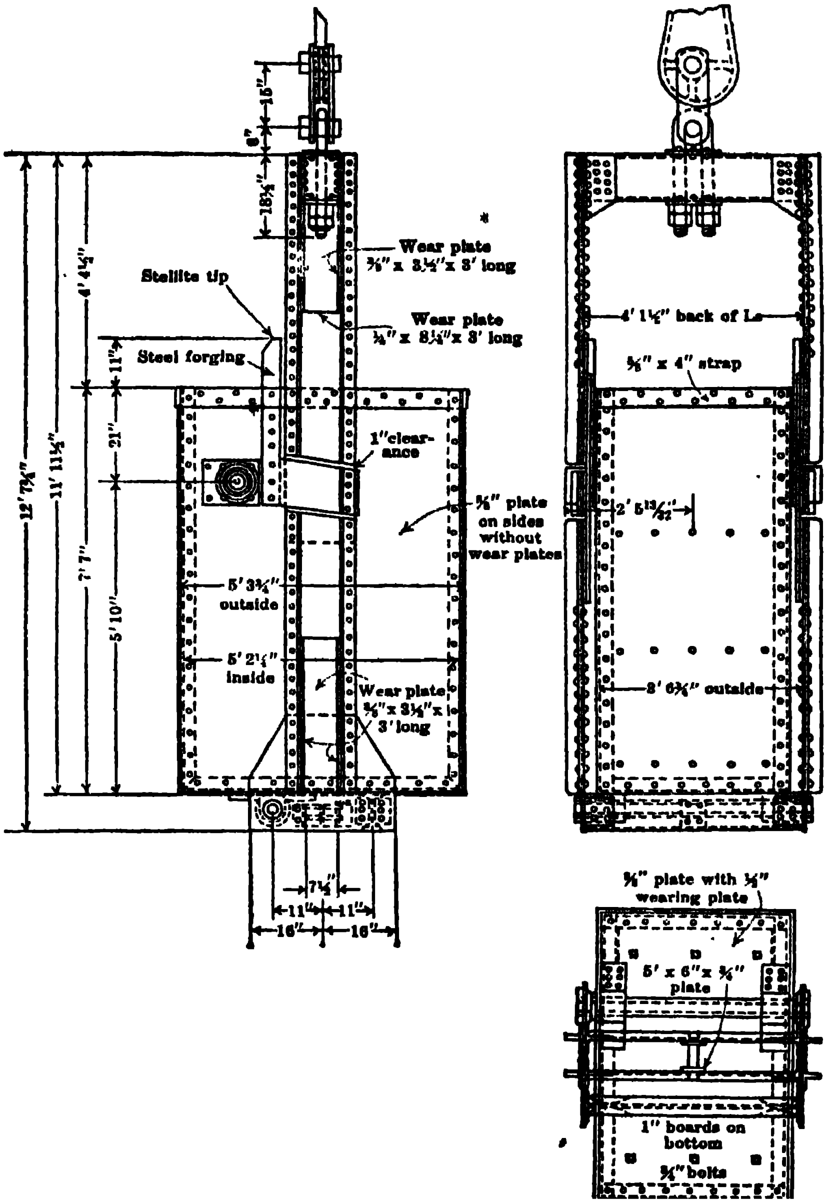

Fig 130. 9-ton Kimberley-type Skip, Montreal Mining Co, Wis (80)

though 5 ton is the ordinary load. Main vert frame is of 10-in, 20-lb channels, spliced between cage and skip for convenience of handling and renewal of parts.

Coal skips ("gunboats"). Although use of skips tends to cause more breakage of coal, due to additional dumping, improvements in methods of loading and dumping have partly overcome this objection, and they are now common for large output (78). As coal is more bulky than ores, the volumetric capac is much greater than that of ore skips.

There are two types, overturning and bottom discharge. Breakage of coal is lessened: (*a*) in the overturning skip (Fig 133), by shape of bottom and front side and special arrangement of dumping chute; (*b*) in bottom-discharge type (Fig 135), by discharging through lower part of front, which opens and forms an apron between skip and chute. In Fig 135, revolving chute *2* is hinged at *4*. Toggle links *12* are hinged to shaft *14*, across lower end of chute. Rollers *6*, on moving into

fixed dumping guides *5*, rotate bell-crank *8* about fixed point *9*, thus rotating the chute through 135°. As toggle joint *12-A* is below the line joining *14* and *9*, the gate is self-locking. In each type, the greatest breakage of coal probably occurs during loading.

Loading arrangements. In INCLINED SHAFTS, skips are loaded direct from cars, the skip holding 1, 2 or more carloads; or from a pocket, through a gate controlled from landing above. Latter plan is best, since cars and skip are independent of each other, and on reaching shaft station, the skip is loaded promptly, without waiting for cars. In VERT SHAFTS, a skip holding 1 or 2 carloads may also be loaded direct (Fig 135, *a*); but pockets are always preferable (see Shaft Pockets, Art 35).

Fig 131. Rubber Skip Lining (37)

Arrangements for dumping are more varied than those for loading. For INCLINED SHAFTS, a "knuckle" is formed at dumping point by curving main rails inward to horizontal. The narrow-tread front wheels run forward on these bent rails, while broad-tread rear wheels continue up the regular slope on a pair of auxiliary rails set at wider gage, beginning at the knuckle.

Fig 135, *b* shows a modification of this typical dump, as used at Quincy mine, Mich, for an 8-ton skip. By curving upward the broad-gage rails, the skip is brought more quickly to proper dumping angle. Design must be such that, when skip is lowered, it cannot go down the shaft head first. If, as in Fig 127, the whole tread of the wide rear wheels is of one diameter, guard rails may be necessary to prevent rear of the skip from slipping sidewise. Or, as in Fig 126, diameter of outer part of tread may be 2 to 3 in less than that of inner part, the shoulder so formed acting as a flange on the auxiliary rails.

It may be necessary to dump at more than one point, as for putting different grades of ore into separate bins. At Quincy mine, Mich, gaps in main rails at dumping point, through which front wheels pass, are opened or closed by a plate, moved sidewise by an attendant, by rods and levers. ANGROVE DUMP for intermittent service (Fig 136), as used by Copper Range Mining Co, has no break in main rails. The wide-tread rear wheels follow curved auxiliary rails *K*, and when skip reaches a proper dumping angle, the front edge is supported by rollers *L*, otherwise front end of skip would drop. Points *B* of auxiliary rails are hinged at *A*; and, by a system of counterweighted rods and levers, may be raised to dotted position *B'*, if skip is to pass up to a higher dumping point.

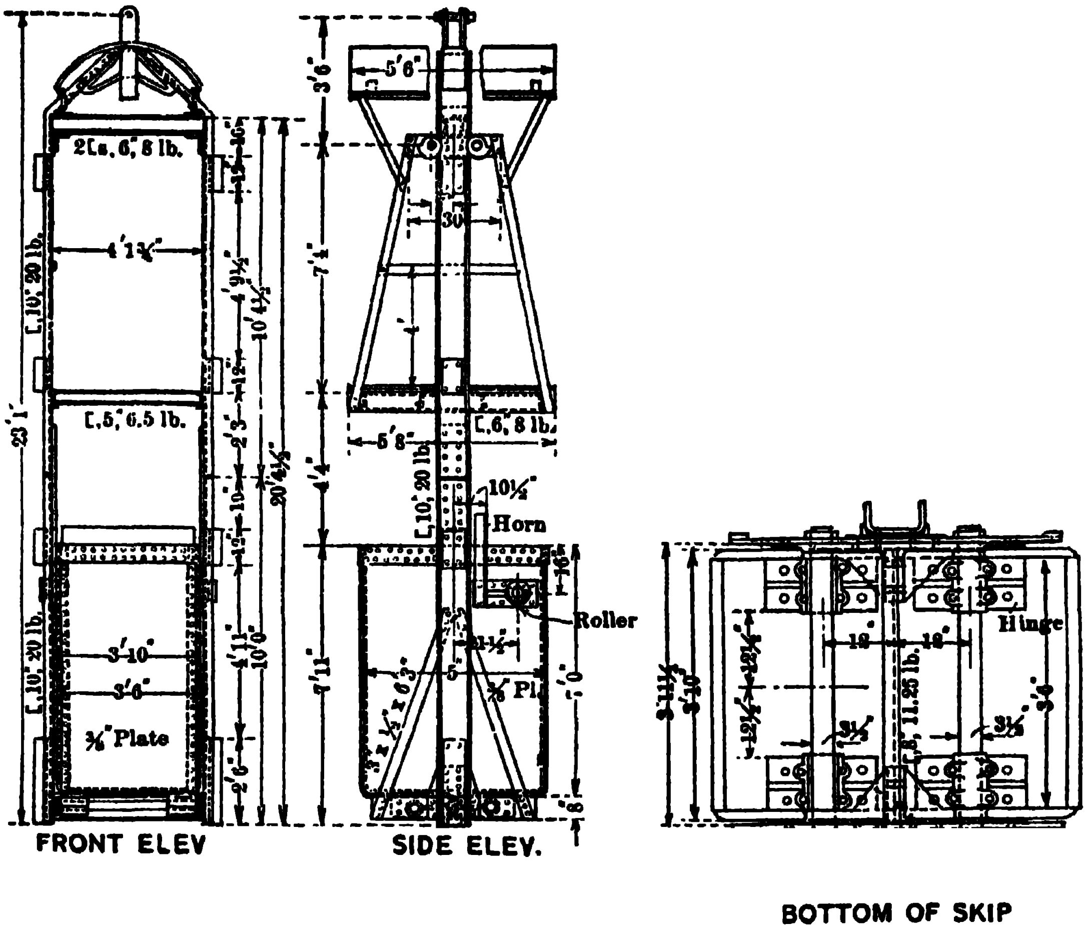

Fig 132. Combined Skip and Cage

For VERTICAL SHAFTS the skip body, which is pivoted at bottom to the rigid guide frame, is thrown outwards and supported at a dumping angle by a pair of small wheels, near upper edge of skip (Fig 137), which run into a curved slot-like track attached to head-frame at the dumping point.

Fig 137 shows dumping track for the skip in Fig 130. The skip body rests on two parallel shafts bolted to the guide frame, and far enough apart to insure stability of the skip while being hoisted. One shaft passes through 2 heavy pillow blocks with caps, bolted to skip body, thus forming a pivot on which the body rotates. The other shaft rests in pillow blocks without caps, also bolted to the skip bottom. Track must be so designed that skip body will not reverse, and go down head first when lowered. Generally, a pair of roller wheels is attached to side plates of dumping track (Fig 137) in such position that the horns (Fig 128, 133) projecting forward from front end of skip body will just slide over them; these rollers thus carry wt of skip while dumping wheels are being lifted across gap to reversed portion of dumping track, and on down trip they insure that skip body will be turned right side up. Instead of 2 rollers, a continuous bar or roller spanning gage of track is

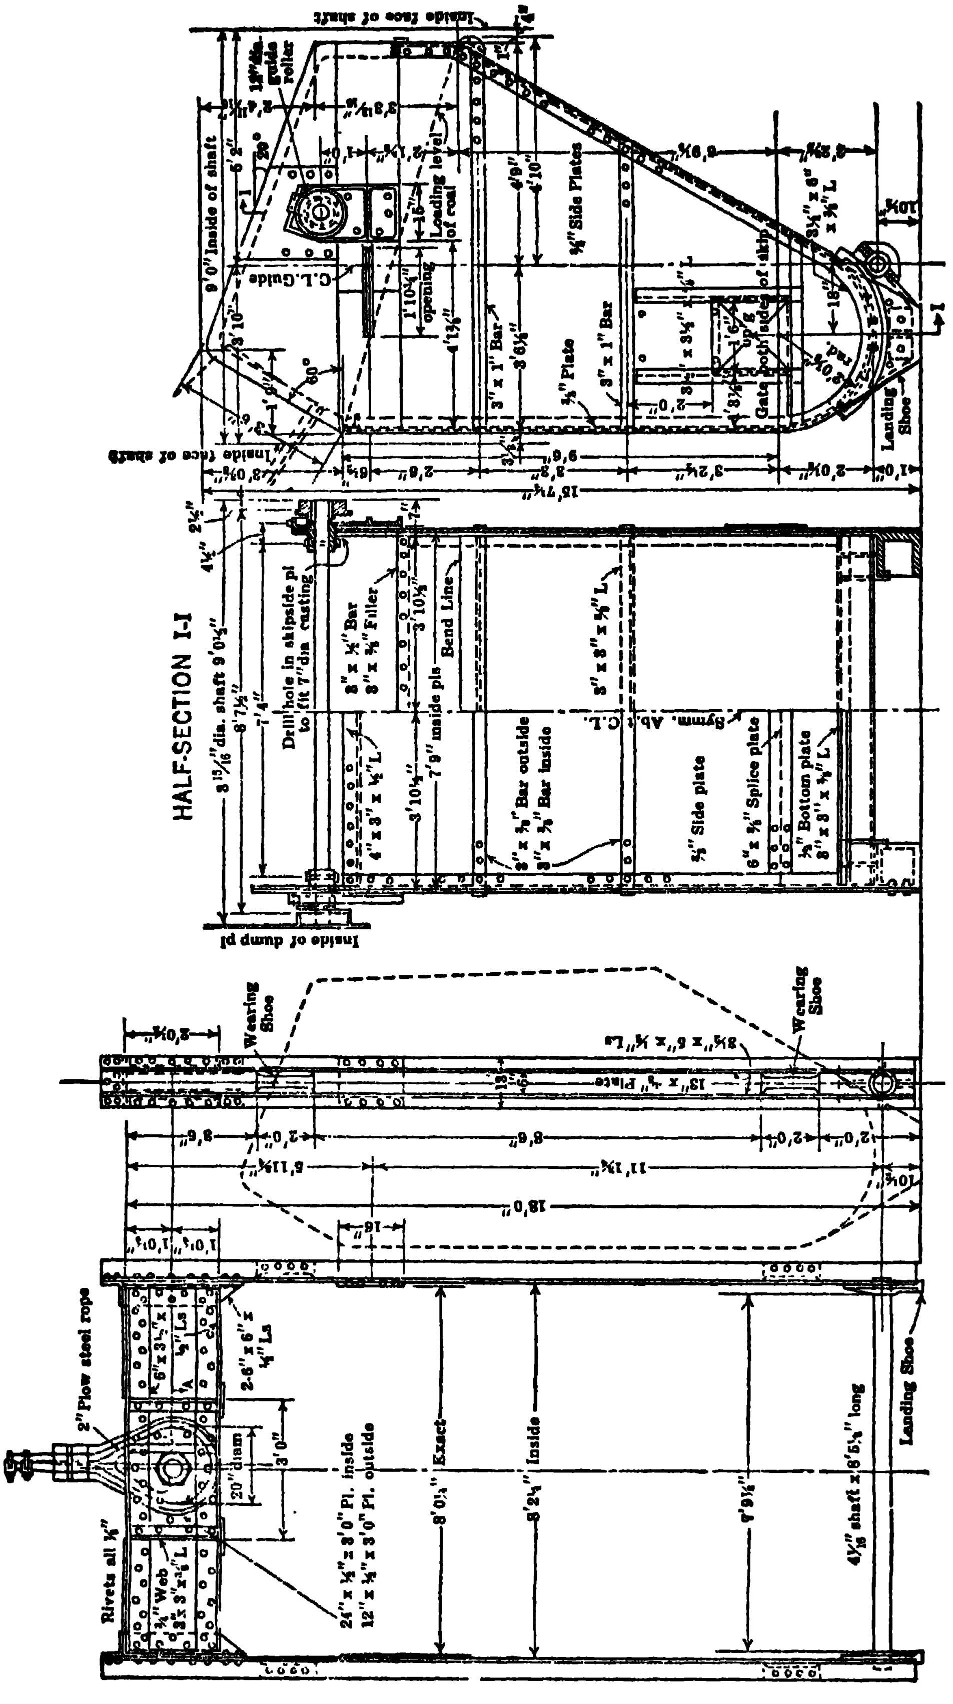

Fig 133. Allen & Garcia Skip, C W & F Coal Co, West Frankfort, Ill; Capac, 484 cu ft

sometimes used, but it may interfere with free dumping. Dumping wheels (Fig 128) should be placed close to dumping side of skip, so that ends of pivoting shaft will have clearance space between the main and dumping guides. The farther this shaft is from center line of skip, the less the liability to accidental overturning, but the greater is the force required to dump skip, thus throwing excessive stresses on guides. Main guides sustain heavy side thrust at dumping point, and must be well

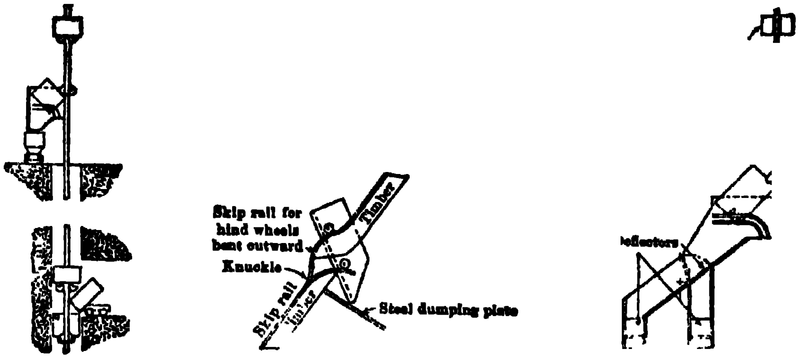

Fig 134. Arrangements for Loading and Dumping Skips

reinforced and bolted to headframe. Pivoting shaft is usually placed at 0.33 to 0.5 the distance from center line to side of body, 0.375 being good practice. For small skips the side plates are 1/4 to 5/16 in; front plate, 3/8 in; bottom plate, 3/8 to 1/2 in. For large skips, sides are 1/2 in, and front and bottom 3/8 to 3/4 in; in some Mich copper mines, even heavier.

Handling men in vertical-skip shafts. For large numbers of men, a double or triple-deck cage is substituted for the skip at end of shift. The change may be made quickly by hinging a section of the guides above shaft collar, and handling skip and cage by a small crane; as at Butte, Mont, and elsewhere (92).

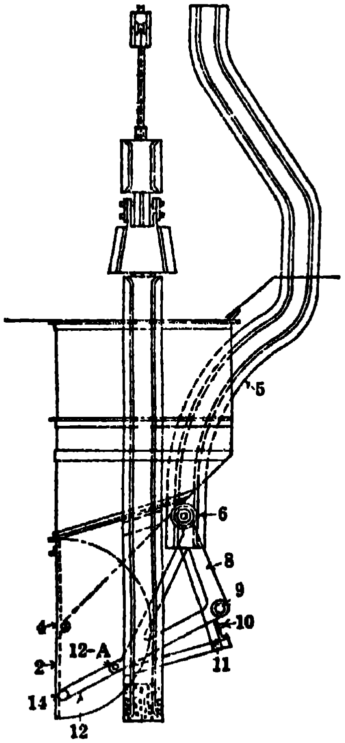

Fig 135. Lepley Bottom-discharge Coal Skip. Diagram of Mode of Dumping

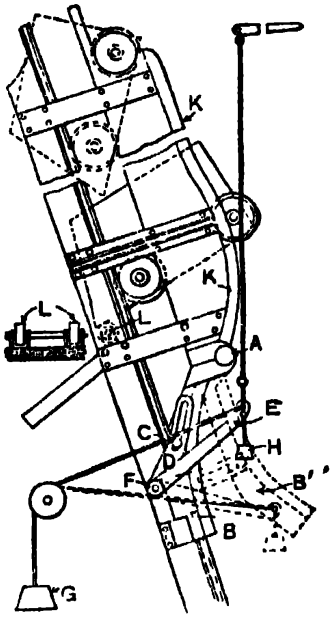

Fig 136. Skip Dump for Intermittent Service (*E & M J*)

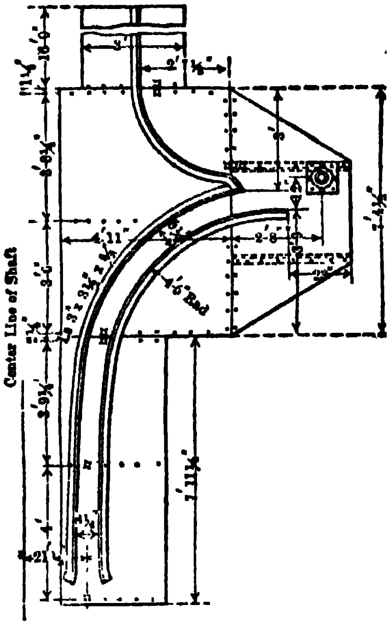

Fig 137. Dump Tracks for Vertical Skip

Weight and cost of skips. Weight is commonly 40–60% of wt of ore, reckoned at 110–120 lb per cu ft. Cost: usual designs, 10–14¢ per lb at factory; vert skips, with safety catches, 14–16¢ per lb. Dumping guides, with supporting plates and rollers weigh 2 000–3 000 lb for 30- to 60- cu ft skips, to 4 500 lb for 100-cu ft capac.

34. OVERWINDING

Overwinding occurs when for any reason the hoisting engineer fails to check engine in time to bring cage to rest at surface landing. In such case the cage may rise at high speed into the sheave and its supporting timbers at top of headframe. Height of headframe should be sufficient to allow reasonable clearance between rope socket and center of sheave, when cage is at landing. This clearance is a function of hoisting speed. In general it should not be less than two-thirds the circumference of the drum (Art 23).

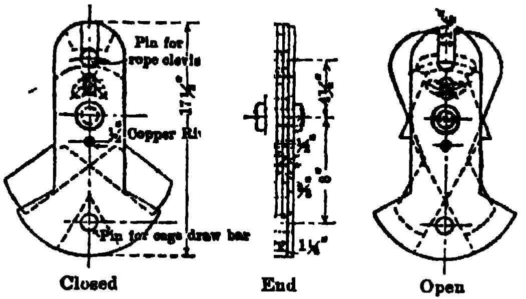

Fig 138. 4-Ton Humble Detaching Hook

Detaching hooks release rope from cage or skip in case of overwinding, and at same time hold cage suspended in headframe. They are not in general use, although required by law in some districts for cages or skips on which men are hoisted. They can be used for vertical shafts only. Original HUMBLE HOOK with 5 leaves or plates, and capacity of 4 tons, is shown in Fig 138. Disengaging plate, into which hook rises, and which opens it for releasing the rope, is bolted to timbers in upper part of headframe. This plate is of C I or steel, with a round opening of a diam about 0.5 in greater than width of hook. Details of the ORMEROD HOOK (a modification of the Humble) with 3 plates instead of 5, and C I-disengaging bushing, are shown in Fig 139 and Table 38. DISENGAGING PLATE OR BUSHING should be placed as high as possible in headframe, and solidly supported to withstand shock of cage, if overwound, and to carry its weight. A well-known hook in Great Britain is the WALKER. If a plain detaching hook, without ears or lugs, is used for holding the cage after rope is released, chairs or catches are set in upper part of headframe. They are so made that cage will pass up through them, and are then thrown outward by springs. Detaching hooks do not grow in favor, chiefly because they are not effectual for high hoisting speeds. A run-away cage, rising into the headframe at a velocity of several thousand ft per min, would wreck itself and also the disengaging bushing, with its timber supports.

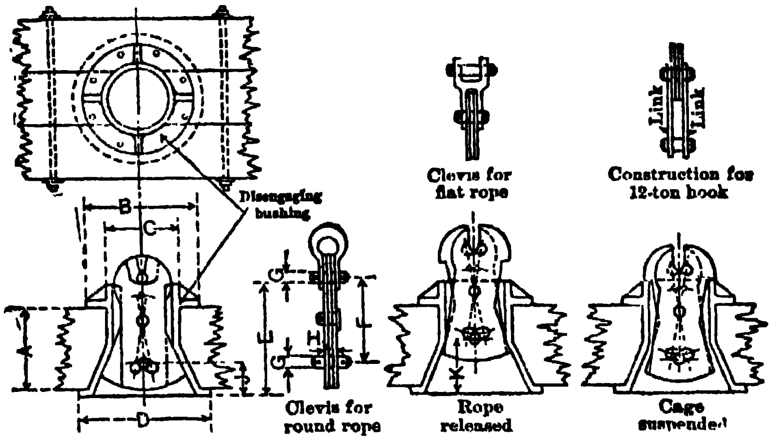

Fig 139. Ormerod Detaching Hook (Wellman-Seaver-Morgan Co)

Safety devices, to prevent overwinding by automatically controlling the engine, generally operate by closing throttle and applying brakes. Some also center the reversing links. Requirements: (*a*) simplicity; (*b*) all parts should be accessible for inspection and testing; (*c*) derangement or failure of any part should cause the stop to operate; (*d*) steam should be cut off close to the valve chests; (*e*) steam should be throttled as cage approaches surface, and brakes applied for bringing the engine gradually to rest; (*f*) the apparatus should come into operation automatically, if the engineer fails to check the engine at the proper time; it should also be self-locking, so that engine can not again be started until gear has been thrown off and engine reversed.

Lilly hoist controller (81), largely used in U S for both steam and electric hoists, has a fly-ball governor, working through cams and levers controlled by electrical contacts.

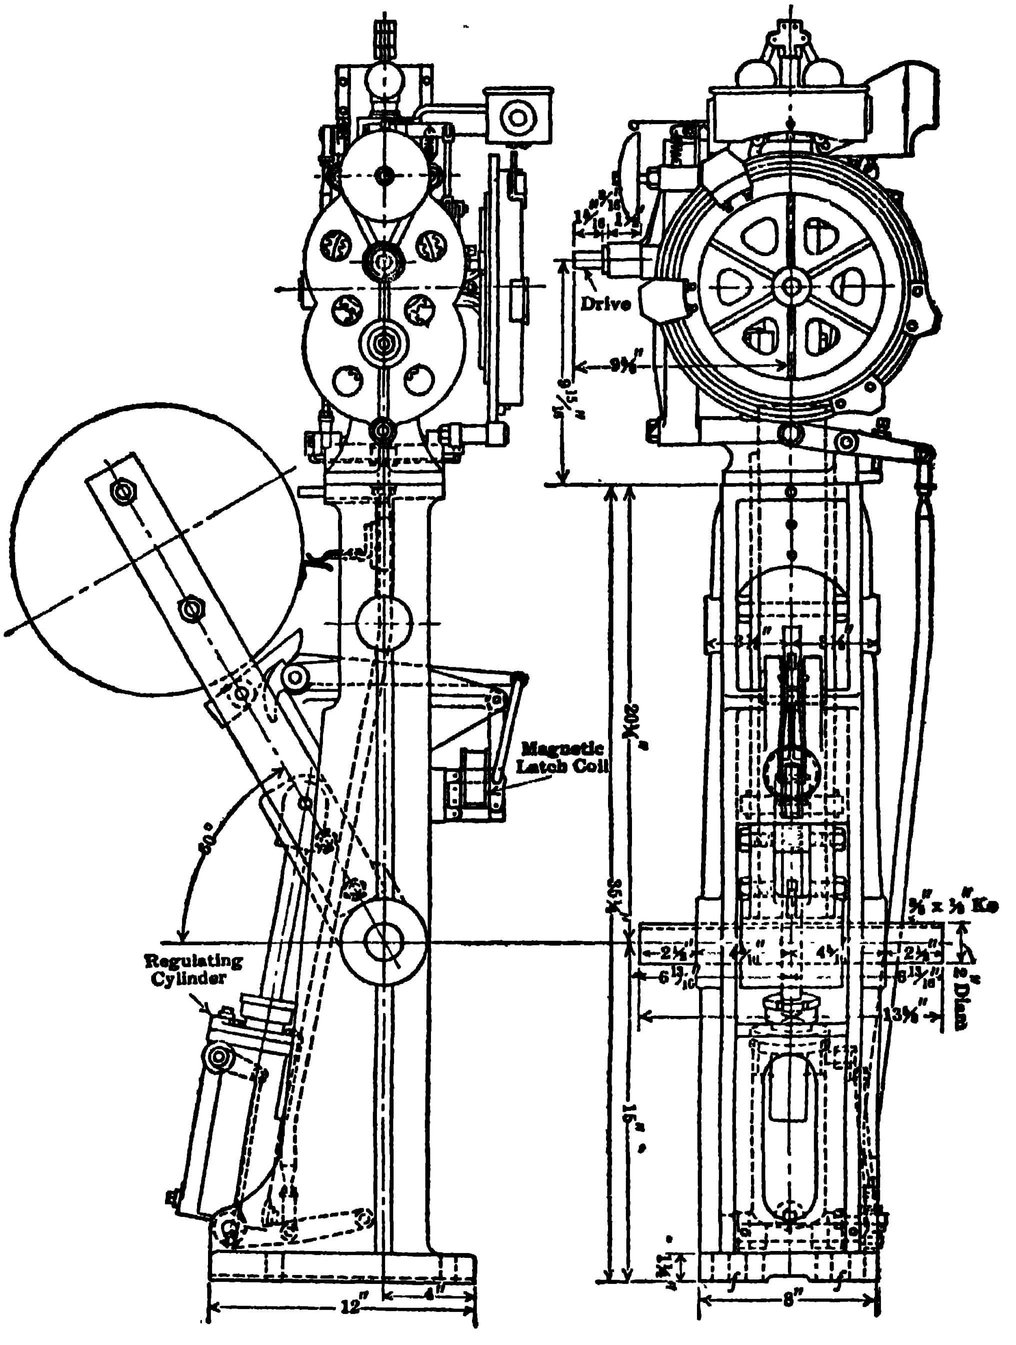

Fig 140. Lilly Controller for Small Electric Hoists

Controller is operated from the drum shaft, or hub of clutch-operated drums, by a train of gears or sprocket chain. It guards against overspeeding, overwinding at ends of trip, and warns engineer by a bell when full speed is exceeded; also acts to reduce speed at proper point, if engineer fails to do so, and to prevent starting engine in wrong direction.

For steam hoists, the current is supplied by batteries; for electric hoists, power circuit supplies current. On steam hoists the controller acts by releasing a wt, which closes throttle; on electric hoists by controlling the power circuit. If hoist has power-released gravity brakes, they are applied

by an auxiliary weight, which operates the brake-engine valve. For small hoists, hand brakes are applied by a weighted lever, automatically controlled through an oil cylinder having a by-pass and valve to prevent too sudden application of brake except at extreme limit of travel. For high-speed hoists, the controller has an auxiliary attachment, set to prevent excessive speed when hoisting men. Fig 140 shows a form used for small elec hoists, with hand-brakes.

Futer's safety stop (82) **acts directly on the cutoff, shortening it as the cage rises above a fixed point in the shaft, centering the valves at a predetermined point, and gradually applying the brakes. Its best features are: it shuts off steam directly at the cylinders, and gradually applies the brake.**

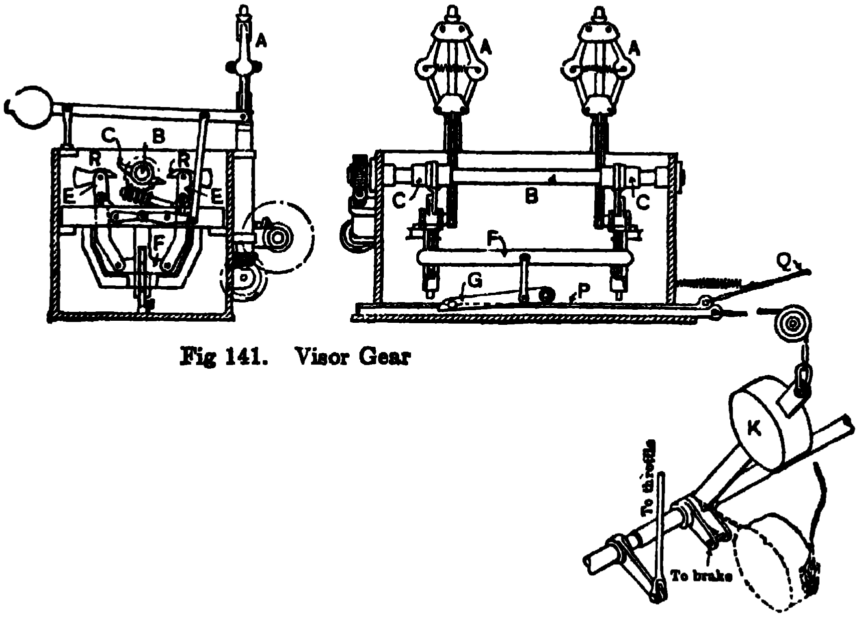

Fig 141. Visor Gear

Some safety stops are operated by the indicator pointer, which releases a latch allowing weights to close the throttle and apply the brakes; but their action is too sudden for use with high speeds. "Visor" gear (John Wood & Sons, Wigan, England) is shown in its simplest form in Fig 141. Governors *A* and shaft *B* are driven by worm gear from drum shaft. *B*, making approximately one rev per hoist, carries the cams *C*. When speed is attained the governors cause levers *E* with their hooks *R* to move into line of contact of cams *C*. If steam is not shut off at the proper point the cams engage with hooks, *R*, lifting frame *F* and pawl *G*, thus allowing weight *K* to close throttle and apply brakes. *P* and *Q* are parts of an auxiliary stop, to prevent starting engine in wrong direction. By providing cams *C* with several beaks of increasing radii, steam may be shut off gradually as the cage nears the point where the throttle should be closed. (For safety stops for elec hoists see also Sec 16.)

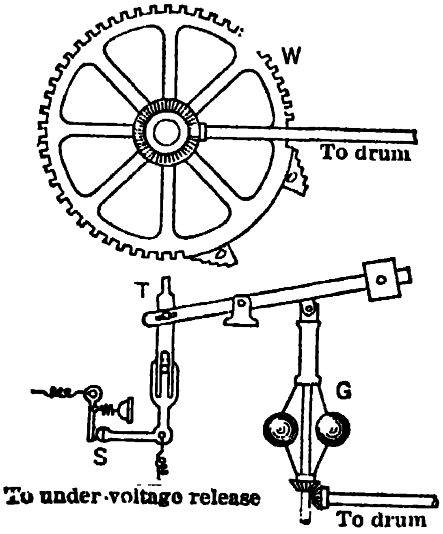

Fig 142. Diagram of Mechanical Overwind Device for Mine Hoists (3)

Speed governors, in addition to safety stops, are necessary for high-speed hoisting engines. They are usually of the flyball type. With Corliss valves they act by shortening the cutoff; with slide and piston valves they throttle the steam.

A system of protection for electric hoists is shown in Fig 142 (3). The notched wheel *W*, carrying an adjustable tripping dog *D*, is geared to the drum to make not more than one revolution for the max lift. Governor *G*, also geared to drum, determines the position at which the trip *T* for the circuit-opening switch *S* (wired in the "undervoltage" release circuit) is operated by the notches of the dog on wheel *W*. Dog *D* is placed to correspond to positions near end of travel and the graduated steps correspond to distances between the point at which slow-down should start and the limit of travel. Opening of switch *S* is determined by relative positions of *T* and *D*; the former governed by speed of drum and the latter by position of cage in the shaft. The last tripping position of *D* corresponds to an actual overtravel of the cage, and opens *S* irrespective of the speed. The notches on *W* protect against overspeeding at any point. These devices may differ considerably in construction. They usually have a hand resetting device. For further protection, it is customary to install in the shaft guides above the landing, a "shaft limit-switch," operated directly by the cage or skip. If the hoist is stopped by either device, means must be provided to prevent starting again in the same direction. This is done by a small double-throw controller, reestablishing the power supply and releasing the brakes, but permitting closure of only that primary contactor which will allow the over-wound skip to be backed down.

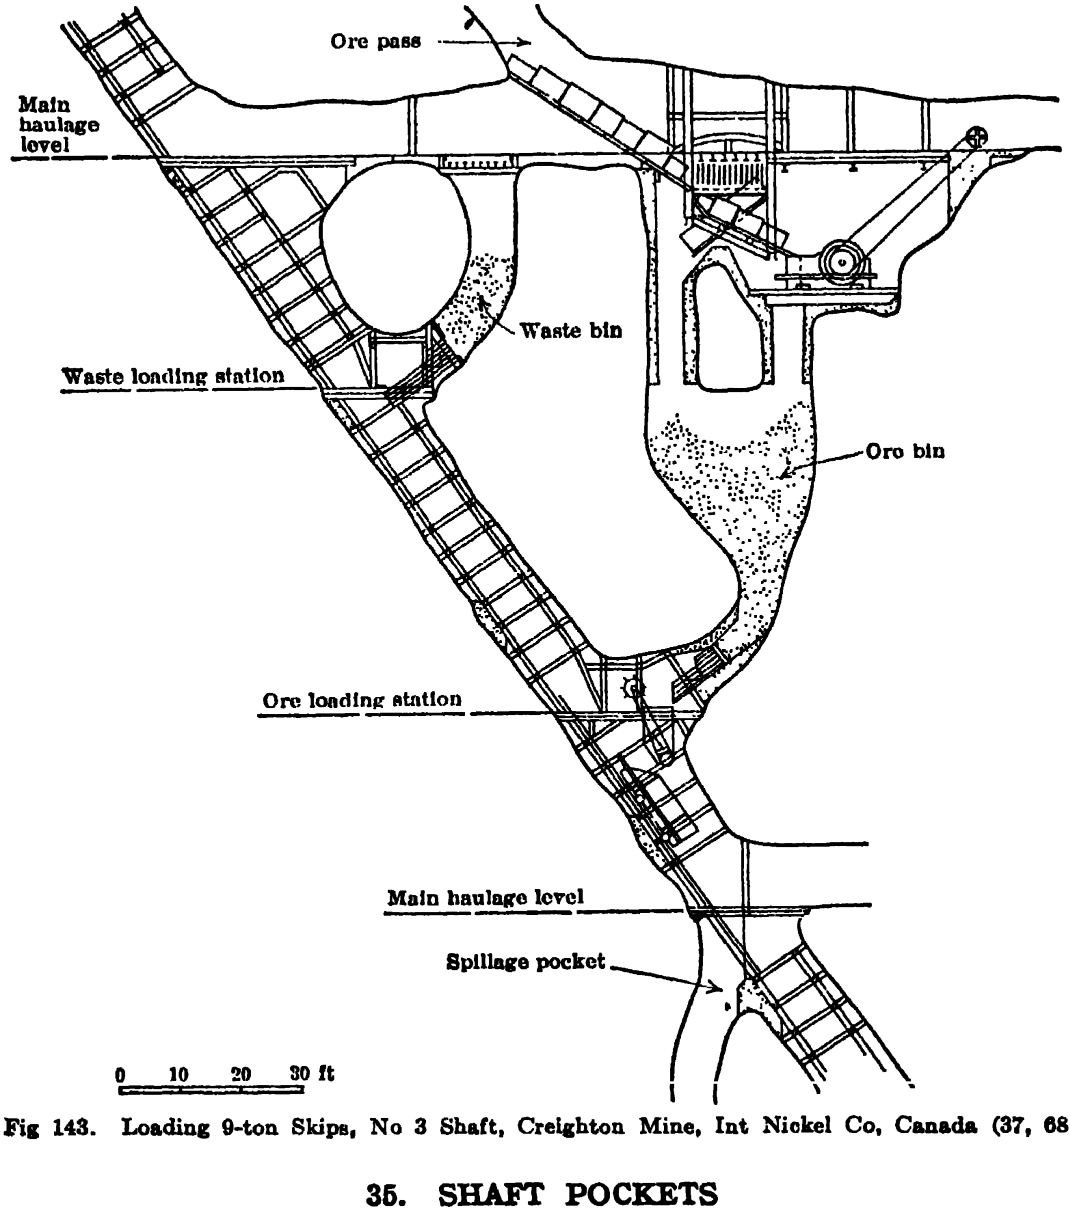

Fig 143. Loading 9-ton Skips, No 3 Shaft, Creighton Mine, Int Nickel Co, Canada (37, 68)

35. SHAFT POCKETS

Shaft pockets at loading stations decrease time required to load a skip, and furnish reserve ore capacity, so that hoisting and tramming are not directly dependent on each other. Filling a skip from a pocket also involves less likelihood of spilling ore down the shaft. **Capacity** of pockets depends upon tonnage hoisted, size of ore cars or trains of cars, and storage need at the level to take care of ore trammed while hoisting is being done from

other levels. It may reach 1 500 tons or more. As a rule, a measuring pocket is placed below the storage pocket. It holds one skip load and is filled from main pocket, thus saving time and avoiding danger of overfilling skip, if gate should stick or break. This also permits dividing main bin into 2 or more pockets for different grades of ore; then, with swinging chutes between main-bin gates and measuring pockets, any grade of ore may be loaded into either skip. SUPPORT of shaft pockets depends on capacity, nature of the rock in which they are built, and life of the shaft. In dry shafts, use only concrete or steel with perhaps a few large timbers to carry front wall, lining being of steel plate.

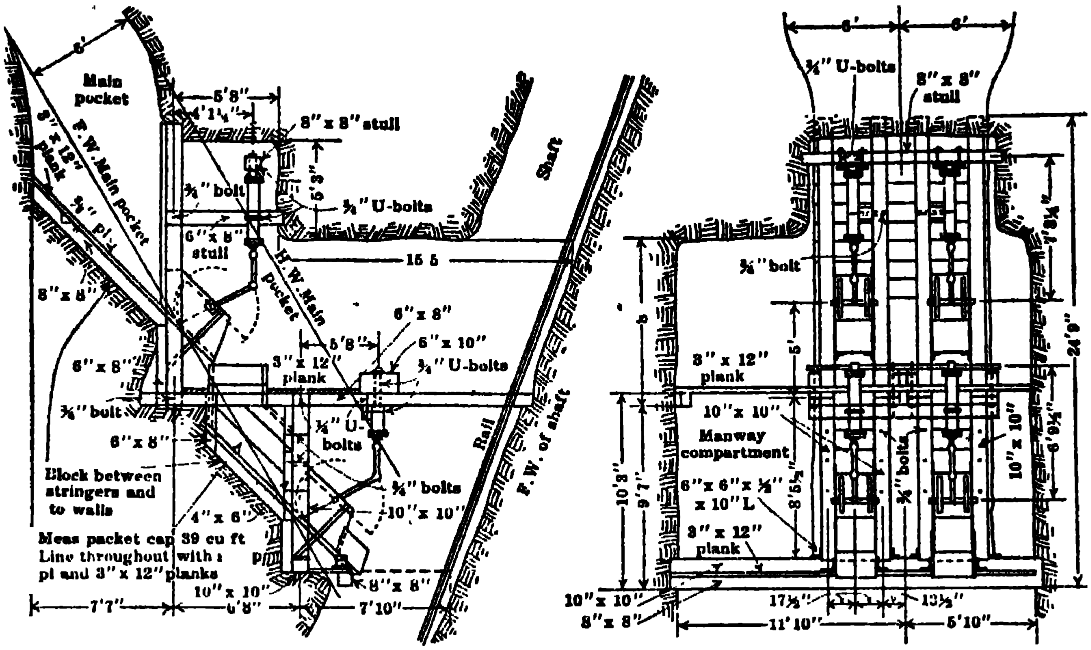

Fig 144. Skip Pocket for Inclined Shaft, Cerro de Pasco Copper Corp, Peru (37, 71)

Pockets for inclined shafts, except the measuring pocket, are excavated in hanging wall, the only timbering required being that for the gates. Examples:

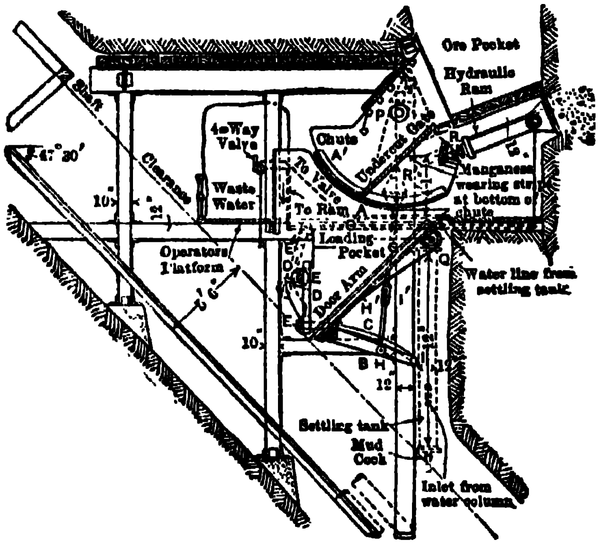

Fig 145. Shaft Pockets, Franklin Furnace, N J (*E & M Jour*)

I. Large pockets at 14th, 20th and 26th levels of No 3 shaft, Creighton Mine, Ontario, are shown in Fig 143. Dip of shaft, 55°. Ore hoisted in 9-ton skips, weighing 12 200 lb. Shaft has 5 compartments, 2 for ore, 2 for men and supplies, and 1 for ladders, pipes and cables. A 30- by 42-in Farrell jaw crusher, with 6-in opening, breaks the ore before it enters pocket. A measuring box of 9 ton capac handles ore from bin to skip (68, 37).

II. At the Francisco Mine, Cerro de Pasco Copper Co, Peru, the skip pocket (Fig 144) has a bottom of 3 by 12-in plank, covered with scrap plate and inclined at 45°. The measuring pocket holds 39 cu ft (one skip load). Gates operated by air cylinders are used in both main and measuring pockets. Gates should shut off ore flow by rising, but with sufficient power they may close from the top. Valves for the 4 gates are operated from a platform in front of main pocket. All gates and signalling are controlled by one man (37, 71).

III. At Palmer shaft, N J Zinc Co, Franklin, N J, both main and measuring pockets are of steel (Fig 145). Main gate and loading chute are moved by a hydraulic ram, taking its water from the column pipe in the shaft. The cut shows the closed apparatus; lower door closed and upper undercut gate open, allowing ore to fill measuring bin. When the angle of repose is reached flow stops, with pocket and upper chute full. To load skip, the ram moves out along the arc shown until edge of undercut gate is at *A'*. At same time rod *G* moves to position *G'*, moving levers *B* and *C* so that pins *H* and *I* assume positions *H'* and *I'*. Door *D*, held in position by arms pivoted at *Q* and *E*, is forced to position *D'* by movement of *B* and *C*. The advance of cutoff gate *A* is at first more rapid than that of *D*, but *D* closes first, so that the measuring pocket is ready to fill when *A* has opened. Gate *A* can not jam, as it cuts upward through the ore. The operation is controlled by one 4-way valve. With 6-ton skips over 2 000 ton have been hoisted in 8.5 hr.

Cable
Measuring hopper
This chute is lowered as skip descends and is raised as skip ascends
Skip

Fig 146. Shaft Bottom Dumping Arrangement, Standard No 2 Mine, Schoper, Ill (37, 69)

Vertical-shaft pockets. In their construction, concrete is more generally used than for pockets in inclined shafts. Examples:

I. At Standard No 2 coal mine of the Standard Oil Co of Indiana (Fig 146), there are 2 rotary dumps in which cars are dumped singly into a 40-ton hopper, from which coal goes to a 12-ton measuring hopper holding a skip load. The empty descending skip closes discharge gate of storage hopper, and opens that of measuring hopper; ascending skip closes measuring-hopper gate and opens that of storage hopper. Amount of ore discharged into measuring hopper may be varied by a dam in upper part of hopper. This procedure does away with spillage (69, 37).

II. Shaft No 3, Negaunee mine, Mich, is circular in section, with 2 skip compartments (83). Storage pockets (Fig 147) are 12 ft 6 in wide, 18 ft 6 in deep, and 23 ft 3 in long at the top; divided into compartments for 3 grades of ore. Center compartment has 2 gates, for loading into either skip. End compartments have 1 gate, and load into but 1 skip. Front wall of the pocket is supported by horizontal timbers, lined with 5- by 7-in vertical timbers, covered with 0.5-in steel plate near bottom and 0.25-in plate at top. Sides are concreted, and lined with 0.5-in and 0.25-in plates bolted to timbers embedded in the concrete; plates are put in position and concrete poured behind them, thus making forms unnecessary. Bottom is concreted and lined with 2 layers of 3-in hardwood planks, spiked to 5 by 7-in timbers embedded in the concrete. This lining also is placed before concrete is poured, thus serving as forms. Gates are vertical finger bars, about 4 in square, suspended by chains from a crosshead attached to piston of an air cylinder with 3-ft stroke. Each

measuring pocket holds a skip load. Their gates, of 2 thicknesses of 0.5-in plate, counterweighted, and opened and closed by an air cylinder, open away from the shaft, so that no part shall project into the hoisting compartments. Ore drops through a stationary chute into skip. Measuring pockets are of steel plate, their fronts being supported by I-beams across the openings in the concrete shaft lining.

III. At No 3 shaft, Village Deep mine, So Africa, an incline from level above, used for ore storage, discharges into a steel measuring pocket, for loading the skip (Fig 148). The gate forms a chute between pocket and skip, and a sloping spill plate diverts spillage into the level below; thus preventing it from falling into the sump, and interfering with tail-rope sheave.

IV. Thermal Mine No 4, Donk Bros Coal and Coke Co, Madison Co, Ill, has no storage pockets, as they increase breakage. A rotary dump discharges cars into weigh pans of scales, one for each compartment (Fig 149). Car loads are weighed separately, 2 cars filling a 6-ton skip (84). Descending skip trips a lever, which opens the rotary gate of chute between scale pan and skip, the same movement opening the discharge of scale pan. Coal may be dumped from scale pan before the skip arrives, as the chute does not open until skip is landed. When skip rises, the gate closes automatically. For very high speeds, mechanical control of the chute is unsatisfactory, and electric control is used. A constant-running motor is connected through a magnetic clutch and gear train with the rotary gate of skip chute. Descending skip makes an elec contact at the proper point, energizing the clutch and opening the gate. As skip rises, current is broken, closing the gate.

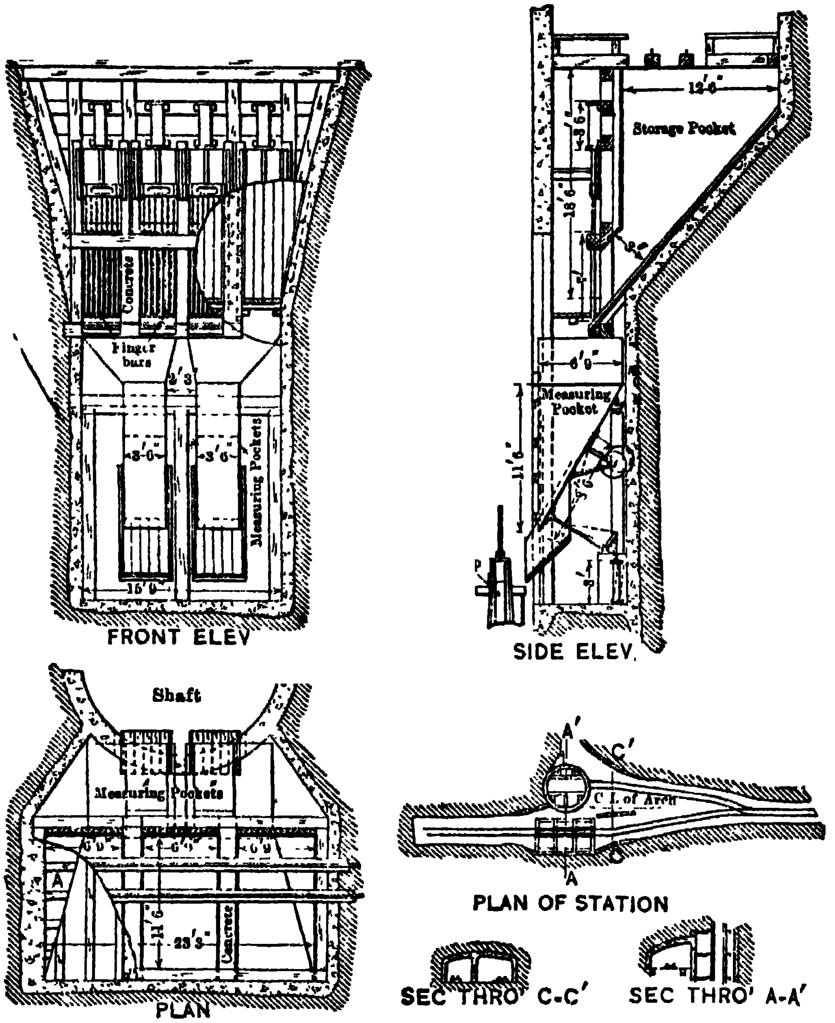

Fig 147. Stations and Storage Pockets, Negaunee No 3 Shaft (83)

V. Skip loading at Porphyry shaft, Inspiration, Ariz (Fig 150), exemplifies extreme mechanical control. Ore is dumped into 2 cylindrical, concrete-lined storage bins, 30 ft diam by 40 ft deep; total capac, 1 600 tons. One gate in bottom of each bin discharges to pan feeders, 48 in by 7.5 ft, which deliver to a 12-ton steel hopper supported on knife edges. When hopper is full, feeder stops automatically. Descending skip, on coming to rest on chairs, opens the gate for loading; it then closes and starts feeder (77).

Stresses in shaft pockets. Pressures on walls are computed as for surface ore bins (Art 36, 37), but, because the service conditions are severe, and construction may not be so carefully carried out as for surface structures, a larger safety factor is advisable. If bin structure supports also the walls of the excavation, this fact would generally be the determining factor in design. For deep pockets, excavated in ore or rock, the gate or chute and its support should be carefully designed, since it may be subjected to unusual loads due to ore bridging above and then falling from some height.

36. ORE BINS

Types. For ore, crushed stone and coal, bins are designed: (*a*) of rectangular section, with flat bottom; (*b*) with hopper bottom, either inverted pyramid or wedge-shaped; (*c*) of circular section with flat, conical or hemispherical bottom; (*d*) as a suspension bunker or bin. FLAT BOTTOM BINS (Fig 155) are built entirely of timber, steel frame with timber cribbing, all steel, or reinforced concrete. They are best suited to conditions where the material is discharged at center, or at various points of the bottom, onto conveyers or into cars. Advantages: larger storage capacity for the same floor space occupied; simplicity of construction; the ore forms its own bottom and there is no wear on the floor, except around the discharge spouts. Disadvantage: the bin can not be completely emptied without shoveling the material lying below the angle of repose.

Fig 154. Steel Hopper Bins, Cananea Consol Copper Co (85)

Hopper-bottom bins (Fig 154) are of timber, steel, or reinforced concrete. If of timber, the sloping sides of hopper portion should be lined with steel plate. ¶If bottom is pyramidal, the bin can be discharged completely; but, if the vertical cross-section is triangular or wedge-shaped, there will always be a block of ore between chutes that will not run out. Pyramidal bottoms are preferable for discharging material from a point underneath the bin; wedge-shaped bottoms, for discharging at one side. If discharge on each side is desired, bottom is an inverted V (Fig 151). **Cylindrical bins** (Fig 155) are of steel or reinforced concrete. Advantage: economy of material for a given capacity, because the walls are in tension only and but little framework is necessary except for the substructure. As there are no bending stresses in the walls, these bins can be made much deeper, thus securing a larger capacity on same ground space, with same or a less quantity of structural material. Their bottoms are flat, hemispherical or conical. **Suspension bunkers** (Fig 156) are of steel plate or reinforced concrete. The bin body is suspended from 2 side girders, which in turn are supported by columns. Weight of contents causes sides to assume form of the equilibrium polygon (Sec 36), and when fully loaded, stresses in plates are tension only. As form of the curve changes with different degrees of loading, the plates are slightly distorted; and

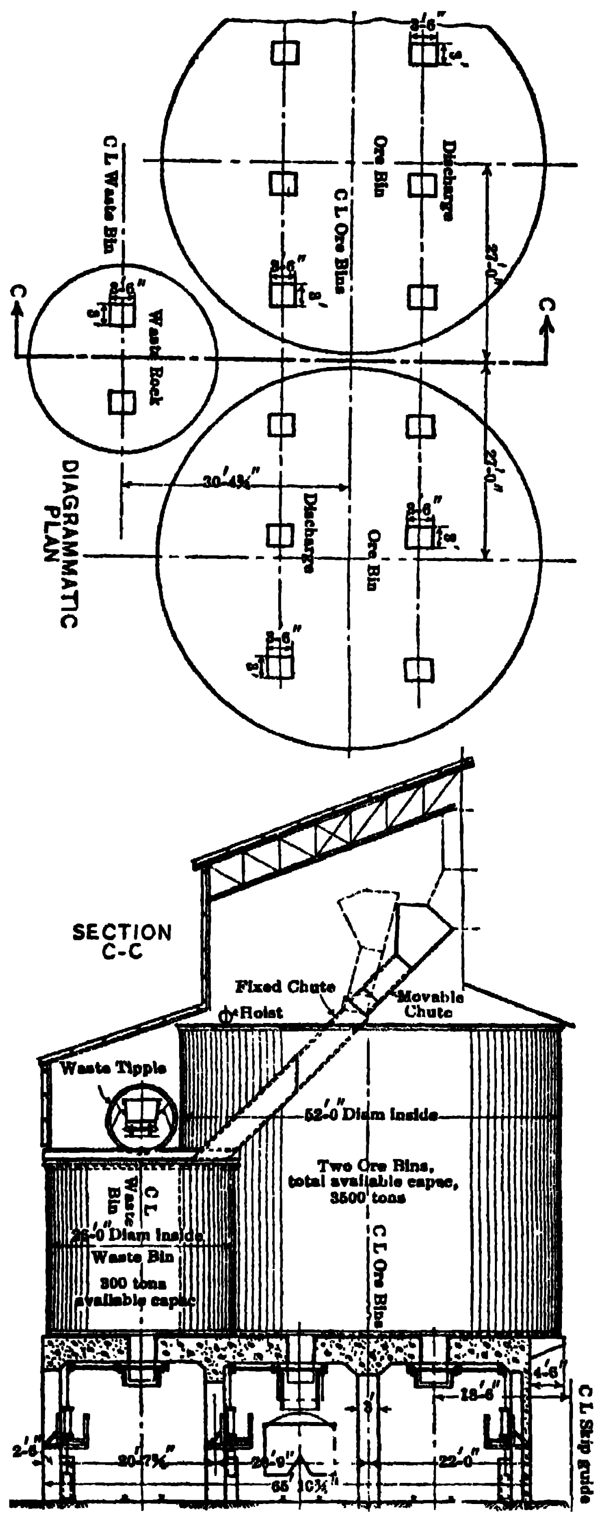

Fig 155. Ore Bins, Porphyry Shaft, Inspiration Mine, Ariz

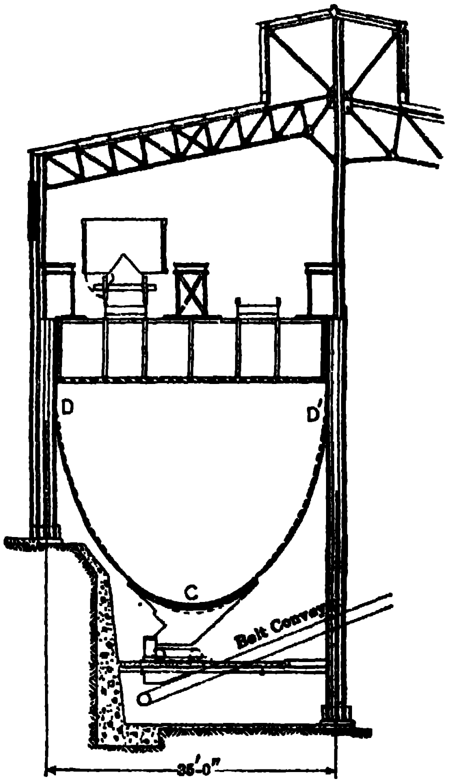

Fig 156. Suspension Mill Bin, Inspiration Copper Co

for reinforced concrete the reinforcing, or steel framework supporting the reinforcing, must carry the load, the concrete serving only to protect the steel.

Examples of this distortion are shown by dotted lines in Fig 156, 159. In Fig 156, the wt of bin contents caused a drawing in of the flanks and lowering of the bottom, sufficient to make the discharge gate interfere with the pan feeder (87). In Fig 159, when bin was full, the flanks moved outward and bottom rose. To prevent such movements from affecting operation of the feeders, these were suspended from the bin; but rigid connection between gates and bin plates was sometimes broken by distortion.

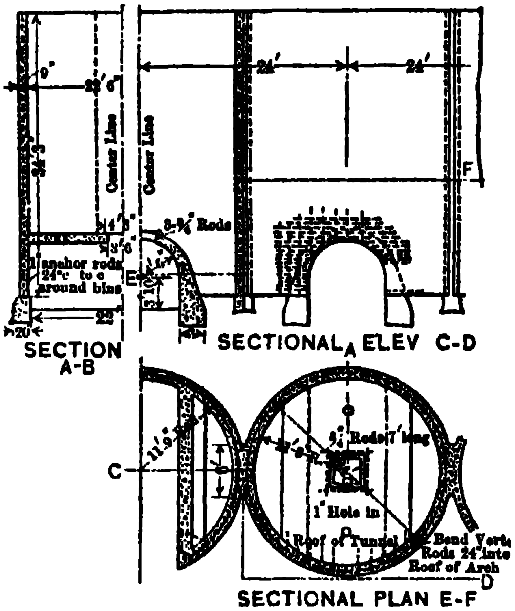

Fig 157. Reinforced Concrete Bins, Croton Iron Mines (88)

Suspension bins are rarely used at mines for coarse ore, as large pieces may cause unequal stresses in the plates; they are commoner for mill bins, after at least one crushing. Examples:

I. A flat-bottom wooden bin, for loading ore or crushed stone into R R cars, has following dimensions: width, 26 ft; length, 40 ft; depth, 12 ft; bottom of bin, 18 ft above foundations; top of R R ties 22 ft below bin bottom; bin supported on eight 12 by 12-in and eight 8 by 10-in posts.

II. Fig 151 shows steel bins for coal storage, at Phillips mine, H. C. Frick Coal and Coke Co, Pa. Capacity, 800 tons. The coal is discharged into the bins from self-dumping cages. Sides are lined with 0.25-in buckled plates, supported by 15-in, 42-lb I-beams, spaced 3 ft 5 1/4-in centers. Inclined bottom is of 3/8-in plate, its framing consisting of plate girders with 48 in by 3/8-in web and flanges of 6 by 6 by 7/16-in angles. Girders are spaced 3 ft 5 1/4-in centers, and tied together by 2 angles 8 by 8 by 0.75-in and 1 plate 17 by 0.5 in at the bottom and 15-in, 42-lb I-beams at the top. Main side girders consist of two 15-in 42-lb I-beams and one 15-in 33-lb channel. Floor is carried on 12-in I-beams, spaced 1 ft 6 in centers. Coal is discharged through gates in vertical side walls.

III. Fig 152 shows a timber bin, designed for a jaw crusher to be mounted on its top and to receive fine ore from the grizzly. Ore is discharged to carriers of an aerial tramway. Total timber required was 21 700 ft B M; 14 300 ft for the bin proper, and 7 400 ft for crusher floor, roof structure, and siding. Capacity, 2 200 cu ft, or 110 tons of ore weighing 100 lb per cu ft, equivalent to 6.5 ft B M of lumber per cu ft capacity for the bin proper.

IV. Fig 153 shows a timber bin, somewhat similar to, but larger than the preceding. Planking is 5 in thick on bottom and front; 3 in on ends. Bottom and front have a replaceable 2-in lining.

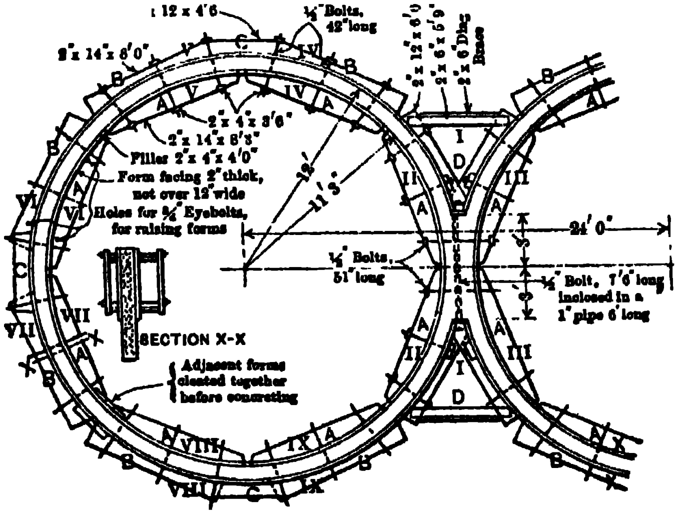

Fig 158. Concrete Forms for Bins in Fig 157

V. Fig 154 shows steel hopper bins of Cananea Consol Copper Co, receiving lump ore from R R cars on top. Ore is drawn off onto a conveyer, through rack and pinion gates in bottom of each hopper. Bin is divided into 8 pockets, approximately 15 ft square; capacity of each 2 640 cu ft, or 200 tons. Side plates are 0.25-in, stiffened with 7-in channels, spaced 4 ft apart. Hopper plates are 3/8-in, stiffened with 10-in channels (85).

VI. At No 3 Mill, Witherbee, Sherman & Co, Mineville, N Y (86), a cylindrical reinforced-concrete bin is used for mill storage. Ore is magnetite, of 4-in size, delivered by belt conveyers. The flat bottom is carried on a concrete arch, which houses the feeder and conveyer taking the discharge from bin. Capacity, 1 000 long tons. Outside diam, 25 ft; height, 50 ft. Inside diam is stepped in from 2 ft thick at bottom to 1 ft at top. Forms were built in 6-ft sections, of 7/8-in matched lumber. The reinforcing is 1 1/8-in discarded hoisting rope; coils placed 1 ft apart for vertical reinforcing and 2 ft apart for horizontal.

VII. Porphyry shaft, Inspiration mine, Ariz, has 3 cylindrical bins (93): two, 54 ft diam by 43 ft deep, for ore; the third, 26 ft diam by 24 ft deep, receives waste rock from skips through a movable chute (Fig 155). Bin walls are of steel plate; bottoms, reinforced concrete. Total capac

of large bins, 3 500 ton; small bin, 500 ton. Ore is discharged into R R cars, through 6 gates in bottom of each ore bin and 2 gates in waste bin.

VIII. Fig 156 (87) is a section of a suspension-type mill bin, also of Inspiration Consol Copper Co. Width between rows of columns, 35 ft; columns spaced 16 ft 8 in longitudinally. Length, 330 ft; cross-sec area, 800 sq ft; capac, 40 tons per lineal ft. Top of bin plates is reinforced, forming a girder between columns. Discharge gates are in center of each bay.

IX. A set of 4 cylindrical concrete bins, built 1914, at Croton iron mines, Brewster, N Y (88), are arranged in line (Fig 157). The bins are 22 ft 6 in inside diam by 34 ft 3 in high; capacity of each, 390 cu yd, or 500 tons. Ore is withdrawn through hoppers onto belt conveyers, running in arched tunnels under each bin. Bin walls are 9 in thick, reinforced vertically by 0.5-in round rods 18 in apart, and horizontally by old 0.75-in cable, spaced 4.25 in apart for the first 5 ft, 6 in apart for 10 ft, and then 9 in apart to the top. Forms (Fig 158) were 4 ft high, of rough 2-in chestnut. They were made by nailing face boards (not over 12 in wide) to 2 ribs cut to proper radius. Inner and outer forms were held together by 2 rows of 0.5-in bolts, long enough to pass through 2 by 4-in vertical bolting pieces outside the ribs. These bolts being greased and withdrawn, were used over and over. Each rise of the forms held 25.5 cu yd of concrete, and was filled in 10 to 11.5 hr by 9 men, including engineer and fireman for the hoist. A 0.1-cu yd batch mixer was used, concrete being hoisted at one end of line of bins to scaffolding above the form. Foundation mixture was 1 : 3 : 6; walls, 1 : 2 : 4. Coarse aggregate of 2.5-in stone was used in the 9-in walls, with careful tamping.

X. Mill bin of New Cornelia Copper Co, Ajo, Ariz (87), is of suspension type (Fig 159). Area of cross-sec, about 665 sq ft; length, 300 ft; capac, per lineal ft, 33 ton; width, c to c of columns, 32 ft; columns spaced 20 ft. Top edge of side plates is reinforced, to act as a girder. Six discharge gates, 10 ft apart.

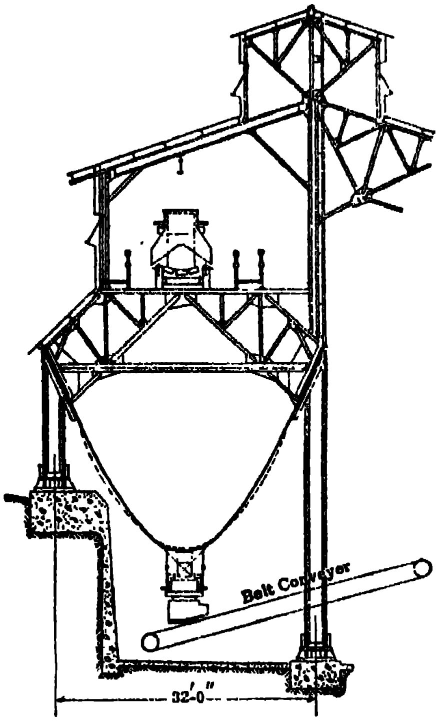

Fig 159. Suspension Bin, New Cornelia Copper Co, Ajo, Ariz (*E & M J*)

Cost of timber bins. Labor, nails, bolts, and iron work, exclusive of steel plate lining, cost $25 to $35 per 1 000 bd ft, to which is added the timber cost.

Cost of concrete bins. Four bins of the Croton iron mines (Example IX) cost, after crediting the future value of the form lumber: for foundations, 221 cu yd at $3.81, $842.61; structure above foundations, 380 cu yd at $9.76, $3 710.28; total, $4 552.89.

This includes labor and material, lumber and reinforcement, but not the cost of excavation, nor charges for superintendence and depreciation of plant.

A 400-ton reinforced-concrete coal pocket, at the Atlantic City (N J) water works, is 30 ft diam, with conical bottom and pyramidal roof. Concrete was 1 cement, 2.5 sand, 5 gravel. Plain reinforcing bars were used. Excavation, 233 cu yd; concrete, 317 cu yd; steel for reinforcing, 13 700 lb; steel beams, plates, etc, 3 250 lb. Contract price, $3 795.

A group of 4 reinforced concrete bins for sand storage, with a total capacity of 2 200 cu yd, required 680 cu yd of concrete and 4 510 lb of steel reinforcing. Labor, 60 working days for 11 carpenters and 14 laborers.

The above figures on concrete bins are based on costs prior to 1915; for cost in 1938 add 80–100%.

Cost of steel bins comprises: (*a*) material; (*b*) fabrication; (*c*) erection; (*d*) transportation. Cost varies with local conditions, and largely with design. For preliminary

Table 39. Cost of Steel, V-bottom Bins (1914); for 1938, add 80–100%

	Labor	Material	Total	Quantity	Total unit cost
Excavation	$2 303.11	$ 39.16	$ 2 342.27	1 428 cu yd	$ 1.64
Foundations	1 235.51	2 247.70	3 483.21	612.3 cu yd	5.69
Steel structure	....	....	29 276.63	353 09 tons	82.92

Conveyer No 1	310.92	2 947.19	3 258.11	97.3 ft	33 49
Conveyer No 2	355.19	2 498.03	2 853.22	117.3 ft	24.33
Lighting	60.87	24.67	85.54	22 drops	3.89
Total	....	....	$44 185.06	...	.....

estimates, following figures in ¢ per lb may be used: (*a*) material, 3¢; (*b*) fabrication, including drafting, mill details and shop labor, painting, and transport from mill to shop, 3.5¢; (*c*) erection, 1.5¢; total, exclusive of freight from shop to point of erection, 8¢.

According to M. S. Ketchum (85) the costs of bins of different materials and designs is as follows: Wooden bins cost about half as much as steel or concrete. Suspension bunkers are cheaper than other types, costing 50 to 70% as much as rectangular bins. Cylindrical bins are slightly cheaper than rectangular. Reinforced-concrete bins cost approximately the same as steel bins of same type.

Cost of steel V-bottom receiving bins (Fig 160), at the smelter of the Arizona Copper Co, Clifton, Ariz, is given in Table 39 (89). Bins are in 2 separate structures: coarse-ore bin, 25 by 70 ft, divided into 4 pockets; concentrate bin, 25 by 100 ft, divided into 6 pockets. Fig 160 shows a cross section of bins and gates. Excavation for each pier was 7 by 7 ft, in gravel 16 to 25 ft deep. For foundations only 5% of the concrete required forms. In the bin structure are 11.35 tons of corrugated steel and 341.74 tons of structural steel. Gates are operated by rack and pinion, 12 for the coarse-ore bin cutting upward through the stream, and 16 for the concentrate bin cutting downward. No 1 conveyer, 97 ft centers, has a 30-in belt, and includes traveling feeder, motor for drive, and all accessories except steel frame for supporting the idlers. Conveyer No 2, 117 ft centers, has a 20-in belt, and includes the same items as No 1 conveyer (Table 39).

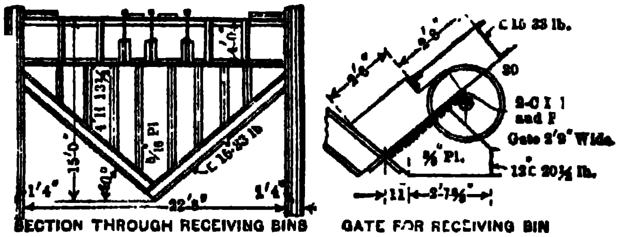

Fig 160. V-bottom Bins, Ariz Copper Co (89)

37. STRESSES IN ORE BINS

Forces acting on bin walls depend upon the weight per unit of volume, angle of repose and moisture content of the bin filling, and angle of friction of the filling on bin walls.

Shallow bins. When the walls are flat, and the plane of rupture cuts the free surface of the contents, the theory and formulas for retaining walls apply. According to Coulomb's theory, the plane of rupture forms with the bin wall a "wedge of maximum thrust," which exerts pressure on the wall. For a vertical wall, without surcharge or heaping of the material above the top, the plane of rupture bisects the angle between the wall and the plane of repose of the filling, provided the resultant thrust is normal to the wall. In this case, the resultant thrust may be assumed as making an angle with a normal to the wall equal to the angle of friction between the filling and the bin wall. Rankine's theory, on the other hand, assumes that the direction of the resultant thrust on a vertical wall is always parallel to the top surface of the filling; so, that the angle between the direction of the resultant thrust and a normal to the wall is never greater than the angle of repose of the bin filling. In both methods of solution the point of application of the resultant stress is assumed at one third the height of wall.

Algebraic methods. Factors in the formulas for pressure on bin walls are: P = resultant pressure per ft of length of wall; N = total normal pressure per ft of length of wall; ϕ = angle of repose of bin filling; ϕ' = angle of friction of the filling on the wall; θ = angle between plane of wall and the horizontal measured on loaded side; δ = angle of surcharge; z = angle between direction of P and a normal to wall; λ = angle between P and the horizontal; h = vertical height of wall; w = wt of bin contents per cu ft.

Rankine's formula, for a vertical wall without surcharge, is

$$P = \frac{1}{2} wh^2 \frac{1 - \sin\phi}{1 + \sin\phi} \tag{1}$$

and for a vertical wall with surcharge δ:

$$P = \frac{1}{2} wh^2 \cos\delta \frac{\cos\delta - \sqrt{\cos^2\delta - \cos^2\phi}}{\cos\delta + \sqrt{\cos^2\delta - \cos^2\phi}} \tag{2}$$

If $\delta = \phi$, then

$$P = \frac{1}{2} wh^2 \cos\delta \tag{3}$$

In Eq 1, 2, and 3, the direction of P is assumed parallel to upper surface of the bin contents, and its point of application at one-third of the vertical height.

Coulomb's theory gives the following formulas:

$$\frac{1}{2} wh^2 \frac{\sin^2(\theta - \phi)}{\sin^2\theta \sin(\theta + z)\left(1 + \sqrt{\frac{\sin(z + \phi)\sin(\phi - \delta)}{\sin(\theta + z)\sin(\theta - \delta)}}\right)^2} \tag{4}$$

If, in Eq 4, z be made equal to zero, $P = N$ and

$$N = \frac{1}{2} wh^2 \frac{\sin^2 (\theta - \phi)}{\sin^2 \theta \left(1 + \sqrt{\dfrac{\sin \phi \cdot \sin (\phi - \delta)}{\sin \theta \cdot \sin (\theta - \delta)}}\right)^2} \tag{5}$$

For a vertical wall $\theta = 90°$, and Eq 5 reduces to

$$N = \frac{1}{2} wh^2 \frac{\cos^2 \phi}{\left(1 + \sqrt{\dfrac{\sin \phi \cdot \sin (\phi - \delta)}{\cos \delta}}\right)^2} \tag{6}$$

For a level top surface $\delta = 0°$, and Eq 6 reduces to

$$N = \frac{1}{2} wh^2 \frac{1 - \sin \phi}{1 + \sin \phi} \tag{7}$$

which is identical with Rankine's formula (Eq 1) for a vertical wall, with upper surface of filling material level with the top.

Cain's formulas assume that $z = \phi'$, Eq 8 to 22 applying also to shallow bins. In addition to previous nomenclature, N' = normal pressure on the wall when $\phi = 0$.

(*a*) Vertical wall, surface of filling level, $z = \phi'$,

$$P = \frac{1}{2} wh^2 \frac{\cos^2 \phi}{\cos \phi' \left(1 + \sqrt{\dfrac{\sin (\phi + \phi') \sin \phi}{\cos \phi'}}\right)^2} \tag{8}$$

and $$N = P \cos \phi' \tag{9}$$

If $$\phi = \phi', \quad P = \frac{1}{2} wh^2 \frac{\cos \phi}{(1 + \sin \phi \sqrt{2})^2} \tag{10}$$

If $$\phi' = 0, \quad N' = \frac{1}{2} wh^2 \tan^2 \left(45° - \frac{\phi}{2}\right) \tag{11}$$

(*b*) Vertical wall, surcharge = δ, $z = \phi'$,

$$P = \frac{1}{2} wh^2 \frac{\cos^2 \phi}{\cos \phi' \left(1 + \sqrt{\dfrac{\sin (\phi + \phi') \sin (\phi - \delta)}{\cos \phi' \cdot \cos \delta}}\right)^2} \tag{12}$$

If $$\delta = \phi, \quad P = \frac{1}{2} wh^2 \frac{\cos^2 \phi}{\cos \phi'} \tag{13}$$

and $$N = P \cos \phi' = \frac{1}{2} wh^2 \cos^2 \phi \tag{14}$$

If $$\phi' = 0, \quad N = \frac{1}{2} wh^2 \cos^2 \phi \tag{15}$$

(*c*) Wall sloping outward, $\theta < 90° + \phi'$, $\delta = 0$,

$$P = \frac{1}{2} wh^2 \frac{\sin^2 (\theta - \phi)}{\sin (\phi' + \theta) \sin^2 \theta \left(1 + \sqrt{\dfrac{\sin (\phi + \phi') \sin \phi}{\sin (\phi' + \theta) \sin \theta}}\right)^2} \tag{16}$$

$$N = P \cos \phi' \tag{17}$$

(*d*) Wall sloping outward, $\theta < 90° + \phi'$, surface surcharged,

$$P = \frac{1}{2} wh^2 \frac{\sin^2 (\theta - \phi)}{\sin (\phi' + \theta) \sin^2 \theta \left(1 + \sqrt{\dfrac{\sin (\phi + \phi') \sin (\phi - \delta)}{\sin (\phi' + \theta) \sin (\theta - \delta)}}\right)^2} \tag{18}$$

$$N = P \cos \phi' \tag{19}$$

(*e*) Wall sloping outward, $\theta > 90° + \phi'$, $\delta = 0$,

$$P = \frac{1}{2} wh^2 \sqrt{\tan^2 \theta + \tan^4 \left(45° - \frac{\phi}{2}\right)} \tag{20}$$

$$N = P \cos \phi' \tag{21}$$

In above cases, if T is the component of P parallel to wall, the thrust in plane of wall is

$$T = P \sin \phi' \tag{22}$$

Deep bins. The preceding formulas for shallow bins do not apply when a bin is so deep that the plane of rupture of contents cuts the bin walls. Following formulas are by M. S. Ketchum (85):

$$V = \frac{wR}{k\mu'}\left(1 - e^{-\frac{k\mu' h}{R}}\right) \tag{23}$$

$$L = \frac{wR}{\mu'}\left(1 - e^{-\frac{k\mu' h}{R}}\right) \tag{24}$$

in which, in addition to previous notation: V = vertical pressure of filling, lb per sq ft; L = lateral pressure of filling, lb per sq ft; R = area of bin in sq ft ÷ circumference of bin in ft = "hydraulic radius" of bin; h = depth of filling at any point, ft; $\mu = \tan \phi$ = coef of friction of filling on filling; $\mu' = \tan \phi'$ = coef of friction of filling on bin walls; k = constant depending on character of filling; e = base of Nap log = 2.71828.

The approximate value of k may be calculated from $k = (1 - \sin \phi) \div (1 + \sin \phi)$.

Constants applying to materials in bins are tabulated from various sources in Table 40.

Table 40. Constants Applying to Materials Stored in Bins

Material	Wt, lb per cu ft	Angle of repose ϕ, degrees	Angle of friction ϕ' on		
			Steel plate	Wood	Concrete
Bituminous coal	47–56	35–40	18	35	35
Anthracite coal	52–56	27–30	16	25	27
Slaked coal	53	38–45	....	....	....
Coke	23–32	45	25	40	40
Ashes	40–45	40	31	40	40
Ore, soft iron	....	35	....	....	....
Ore, various	100–140	38–42	15–20	38–40	38–40
Crushed shale	90	39	....	....	....
Portland cement	103	30–35	....	....	....
Sand	90–120	34	18	30	30

Suspension bunkers. The stresses are due to a load which varies from zero at the support to a maximum at the center, and the loading varies nearly as the ordinates to a straight line (Fig 161).

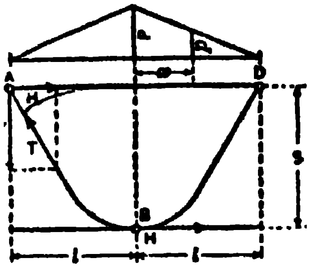

Fig 161. Diagram of Suspension Bunker

P = maximum load at center of bin, lb
l = one-half bin span, ft
S = depth of bin, ft
w = wt per cu ft of bin filling
T = maximum tension in plate per ft of length
C = capacity of bunker in cu ft per lineal ft of bin
B = lowest point of bin and origin of coordinates

The equation of the curve of the bunker is,

$$y = \frac{1}{2}\frac{S}{l^2}\left(3x^2 - \frac{x^3}{l}\right) \qquad (25)$$

which shows that the shape of the curve is independent of maximum load and depends only on width and depth of bin.

Capacity of a bunker level full is $C = {}^5/_4\, lS$ (26)

Max pressure P at center is calculated as follows:

$$Pl = Cw, \quad P = Cw \div l, \text{ and from Eq 26 for a bunker level full, } P = {}^5/_4\, Sw \qquad (27)$$

Tension in the plates at supports A and D is

$$Cw\sqrt{\frac{1}{4} + \frac{l^2}{9\,S^2}} \qquad (28)$$

Length of bin curve is not exactly determinate. If L be the length for one-half ~~the curve~~

$$L = \int_0^l \sqrt{dx^2 + dy^2}$$

By substituting values of dx and dy from Eq 25, the length of one-half the curve is

$$L = \frac{1}{2\,l^3}\int_0^l \sqrt{4\,l^6 + 9\,S^2\,(2\,xl - x^2)^2}\,dx \qquad (29)$$

By using Simpson's rule for approximate integration, with 10 divisions, one-half the length of curve becomes

$$L = \frac{1}{2\,l^3} \times \frac{l}{30}\,[y_0 + y_{10} + 4\,(y_1 + y_3 + y_5 + y_7 + y_9) + 2\,(y_2 + y_4 + y_6 + y_8)] \qquad (30)$$

in which $y = \sqrt{4\,l^6 + 9\,S^2\,(2\,xl - x^2)}$ (31)

In Eq 30, 31 y_0 = value for $x = 0$; y_1 = value for $x = l \div 10$; y_2 = value for $x = 2\,l \div 10$; and so on. Ten divisions give sufficiently accurate results for practical purposes.

A diagram due to R. W. Dull for calculating stresses, capacity, and length of curve of suspension bunkers, is given in Fig 162. It is for coal weighing 50 lb per cu ft. For material of different weight multiply the stresses in the diagram, and the capacity per ft of length, by the ratio of the weight of material per cu ft to 50 lb. To use the diagram, assume that a capacity of 5 tons of coal per ft of length is required, and that the bin is to be surcharged. Enter right-hand diagram at 5 tons. Below intersection of horiz line with surcharge curve is depth S = 11.55 ft, and width

L = 19.25 ft; above same intersection, at top of diagram, is length of curve, 372 in. On left-hand diagram, at same horiz line, is reaction R = 5 000 lb; following this horiz line to intersection with heavy diagonal, and thence through light diagonal to left-hand margin, is T = 5 800 lb; vertically below same intersection is H = 2 900 lb.

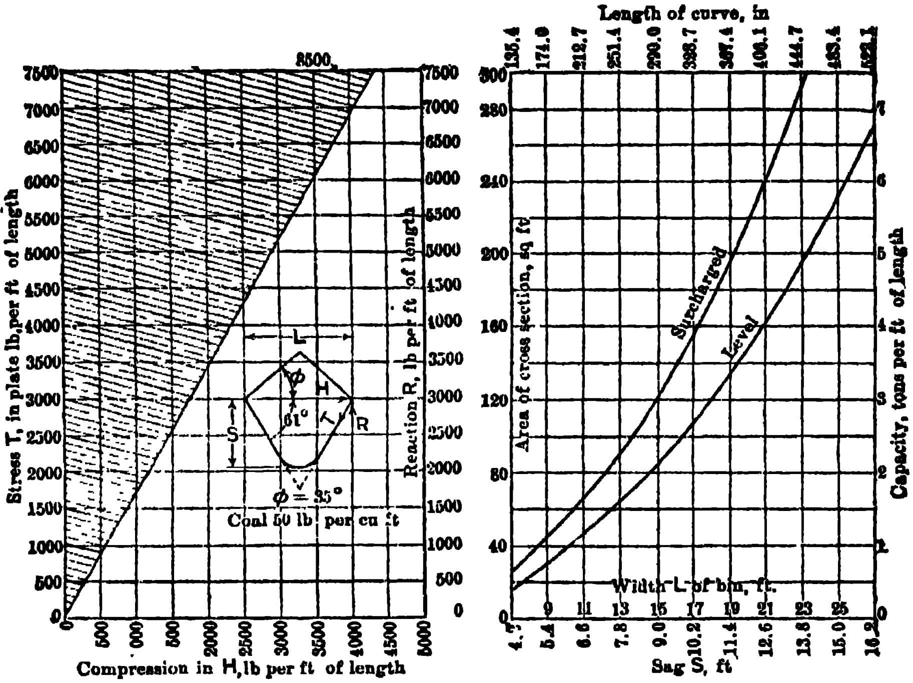

Fig 162. Diagram for Suspension Bunkers (R. W. Dull)

Graphic method. For shallow bins a combination of algebraic and graphic methods gives the simplest solution. In bin $ABCD$ (Fig 163), with smooth walls and loaded level full, the normal pressure on side BC is $N = \frac{1}{2} wh^2 \frac{1 - \sin \phi}{1 + \sin \phi}$. The area of triangle BCa = N, unit press at B = 0, and the unit press Ca = (area BCa) ÷ $^1/_2\,h$. Total normal press

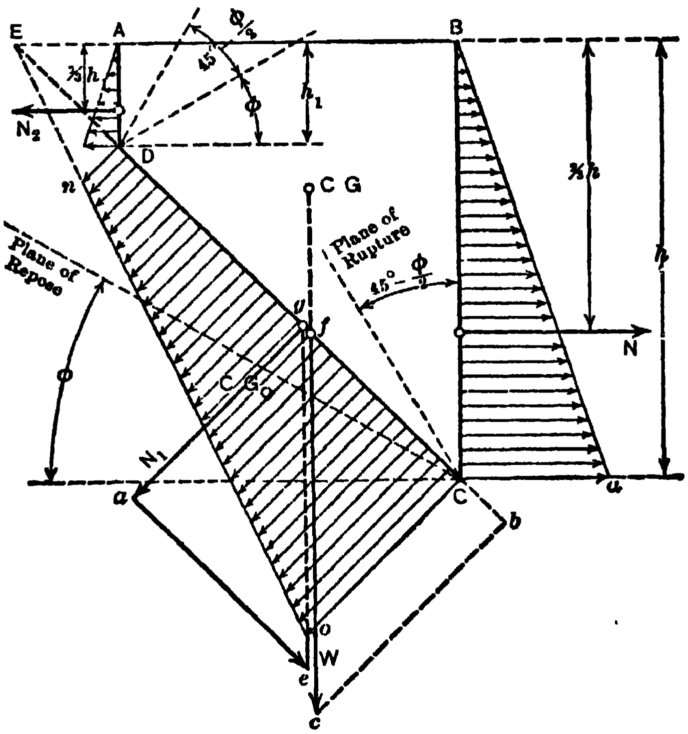

Fig 163 Graphic Solution for Shallow Bins

N_2 and unit pressures on side AD are similarly found. For the bottom DC, continue AB and DC to intersection at E. Weight W of triangle EBC acts through its center of gravity, and by construction the normal press on $EC = cb$, represented by the area of the triangle ECo. The unit normal press Co at C = (area $ECo) \div {}^1/_2\, EC$. Unit normal press Dn at D is found by construction, and the total normal press N_1 on the sloping bottom CD is represented by area of trapezoid $DCon$. It acts at g through the center of gravity of the trapezoid. The component of the weight of the bin filling acting parallel to the plane of DC is ae. If, in Fig 163, the bin be extended, with a horiz bottom, to the right, to such distance that the plane of rupture laid off from C to right of BC (instead of to left, as shown) cuts the surface, the direction of N would be reversed. N would be extended to intersection with W at f, the resultant of N and W laid off acting through f, and a normal from end of resultant to EC extended represents normal press on EC, in a similar manner to cb. With normal press known, the remainder of construction is same as above.

Stresses in the bin framing. Total horiz and vert stresses at the intersection are shown in Fig 164. These are carried by the framework and calculated in ordinary manner.

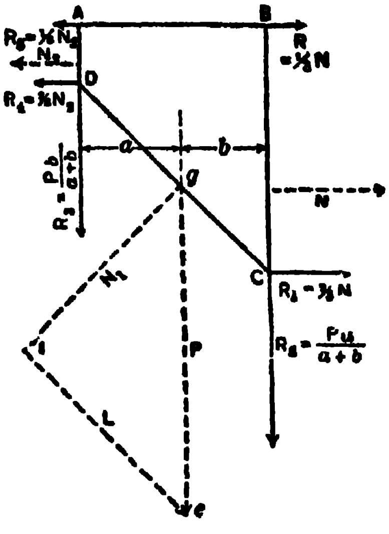

Fig 164. Stresses in Bin Framing

Trautwine's formulas for the pressure on vertical bin walls are:

(*a*) Surface horizontal, horiz press per ft of length of bin is

$$\frac{1}{2}\, wh^2 \tan^2 \left(45 - \frac{\phi}{2}\right) \tag{32}$$

For anthracite coal, total horiz press = $9.78\, h^2$, and press on lowest foot = $9.78\,(2\,h - 1)$
For bituminous coal, total horiz press = $6.37\, h^2$, and press on lowest foot = $6.37\,(2\,h - 1)$

(*b*) Surface sloping, $\delta = \phi$, horizontal pressure $= wh^2 \sin^2 \left(45 - \frac{\phi}{2}\right)$ (33)

For anthracite coal, total horiz press = $14.22\, h^2$ and press on lowest foot = $14.22\,(2\,h - 1)$
For bituminous coal, total horiz press = $10\, h^2$ and press on lowest foot = $10\,(2\,h - 1)$

Stresses in circular bins are usually calculated the same as for deep bins. For horiz press on walls at any point, Eq 24 applies. Tensile stress in walls per ft of height at any point $= Lr$, in which L = horiz press, lb per sq ft (Eq 24), and r = radius of bin. If bin is shallow, entire weight will be carried by bottom. If deep, Eq 23 applies. For flat bottoms, press is normal and equal at all points. If conical, tensile stress, at any point in the bottom parallel to an element of cone, is

$$H = \frac{\operatorname{cosec}\theta}{2\,\pi r_1}\left(\pi r_1^2\, V + W_1\right) \tag{34}$$

in which θ = angle cone makes with horiz; r_1 = radius of cone at point considered; W_1 = wt of bottom and filling below this point; V = Eq 23, considering radius of bin r_1 instead of r, and $\phi' = \phi$.

Horiz stress at any point in conical bottom is $H_1 = Lr_1$ (35)

in which L is found from Eq 24, using r_1 for r. In spherical bottoms, the tension parallel to any meridian is

$$H_2 = \frac{1}{2}\, Vr' + \frac{W_1 \operatorname{cosec}\theta}{2\,\pi r_1} \tag{36}$$

in which values are same as in Eq 34, θ = angle of tangent to meridian with horiz, and r' = radius of sphere. The tension normal to a meridian at any point is

$$H_3 = {}^1/_2\, Vr' \tag{37}$$

DRAINAGE OF MINES

1. SOURCES AND CONTROL OF MINE WATER

Surface inflow through outcrops is the chief source of mine water in regions of heavy or moderate rainfall, especially where mines are worked to the outcrop, and large drainage areas are above or tributary to extensive outcrop workings. In such cases, mines may be subject to sudden floods, which usually require definite times to reach the workings. Hence records of quantity and character of precipitation, and time and extent of resulting extra inflow, should be kept for their value in giving warning. Deposits outcropping under water-bearing surface wash, as in alluvial valleys, while not exposed to similar flooding, are subject to continuous percolation through the strata, the amount dependent upon the character of the measures and closeness of mine workings to buried outcrop. In case of a coal seam in contact with a bed of fire-clay, the latter may be washed out over areas sufficient to cause disastrous inflow. Surface flood water may also find its way into mine openings or open crop-falls (1).

Surface water through cracked or broken measures may be more dangerous and troublesome than that from open outcrops. Where a deposit has been extensively worked by open or by shrinkage stopes under fissured rock cover, cracks and crevices may admit large quantities of both surface and ground water, combining serious permanent flow with periodical flooding from rainfall.

Flooding may also come from caves extending into water-bearing wash or water-soaked depositions, from mining under too thin a rock cover, or cutting into " pot-holes " or buried valleys. At Nanticoke, Penn, 26 men were buried in quicksand from a pot-hole over 100 feet deeper than the surrounding rock.

Water from permeable measures is always possible, and in formations like soft massive sandstones may be expected. It may enter as seepage, or under pressure, often from large areas, resulting in persistent inflows. Relief can be obtained only by draining entire basins, or by general lowering of ground-water level. **WATER FROM CREVICES OR UNDERGROUND CHANNELS** is sometimes encountered in shaft sinking or in mining itself, coming in unexpectedly and in large volume. It may persist to the complete drainage of territory tapped. **WATER FROM UNSUSPECTED UNDERGROUND CAVITIES**, either natural caves or abandoned workings, is fortunately rare. Its serious aspect, aside from quantity of water, is suddenness of inflow, which may endanger life and quickly flood lower workings.

2. PREVENTION OF INFLOW

Surface. It is generally cheaper to keep water out of mines than to remove it after it has entered. While it may be impossible to prevent the entrance of all water, the amount can usually be decreased by attention to sources of inflow. In impervious soil, entrance of surface water can be minimized by well-planned ditching around outcrop or fractured areas. In permeable soil, ditches should be lined, or wooden or concrete flumes installed. If streams or drainage channels cross outcrops or fractured areas they should be flumed, or diverted by canals, designed to take maximum flood volumes, and located to minimize danger of rupture from surface settlement often occurring during flood periods.

Drainage works are sometimes built through extensive districts by a combination of interests, as in Hazleton region, Penn, where Black Creek has been diverted outside of the coal measures for miles, relieving the drainage situation in a number of collieries, each of which formerly pumped practically the entire creek flow.

Besides diverting surface water, the discharge of mine pumps must be delivered outside of drainage area of mine. This may cause contamination of streams. Some state courts have ruled that discharge of mine water into its natural drainage channels is permissible, but that damages may be recovered for its discharge into streams not reached by gravity in case the mine should fill. Thus, drainage tunnels discharging onto unpolluted watersheds may furnish ground for damages.

Entrance of flood water through openings other than crop-falls or cracked measures should be impossible. If there are openings below flood level, along creeks or in alluvial flood plains, shut-off doors or temporary dams should be installed. In planning new openings flood records should be obtained, and openings placed well above danger line. Damage from flooding may be so serious as to warrant considerable expenditure to avoid it. In case of shafts, the cost of extending waterproof curbs above possible flood level is small, and the shaft spoil may be economically used for

filling necessary to raise plant above high-water mark. This has been done at many shafts in the flood plain of Susquehanna River, Penn, shaft curbs being at least 5 ft above highest recorded flood mark; also, provision is made for shutting openings promptly in case of possible higher floods.

Underground. In mining under heavy water-bearing wash or quicksand, it is imperative to leave sufficient rock cover, and to keep workings far enough below buried outcrops to avoid danger. Preliminary exploration of rock surface should be done by borings sufficiently close together for making a fairly reliable contour map of the buried rock surface.

Fig 1 is a map of a small area of the buried valley of Susquehanna River, showing the great irregularities of rock surface revealed by borings. The wash varies from less than 100 to nearly 300 ft deep, and without borings the workings might easily have been extended into unsuspected deep recesses in the rock. In such boring, especially in stratified measures, some holes must be continued into the rock, to determine its nature. These holes should be grouted to the rock surface, to prevent entrance of water through them to subsequent mine workings.

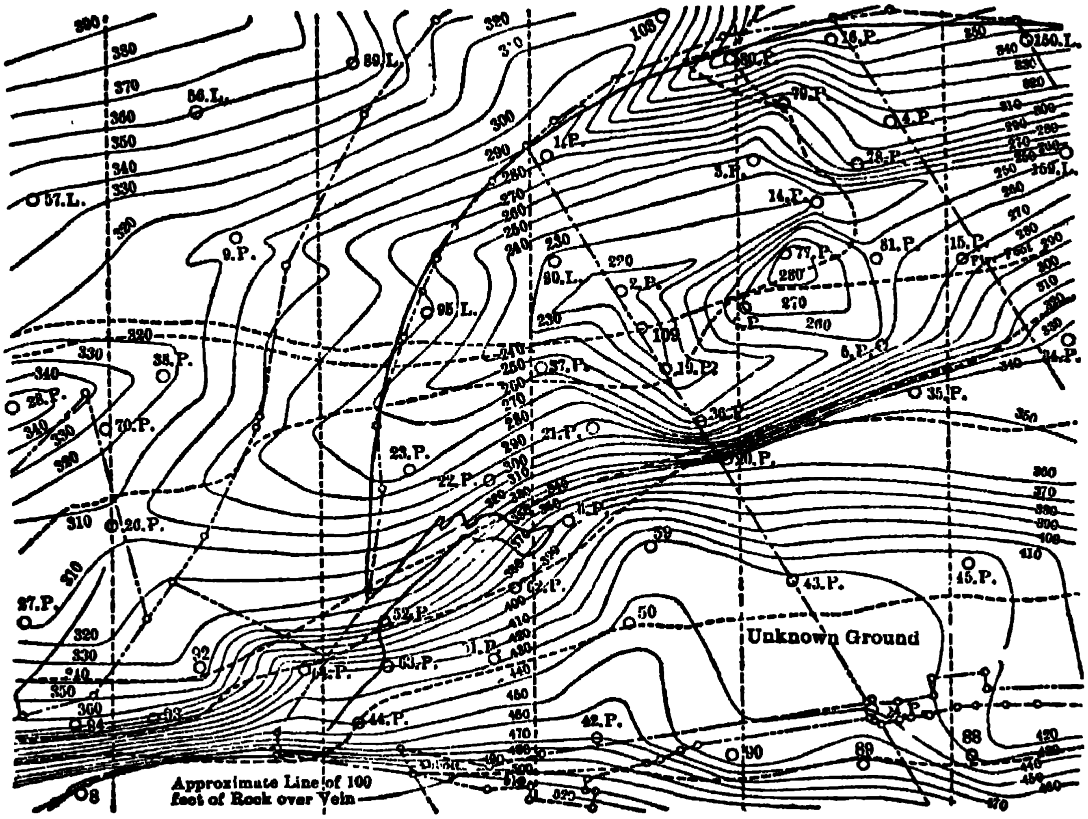

Fig 1. Map of Rock Surface of Buried Valley

Rock thickness required between workings and overlying wash depends so largely on character of deposit, nature of overlying rock and method of mining, that no general rule is possible. In the Wyoming Anthracite Field, Penn, under the Susquehanna Valley and under the river itself, the rock cover varies from 100 to 50 ft minimum; under deeper wash, from 20 to 100% of thickness of wash. Under aver conditions, with sandstones and slates overlying mine openings, and with ample pillars, a rock thickness above workings equal to $^1/_3$ of total cover is a reasonable minimum. In steeply-pitching measures, thickness of cover is determined by the distance from outcrop required to prevent inflow along bedding planes; best determined by test openings toward outcrop.

Douglas Bunting gives the following relations for 24 ft width of mine openings:

$T = 1.5\sqrt{d} + 5$ (strong measures, rock surface fully explored).

$T = 1.5\sqrt{d} + 15$ (softer measures, liable to disintegration, rock surface fully explored).

$T = 1.5\sqrt{d} + 40$ (strong measures, rock surface imperfectly explored).

$T = 1.5\sqrt{d} + 50$ (softer measures, liable to disintegration, rock surface imperfectly explored).

In these formulas: T = thickness of rock cover, d = depth of surface wash, ft.

Grouting and waterproof linings. Inflow from water-bearing strata is avoidable by waterproof linings of shafts and other openings, or by grouting under pressure into surrounding rocks.

In approaching known or possible OLD WORKINGS, and when mining in limestone where cavities may be expected, drill holes, preferably bored through gate valves previously secured, should be kept well in advance of all workings, to avoid disastrous inrushes of water, and to control flow from any orebody which may be tapped by holes, letting water out only in such quantities and at such times as may be suitable for capacity of the pumps.

No means have yet been devised for materially diminishing the inflow of deep ground water, as encountered in porous formations of some western mines. An adequate pumping plant is the sole safeguard. Grouting in advance of sinking may be done through bore holes surrounding proposed shaft location; or during sinking through radiating drill holes; or subsequently behind shaft lining of steel, brick, stone or concrete (Sec 7, 8).

In case of fissured or broken ground the flow may be reduced and sometimes entirely cut off by cement grouting under pressure through bore holes, or by the Kirby (patented) process, consisting of injection through drill holes or into partly-plugged cracks of chopped straw, sawdust or other finely divided material, followed by clay, slimes or mud (first used at the Flat River, Mo, mines of Federal Lead Co, where it practically stopped the flow from a network of fissures previously unconquerable).

Sometimes, when water pressure in cracks or fissures is so great that plugging in preparation for grouting or mudding only results in spreading the water through considerable areas of fractured or permeable rock, the pressure may be relieved by drilling diagonal holes into the cracks, and plugging and grouting cracks, after which the drill holes which have taken the flow temporarily are permanently closed.

Tapping underground reservoirs. When approaching suspected bodies of water under pressure, bore holes should be kept in advance of the face, and bored in such manner as to permit withdrawal of drill rods and closing of hole when water is encountered. One hole (better 2 holes) should be bored straight ahead of face, 10 to 20 ft in hard rock, 75 to 100 ft in soft rock or bituminous coal. Other holes, of about same depth, should be drilled obliquely forward (about 30° from center line) at intervals of 8 to 12 ft. If water be tapped unexpectedly, insert a dry soft-wood plug of diam small enough to enter freely; push to bottom of hole, and hold there by a rod or pipe of suitable length, and a larger plug driven into neck of hole. In several hours the inner plug will have swollen tight, when outer plug can be removed; then enlarge outer 5 or 6 ft of hole. To a piece of heavy pipe screw a sleeve coupling at one end and a straight-way gate valve at other. Insert coupling end into enlarged hole, and wedge with oakum and dry soft-wood wedges; also brace outer end of pipe against timbering, if pressure be great. Insert drill through gate valve, bore through inner plug, withdraw drill, and regulate flow of water by gate valve. If position of water body be known with certainty, the above preparations can be made in advance, and boring finished through a stuffing box attached to end of valve.

Water rings. If complete waterproofing of a shaft be too costly, water rings may be built into the lining, to lead water entering above them into sumps excavated in sides of shaft, whence it may be pumped to surface, saving a material vertical lift, or piped down the shaft, and power thus obtained utilized. Such rings and intermediate sumps are especially desirable for very deep shafts, where pumping is done in two or more lifts, the intermediate sumps then serving for upper pumps.

Chain pillars. In deposits opened by drift or tunnel, and later worked below water level, a chain pillar sufficient to retain permanently all surface water should be left on the water level. Openings to dip are so arranged that water can be led past them and out through tunnel. A chain pillar ties up part of the mineral, which, however, is recoverable before final abandonment of the property, and by reducing pumping throughout life of mine may pay for itself many times over.

3. SUMPS, UNDERGROUND DAMS, BOREHOLES AND PIPING

Drainage levels. In general, water should be intercepted at as high a point in the workings as possible, to avoid unnecessary height of pumping lift. But this principle is modified by considerations as to the best points for locating sumps and installing pumping plant, even at cost of increasing the head for a portion of the water. The main collection point should be determined early in the development of a mine, and all openings driven from it should have a grade of at least 0.25% (0.5% being sometimes adopted, to make haulage resistance nearly equal for both empty and loaded cars. See Sec 11). Water ditches, excavated below or on one side of track, in entries, drifts or tunnels, should be kept clean and open. If main drainage levels are in broken or fissured ground, ditches should be lined with concrete; or wooden flumes, half-round terra cotta tiles, or even pipe, may be used, to prevent water from percolating into lower workings.

For proper drainage, chain pillars should be maintained as long as possible under drainage levels. An exception is where exhausted workings may be allowed to fill with water without detriment to the mine, as in small local basins in a flat deposit. Workings in wet ground should not be extended to the dip, if this would require installation of a number of small, scattered pumps. In such case, water may sometimes be drained off through bore holes to the lower workings. By similar means, water troubles may be avoided in sinking shafts and winzes.

Size of sump is chiefly dependent upon quantity of inflow. It should be large enough to take care of inflow while pumps are stopped for ordinary repairs. A sump capacity of 8 hr max inflow, without submerging the pump, may be considered a minimum; capacities of 24 hr or more are not unusual.

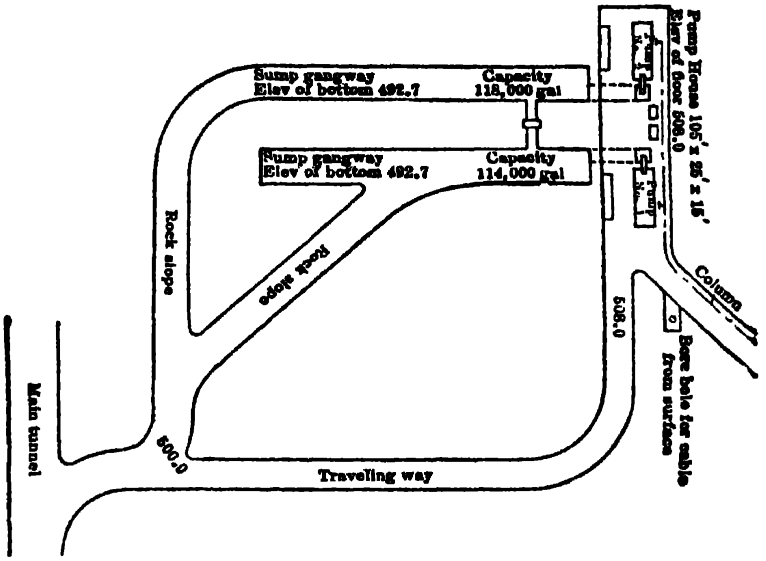

Fig 2. Plan of Sumps and Pump Room, No 6 Mine, Lehigh Nav Coal Co, Lansford, Pa

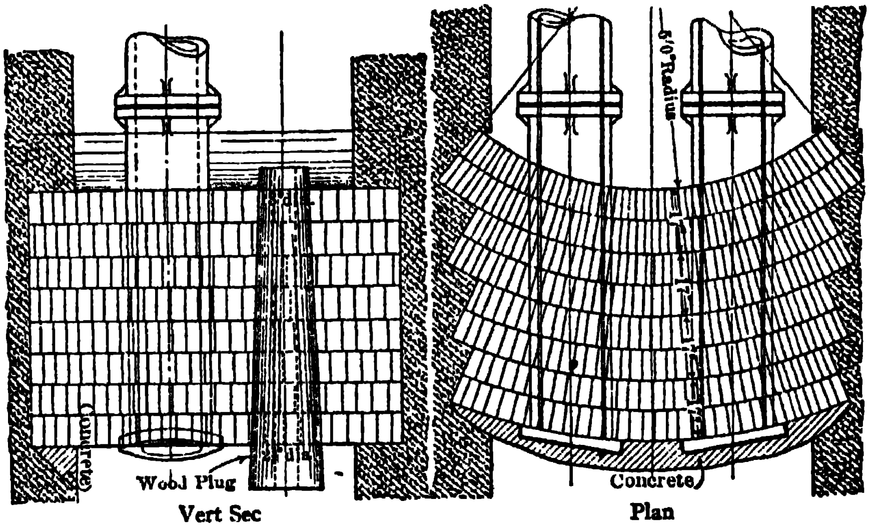
Location of sumps should be carefully considered in layout of mine workings. Since haulage ways, with their drains, gravitate towards shafts, the main sump is usually placed near foot of shaft or slope. Where conditions permit, a good sump is obtained at low cost by working out an area of the deposit to the dip, adjacent to shaft station, leaving chain pillars to isolate sump from lower workings. Sumps should be arranged so that they can be easily cleaned out.



Vert Sec Plan

Fig 3. Details of Underground Dam, Hazleton Shaft Colliery

In pitching deposits, where several veins are worked, the sump is sometimes placed in main workings and pumps in an overlying or underlying vein, the two being connected on main level by a tunnel closed by a dam (Fig 3). The pipe from dam to pump has a shut-off valve, so that if necessary, main workings can be flooded to considerable depths without affecting operation of pumps.

Fig 2 shows a well designed sump at Lansford No 6 mine, Lehigh Navigation Coal Co. There are two centrifugal pumps, each of 2 000 gal per min, and 2 sumps holding 118 000 and 114 000 gal. The sumps are connected, to maintain same water level in both; this is important, as the pumps operate automatically, and are started and stopped by float switches. Switches are so arranged that when pump No 1 can not alone handle the inflow, pump No 2 starts automatically.

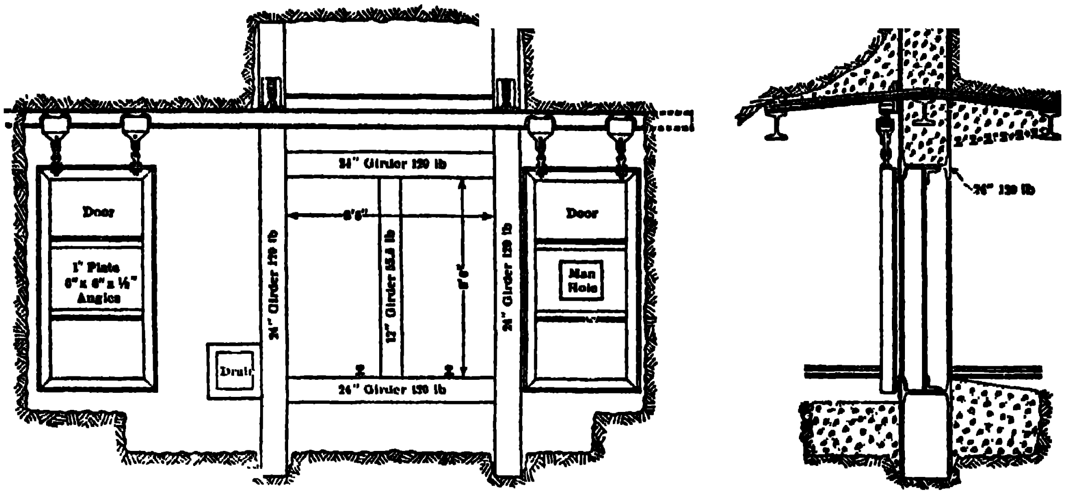


Fig 4. Emergency Flood Dam (for 45-ft Head), Lehigh Nav Coal Co, Tamaqua, Pa

For cleaning one sump, the connecting tunnel is closed and all water from the main tunnel diverted to the other sump. The sump to be cleaned is then pumped out as far as practicable with the main pump, the rest being removed with a small plunger pump. The sediment removed is loaded into mine cars, and pulled out by a motor through the rock slope. Low-water level in the sump should be not more than 20 ft below center line of pump, and end of suction pipe not less than 2 ft from bottom of sump.

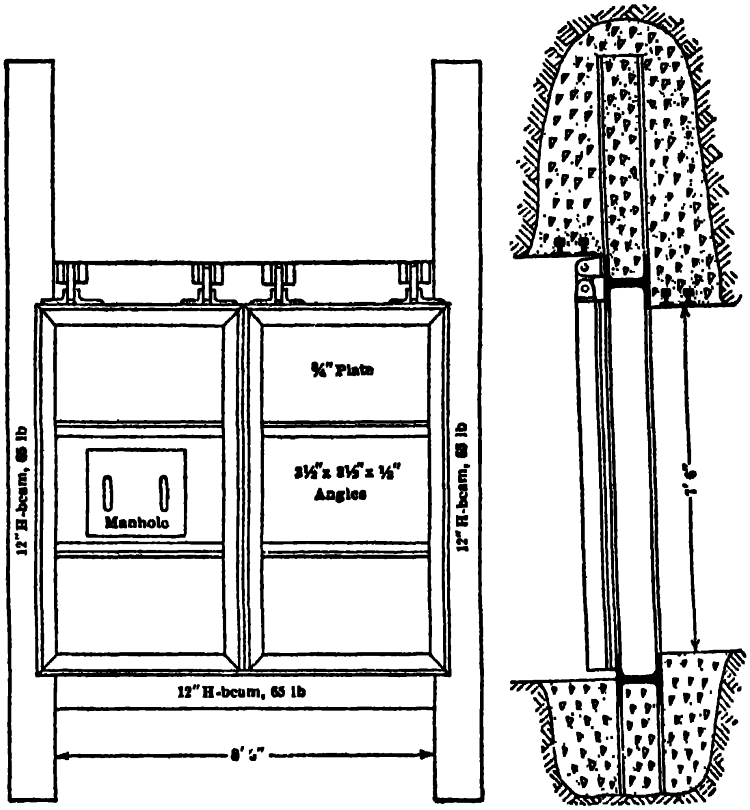

Fig 5. Emergency Flood Dam, 35-ft Head

Underground dams (4) must often hold water under heavy heads, and should be backed by masonry, calculated to resist max possible head of water. They are usually of brick or concrete (Fig 3). Solid abutments are essential; all soft adjacent material must be cut away to insure against bodily movement of the dam. Manholes of ample strength must be provided to drain off water and permit entrance and inspection. Timber dams, single, or better double bulkheaded, with a clay core may be used in case of emergency. Fig 4 and 5 show steel emergency dams which can be readily closed in times of high water. A flat rubber $^1/_4$-in gasket, between frame and door, provides an effective seal.

As mine dams are subject to heavy strains, their strength is a vital matter and careful calculations are necessary. The following formula is for arch dams (Fig 3):

$$t = pw\frac{\sqrt{0.4\,r - 1}}{4\,s}$$

in which: t = thickness, in; r = shorter or external radius, in; w = width of opening or span, in; p = maximum water pressure, lb per sq in; s = safe compressive strength of material used, lb per sq in; factor of safety, not less than 8.

A. Faulds gives (4), quoting W. S. Aldis, using same notation, but with factor of safety 10:

$t = r\left(1 - \sqrt{1 - \frac{2p}{s}}\right)$ for arch dams; $t = r\left(1 - \sqrt[3]{1 - \frac{1.5p}{s}}\right)$ for spherical dams.

Factors $\frac{2p}{s}$ and $\frac{1.5p}{s}$ must be less than unity, or proposed material will be too weak.

A straight or flat concrete dam, necessary where strata will not safely stand thrust of an arch dam, is practically a plate supported on 4 sides, a condition requiring an intricate calculation. For such a plate tests have shown an increase in strength of fully one third over that of a beam supported at both ends. It is safe to calculate a straight dam as a beam having its shortest length loaded uniformly and supported at both ends, using the formula:

$$s = \frac{wl}{2bd^2} \quad \text{whence,} \quad d = \sqrt{\frac{wl}{2bs}}$$

in which: s = unit stress in extreme fibers; b = breadth, in; d = thickness, in; w = total load, lb; l = length, in. In this case the strength of plain concrete in tension should be taken at not over 50 lb per sq in, whence for a dam with span of 7 ft (= 84 in), built to withstand 500 ft head (= 216.6 lb per sq in):

$$w = 84 \times 216.6 = 18\,208 \text{ lb per linear in, and } d = \sqrt{\frac{18\,208 \times 84}{2 \times 50}} = 126 \text{ in}$$

A saving in material can be made by building a flat dam of reinforced concrete.

If the rock formation be of doubtful strength to stand direct thrust of either arched or flat dam, a larger surface of abutment may be obtained by stepping the notches (Fig 6). In a large Schuylkill County, Penn, colliery, a special method was employed (Fig 7) to drown out a fire in upper levels without complete flooding. As the pillars were not considered safe to support the pressure which would be brought on the lower dams, these were relieved by flooding behind auxiliary dams, thus building up a series of counterbalanced pressures. Hence the coal in each pillar took no more pressure than that due to a single lift on any one dam. Fig 8 shows an underground dam and pumping plant in the Hasleton Shaft mine, Lehigh Valley Coal Co.

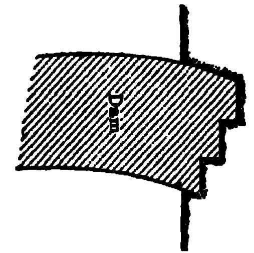

Fig 6. Stepped Abutment, Concrete Dam

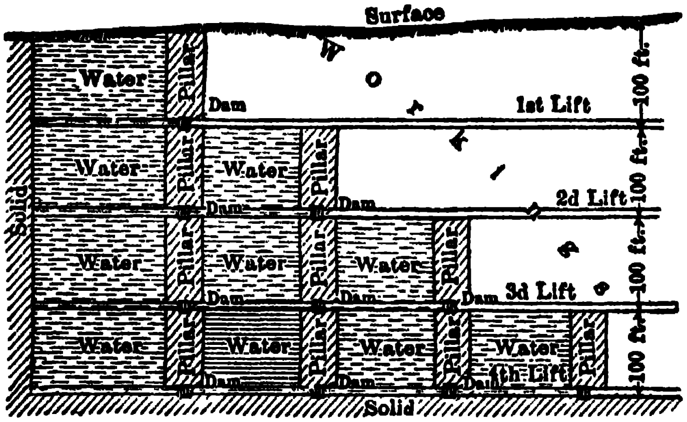

Fig 7. Series of Dams, with Counterbalanced Pressures

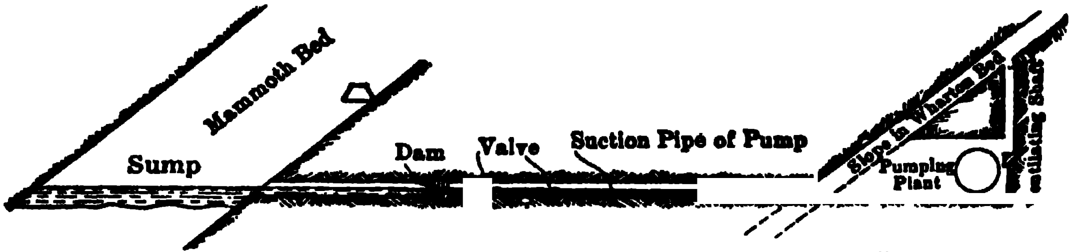

Fig 8. Underground Dam and Pumping Plant, Hasleton Shaft Colliery

Pumping through boreholes is a common practice in both coal and metal mines, the pump delivering directly into holes drilled from surface to mine workings (33). In weak strata the holes are lined with W-I pipe, around which rich cement mortar is poured. If the water is very acid the pipe should be wood-lined, or the boreholes lined with terra-cotta piping. In hard rock no lining is necessary.

By using boreholes the pumping plant can be located to suit the position and shape of the mine openings. They often reduce the lift, save cost of providing space for and installing column pipe, and avoid possibility of damage to mine workings from broken column pipe. Boreholes are 8–24 in diam, drilled by churn or shot drill (Sec 9). Objections to them are the possibility that the holes will be closed by caving or settlement of the strata and the difficulty of renewing worn out pipe lining. In water-bearing, porous strata, boreholes with use of air-lift pumping have successfully lowered water levels in advance of sinking.

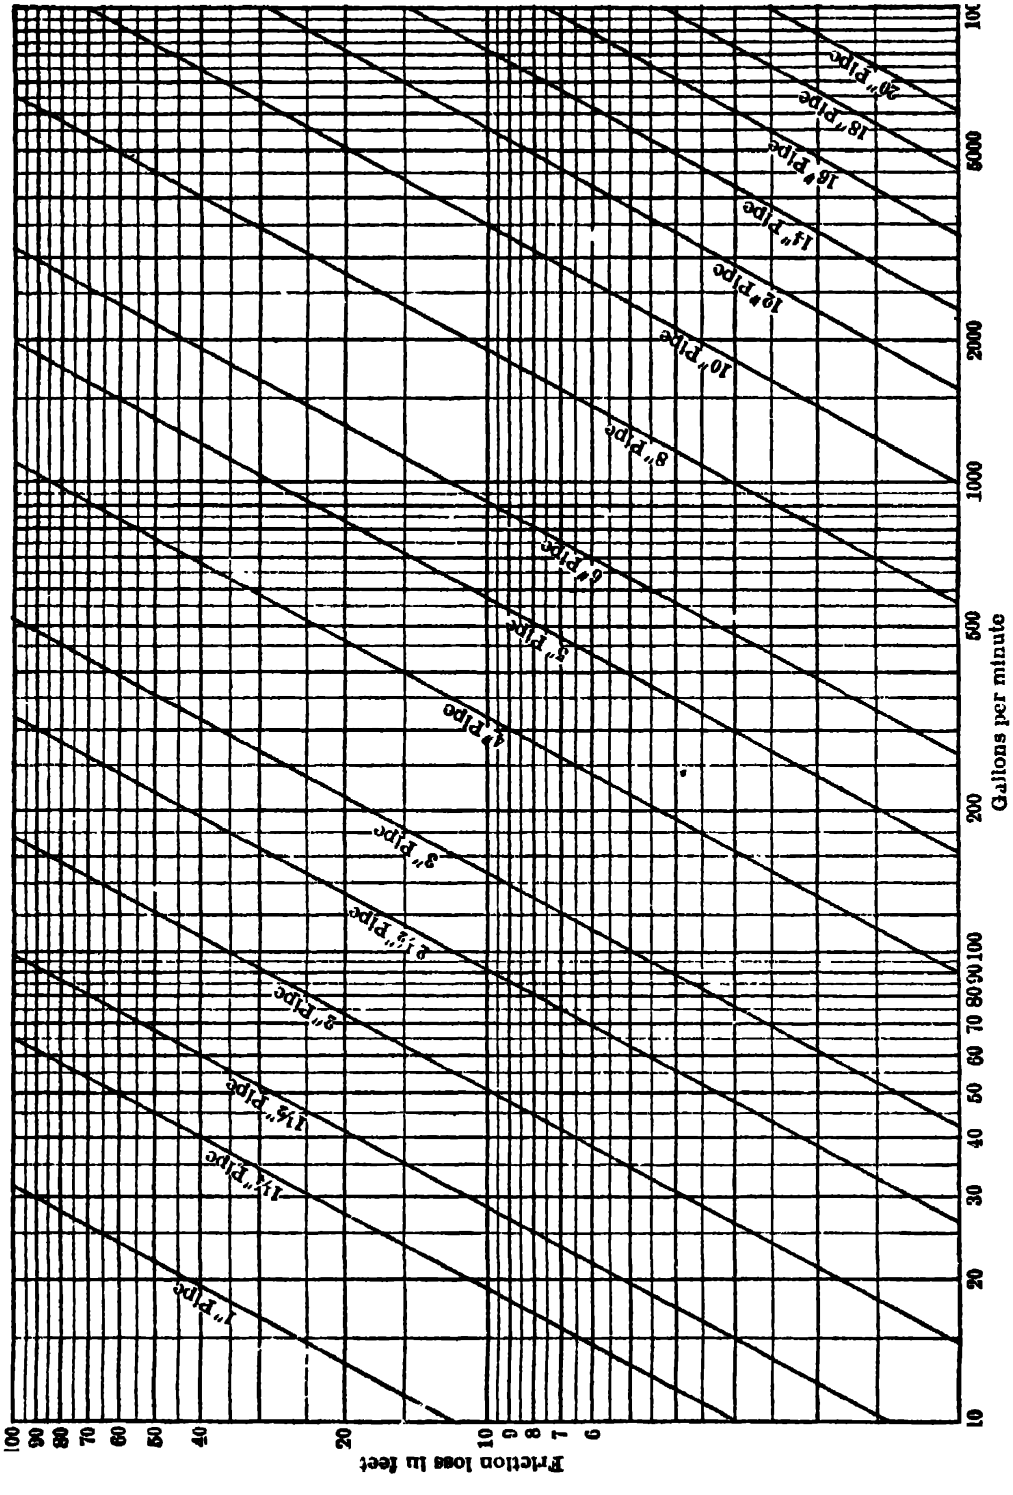

Fig 9. Friction Chart, Discharge of Water through Pipes. (Hazen & Williams.) $C = 100$

Boreholes are sometimes used for dropping water from an upper to a lower level. Quantity of water discharged can be determined from a friction chart (Fig 9). If there were no pipe friction, the water would flow through borehole with increasing speed and be discharged at a veloc $V = 2gH$, where H is the vert distance between upper and lower basin. Pipe friction retards flow, which becomes uniform when the total friction in borehole equals the head H; that is, when the friction becomes 100 ft for every 100 ft of borehole. The capacities causing a friction loss of 100 ft per 100 ft of pipe can be taken from the chart.

Example. A vert borehole 3 in diam will discharge approx 500 gal per min, and a 6-in hole, 3 000 gal per min, regardless of their length, providing there is a sufficient head of water over the inlet to produce the veloc required in the pipe and that the borehole is smooth (37).

For a sloping hole or pipe 3 in diam, 100 ft long, on a grade of 1 in 10, the effective head is 100 divided by 10, or 10 ft. The friction loss per 100 ft of borehole or pipe can not, therefore, be more than 10 ft, corresponding to a max flow of approx 150 gal per min. (See Sec 38.)

Pump piping. SUCTION PIPE should be short as possible, with few bends and should dip directly into the water (Fig 20, Art 11), so that it can be raised from the sump by the crane which should be installed in every pump room. Suction piping must not be wood-lined, as the staves may become loose and block the strainer. For acid water, it is cement-lined, by a mixture of 1 part finely sieved Portland cement and 2 parts sharp silica sand, applied by a long handle trowel, to form a layer about 0.5 in thick; after which, both ends of the pipe are closed with damp canvas to keep out the air until cement has set. If wet cement is exposed to air it will crack. Good cement linings should last for years. DISCHARGE PIPING must be well supported and braced, so that any water hammer caused by closing of the check valve is not transmitted to the pump. Fig 10 shows proper method of supporting column pipe in the shaft. Size of column pipe should be calculated to minimize friction head; increased power due to frictional resistance may cost more than the larger piping.

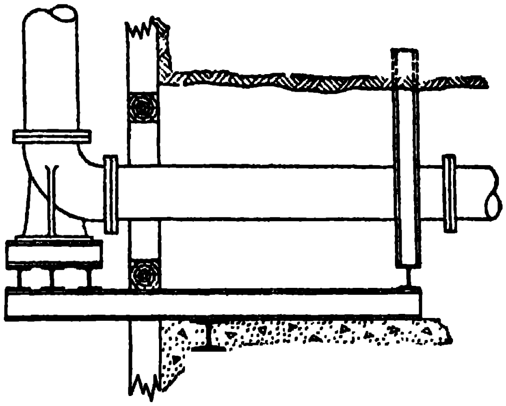

Fig 10. Mode of Supporting Column Pipe in Shaft

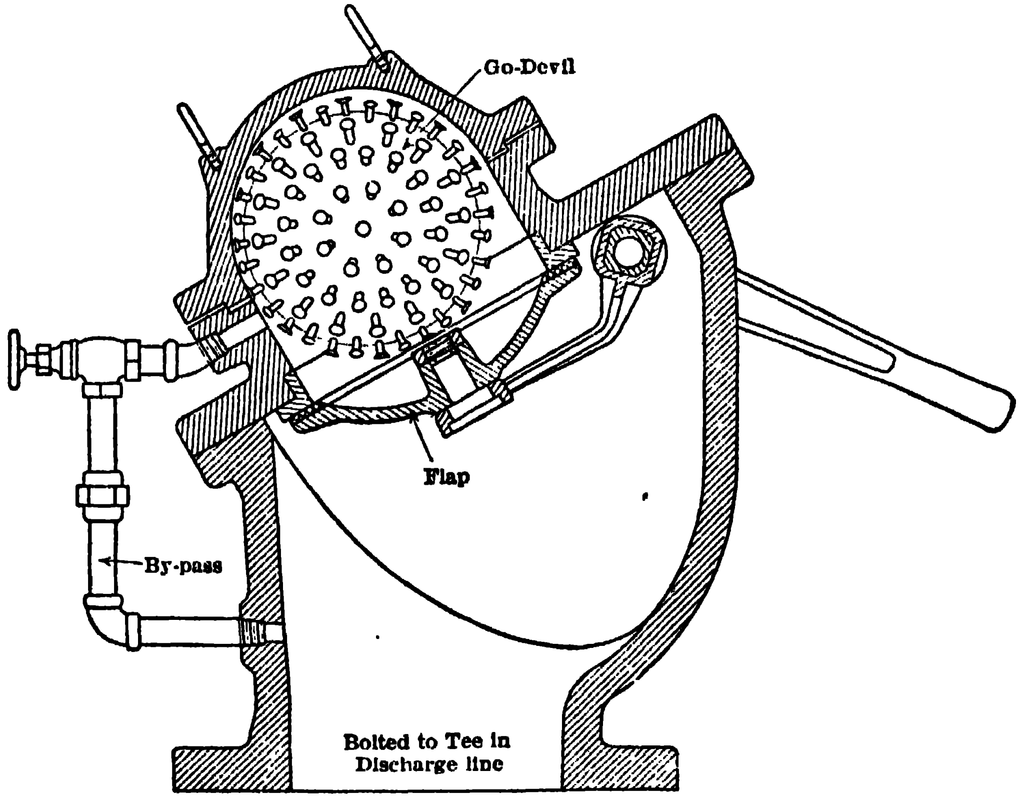

Fig 11. "Go-Devil" and Housing, for Cleaning Column Pipes

As elbows increase resistance, they should be of long radius. Always use Y branches with long bends; avoid tees. C-I flanged pipe is generally in 10- or 12-ft lengths, without male and female joints, as these are troublesome when piping is renewed. Present practice leans to straight flanges, with concentric V-grooves to retain the gasket. A W-I ring, 1/8-1/4 in by 1 in wide, wrapped with tarred hemp, makes a good gasket. Composition fiber gaskets have also been successful. Minor bends in piping may be made with bevel-ring joints (either the iron-ring built-up gasket, or the composition fiber gasket), thus avoiding necessity for lengths of special curved pipe. Column pipe, not otherwise protected, should be coated inside and out by hot asphalt or tar.

Linings for acid water (31, 32). Cement lining for suction piping is satisfactory; lead lining is good, but wears rapidly in gritty water; wood lining is cheap and simple, with excellent wearing and acid-resisting qualities. Wood lining is best of narrow, sawed strips with radial joints, driven dry and swelled with pure water; strips should not be planed, because sawed surfaces, when swelled, interlock and form better joints. For pipes to 8 in diam, liners 0.5 in thick are ample, $^3/_8$-in strips are sometimes used; for 8 to 14-in pipe, 0.75-in liners are sufficient; for over 14 in, usually 1 in.

When column pipes become blocked with incrustations, the sections are disconnected and cleaned by hand, or a cleaner is drawn through the entire line to cut loose the scale. There are various types of cleaners. The " Go-Devil," a wooden ball with a large number of spikes driven into it and protruding 1 to 1$^1/_2$ in, is generally used in the anthracite region for removing " Yellow-Boy " (FeS_2). The balls are sometimes of stainless steel, with spikes or knives welded onto them. As incrustations increase pipe friction and consequently the pumping head, resulting in decreased capac and effic, pipe lines should be cleaned at regular intervals. " Go-Devil " housings (Fig 11) permit introduction of the ball into the pipe line while the pump is in operation. The ball is placed in the upper chamber, and the by-pass is opened, equalizing the pressure on both sides of the flap. The flap is then lowered, the ball falls into the column line and the pump pressure drives it through to the surface.

4. DRAINAGE TUNNELS

These are advantageous where location and topography permit. Though first cost is large, the elimination of pumping charges and freedom from possibility of flooding the mine, due either to accident to pumps or power plant, or to labor troubles, may warrant the investment. In most cases, local conditions are such that only the upper levels of a mine can thus be unwatered by gravity. When workings extend below tunnel level, pumps must be installed. But, drainage tunnels still have the advantage of saving cost of raising the entire volume of water through a height equal to distance below surface at which tunnel intersects deposit. An estimate of length of tunnel justified in comparison with a pumping plant must be made with careful consideration of: cost of driving, maximum quantity of water possible for short periods, and height of lift for which the pumps and power plant must be designed.

Cost of drainage tunnels, and their design, cross-sectional dimensions and speed of driving under different conditions, are given in detail in Sec 6.

Should the tunnel serve also for haulage and ventilation, all of its cost is not chargeable to drainage. To justify driving a tunnel for drainage only, the interest on first cost, plus annual allowance for amortization, must be less than operating expense of pumping, plus allowance for amortization of pumps and power plant. The amortization allowance must be based on a conservative estimate of life of mine. If a tunnel replaces a pumping plant, the final value of plant is its second-hand, or its scrap value, less cost of removal.

5. SIPHONS

Siphons have a limited use as adjuncts of main drainage systems, in conveying water from one part of a mine to another; for example, from a place which, though higher than main sump, is separated from it by still higher intervening ground. A siphon will work only when highest point of pipe is less than 34 ft above water level at inlet end. Joints must be tight, because leakage and presence of entrained air reduce practical limit of suction height, and siphons are unsatisfactory when a (Fig 12) exceeds, say, 20 ft. The working height is proportionately less at altitudes above sea level. The longer or discharge leg of the siphon must fall through a greater height than the short leg, or draft pipe. The difference between these heights is the effective head, h, which causes flow and overcomes pipe friction. If the pipe friction were zero, the water would run down the discharge pipe at increasing veloc, and have a veloc at the outlet of $V = 2gH$. The pipe friction retards the flow and the chart (Fig 9) should be used for calculating siphons.

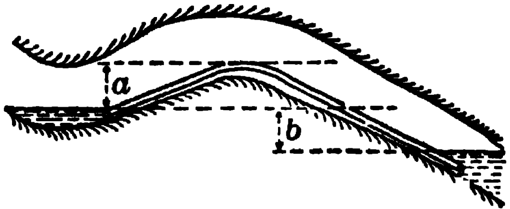

Fig 12. Diagram of Siphon

Example. For a siphon of 2 in diam, 200 ft long, with $a = 10$ ft and $b = 18$ ft, the effective head $H = b - a = 8$ ft. The friction loss in 200 ft of 2-in pipe, therefore, can not exceed 8 ft, or 4 ft per 100 ft, which, according to the chart, corresponds to a flow of approx 30 gal per min. Actual flow is

20% to 40% less, depending on losses at entrance and in bends, and leakage of air into the draft pipe. To charge the siphon for starting, a short stand-pipe is placed at the summit and gate valves at each end of the pipe. The discharge valve is used to regulate the flow if the discharge veloc becomes so great that a vacuum forms at the crown of the siphon.

6. HOISTING WATER IN TANKS

Water hoisting, though less economical than pumping with electric or centrifugal pumps, is useful for unwatering flooded mines. For this emergency service it usually replaces the hoisting of ore or coal, which presumably can not be raised while hoisting water. The mineral hoist of a shaft subject to sudden inrushes of water should be convertible to a water hoist in the least possible time. A water tank is designed either to be attached under each cage or is put on in its place. The shaft should extend at least 30 ft below the bottom level, at which there is a platform with doors (Fig 13). When water is to be hoisted the doors are removed, thus allowing the tank to be lowered into the sump. The false bottom should be tight, so that solid matter can not enter, the sump. A small pump should be installed to pump out the sump occasionally.

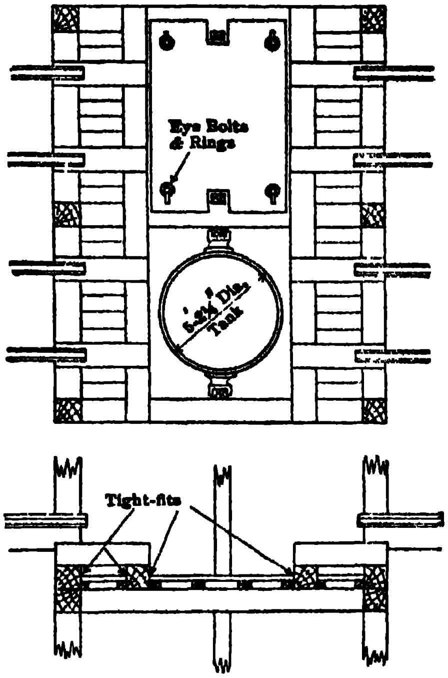

Fig 13. Platform at Bottom Level, No 4 Shaft, Lansford Mine (L Nav C Co)

Readers desiring further information regarding water hoisting by tanks are referred to the previous editions of this book, in which full details of the tanks are given, with costs. See also Bib 27, 28.

7. STEAM PUMPS (4–7)

Current practice tends toward complete electrification of mines. Steam pumps are now rarely installed, most of them having been replaced by centrifugals. But, at mines where there is an excess of boiler fuel and pump and boiler plant are in good condition, it is advisable to maintain steam pumps. If the boiler plant is near the pumproom, and pumps are of compound condensing type, pumping cost compares favorably with that of the best motor-driven centrifugals. New steam-driven units are generally centrifugals, driven by steam turbines, with or without speed reduction gearing. Their advantage over motor drive is that speed can be regulated and capac adjusted to inflow, but they can not be operated safely without an attendant; a decided disadvantage. See Sec 40 for details of pumps and their design.

8. COMPRESSED-AIR DRIVEN PUMPS (see Sec 15) (20)

Though pumping by compressed air is less efficient than by steam or electricity, its use is sometimes warranted: (*a*) in gassy collieries, where electricity is dangerous, and pumps are too far from boiler plant for economical steam transmission; (*b*) in mines where heat from steam pipes is objectionable, or heat combined with moisture would injure roof rock; (*c*) where there is no electric plant and amount of current required would not warrant an installation. It is common to use compressed air in pumps built for steam, and in cylinders not properly proportioned for the pressure employed. Under these conditions it is rare that more than 20% of indicated power at compressor is represented by actual water pumped; with reheated air, the efficiency may rise to about 30%. The chief difficulties are, that ordinary direct-acting pumps fail to make full stroke, and their clearance volume is too great for compressed-air operation. Better results are obtainable from larger fly-wheel pumps, designed for the service. In absence of reheating, trouble from freezing in exhaust ports may be minimized by use of separators and traps in air lines close to the pumps, and by directing a small stream of water, taken under column-pipe pressure, into the exhaust passages below the valves.

9. AIR-LIFT PUMPS (see Sec 15) (Bib, 19–24)

Details are omitted here, as the construction and operation of air-lifts are treated at length in Sec 15, wherein are given also examples embodying results obtained from a number of mine installations. Efficiency is low, rarely exceeding 45% and often much smaller; but this defect is offset by their efficacy under certain conditions, especially for pumping out flooded shafts and mines.

10. ELECTRICALLY-DRIVEN PUMPS (see also Sec 16, 40)

Electric pumps comprise station pumps, and portable pumps used for gathering purposes. Station pumps are generally centrifugals, recent installations having automatic control for starting and stopping. They can be operated safely without an attendant and great savings are thus possible. Plunger pumps must have an attendant, as there is always danger that solid matter will lodge on the valve seats, causing slippage and water-hammer, and broken pipes or valve chambers. Plunger pumps are used only when small volumes are pumped against very high heads; for instance, 100 gal per min against 800 ft. This condition would require a high-speed centrifugal, with 6 or more stages and high upkeep cost, especially when the water is acidulous. High upkeep would be somewhat offset by saving in first cost and maintenance of the column pipe, due to the smooth, non-pulsating discharge from a centrifugal pump. Actual figures are lacking, but practice proves that these savings are considerable.

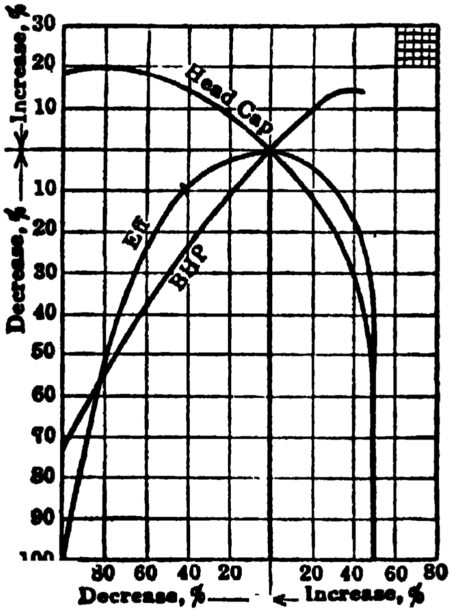

Fig 14. Performance of Volute Pumps

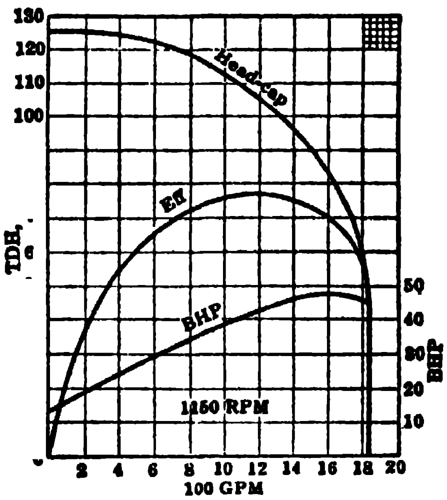

Fig 15. Characteristic Curves of a Centrifugal Pump

Centrifugal pumps. Operating conditions differ entirely from those of plunger pumps. When the discharge pressure of a plunger pump is reduced, the power required falls off; when the head on a centrifugal is reduced, the power increases. The delivery volume of a plunger pump running at constant speed is invariable, regardless of the lift; whereas a centrifugal at constant speed delivers more water at low heads than at high (14, 15).

Performance. Water entering a centrifugal pump is set in rotation by the impellers and issues at the periphery at high veloc. This veloc is gradually reduced in the pump casing and converted into pressure, which in turn overcomes the resistance in the column pipe. Obviously, the volume delivered increases as resistance decreases. The high veloc at which the water leaves the impeller should be reduced in the casing gradually, without shock, and transformed into press with minimum loss. This is effected in a volute casing, or in one having a diffusion ring between impeller and outer casing. Volute casings are the rule for single-stage pumps, and are common also for multi-stage pumps, especially when the water is acid. To obtain high effic in a diffusion-ring pump, the tips of the diffusion vanes must be rather thin, so that acid water soon destroys them. The volute pump has higher effic over a wider range than diffusion-ring pumps. Fig 14 shows the approx performance of volute pumps. If the head and capac at which a pump is most efficient be taken as unity, by increasing the head 15%, the capac decreases about 40%, power decreases 24%, and effic is reduced 9%. If the head decreases 12%, the capac increases 20%, power increases 10%, while effic decreases 4%. An average pump will deliver no water whatever against a head approx 20% higher than that at which the pump shows its best effic.

Centrifugals are usually driven by constant-speed motors. If driven by variable-speed motors, it should be noted that the capac increases or decreases directly as the speed. Head increases or decreases as the square of this ratio, the hp increasing or decreasing as the third power. Thus, if a pump driven by a 1 200-rpm motor, delivering 1 000 gal against 100 ft head, and requiring 35 hp, were connected to an 1 800-rpm motor, the results would be: capac, (1 800 ÷ 1 200) × 1 000 = 1 500 gal per min; head, $(1\,800 \div 1\,200)^2 \times 100 = 225$ ft; power required, $(1\,800 \div 1\,200)^3 \times 35 = 118$ hp.

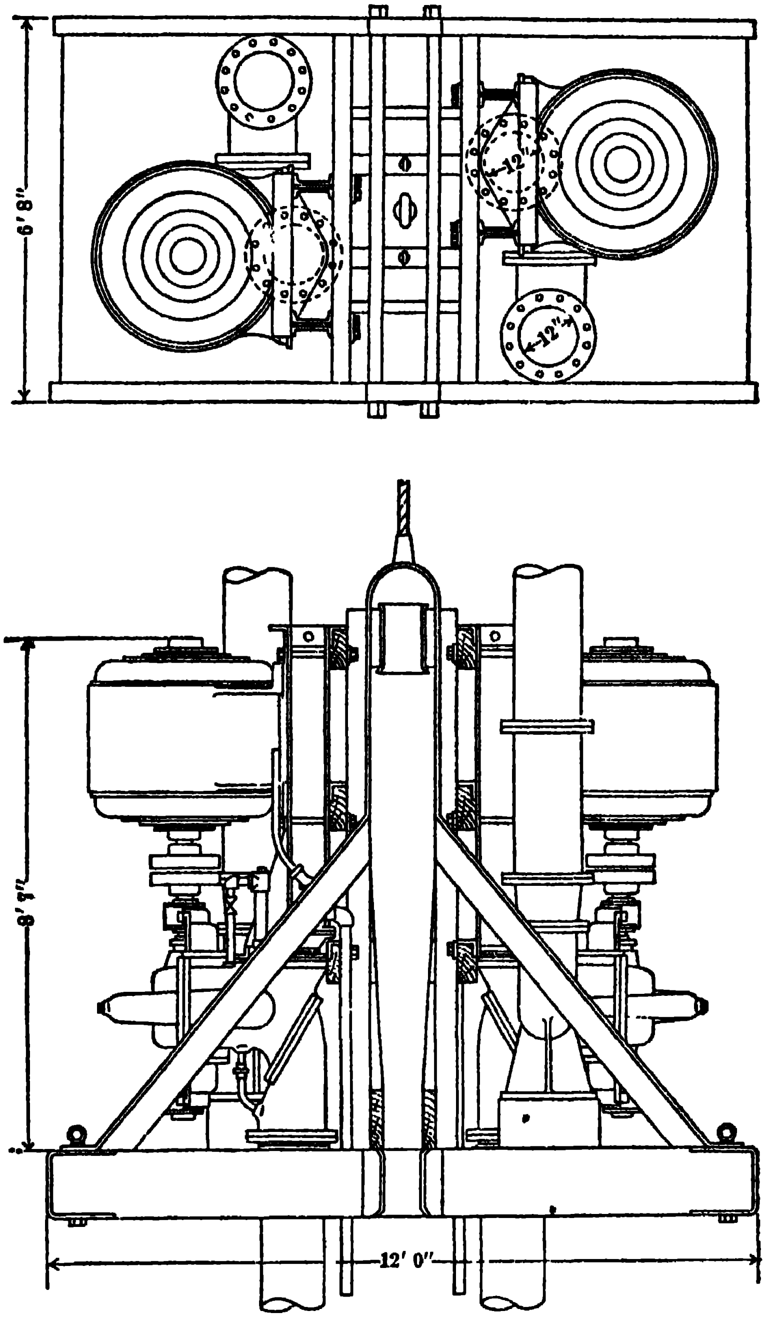

Fig 16. Two 400-hp Hazleton Sinking Pumps, on Cage. (Barrett, Haentjens & Co, Hazleton, Pa)

Before changing speed of a centrifugal pump, the maker should be consulted. Performance curves of different makes vary. If a centrifugal is to work against a fixed head, as in case of a station pump, the shape of the head capac curve and the effic curve are of little importance, and the pump giving highest effic for the specified conditions should be selected. But, if the pump be used for unwatering purposes, or if it may be used in different locations underground, that pump should be selected which gives good effic over a wide range, and does not overload the motor to a dangerous point when the head is reduced. Fig 15 shows the characteristic curves of a pump with effic of 70% and over, for any condition between 700 gal per min against 120 ft head and 1 600 gal against 80 ft head. Max effic occurs when delivering 1 200 gal against 105 ft head.

Single-stage centrifugal pumps can be built for heads up to 600 or 700 ft, but this involves very high speeds. For mine service the head is limited, as a rule, to about 250 ft, and such heads are recommended only if the water is clean and not acid. In general, the head per stage should be limited to approx 100 ft for acid water. Single-stage pumps are usually of the double-suction volute type. Water enters the impeller from both sides, eliminating end thrust. A thrust bearing should, however, be provided, and insisted upon for large-diam impellers.

Multi-stage centrifugal pumps are balanced by opposing the impellers, so that the thrust of one impeller is counterbalanced by the thrust of the next. If they are balanced by a balancing disk, the latter relieves the discharge stuffing box of the high press, and puts it under suction press; a great advantage with high heads. These disks are generally used for fresh water pumps, but are not recommended for very gritty or acid water, which soon cuts out the disk faces.

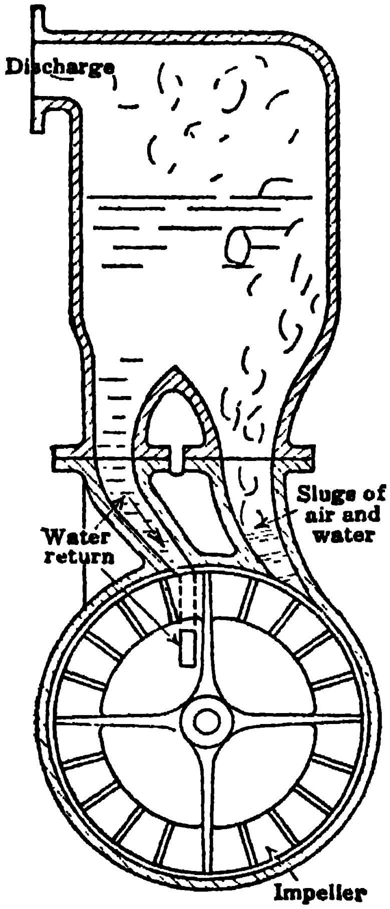

Fig 17. La Bour Pump

Centrifugal pumps are now used almost exclusively for unwatering flooded mines. Single-stage pumps driven by high-speed motors are mounted on trucks, and have large capac. To facilitate moving these pumps, it is advisable to use a metal-stiffened rubber suction hose, with 10–15 ft of ordinary hose on discharge side. A strainer basket should be attached to the end of the suction hose, and a check valve on the discharge hose, so that water hammer can not burst the hose. Workings that were considered hopelessly lost years ago, have been pumped out with high-speed centrifugals at relatively low cost.

Floods in 1936 inundated many coal mines, forcing them to shut down. To return thousands of men to work, the State of Penn agreed to assist in de-watering mines by paying for pumps, pipes and power, but not for labor. The volume of flood water to be handled in the Wyoming Valley was estimated at 8 to 18 billion gal, and the state purchased 18 Hazleton sinking pumps. They were of the single-stage, double-suction type, capable of delivering 4 000 gal per min, against 350 ft head; driven by 400-hp, 4 000-volt, 3-phase, 60-cycle line-start motors, running at 1 750 rpm. The units can be installed either vertically or horizontally and are operated without being bolted down or secured by props, as there is no vibration. The impellers are non-overloading, and the switch can be thrown in regardless of the head. Fig 16 shows two of these pumps mounted vertically on a cage.

In the Uniontown Bituminous Basin, approx 3 billion gal were impounded. The State purchased 3 Deep-well Turbine pumps, each having a capac of 4 000 gal per min, against a head of 450 ft, and driven by 700 hp, 1 160 rpm, 2 300-volt, 3-phase, 60-cycle motors, with reduced voltage starters. Each pump required approx 420 ft of 4-in shafting, running in a 6-in enclosing tube and guided by 85 bearings, which also acted as couplings for the tube. The shaft, with enclosing tube, was placed inside the 20-in column pipe, at the end of which the 6-stage pump was mounted. The whole assembly was hung in the shaft and supported by steel beams extending across top of shaft. The entire 20-in column pipe was vulcanized on the inside with rubber compound, and the tube enclosing the shaft was vulcanized on the outside to protect against corrosion.

11. PUMP ROOMS

Fig 20 shows an up-to-date pump room, containing 3 4-stage centrifugal pumps, each of 2 000 gal per min, against a head of 800 ft. The pumps work automatically, requiring no attendance.

This pump room is provided with an 8-ton traveling crane, to facilitate repairs. The suction pipes drop directly into the sump, and can be lifted out by the crane. Each pump has 2 strainers, one near the pump, the other (a " basket ") at end of suction pipe. The basket strainers have liberal openings, but must prevent large floating objects from entering the intake. Each pump has a check valve, and there is another check valve in the discharge line. There are also 3 priming pumps of the dry vacuum type (Art 12), each of a capac of 50 cu ft per min.

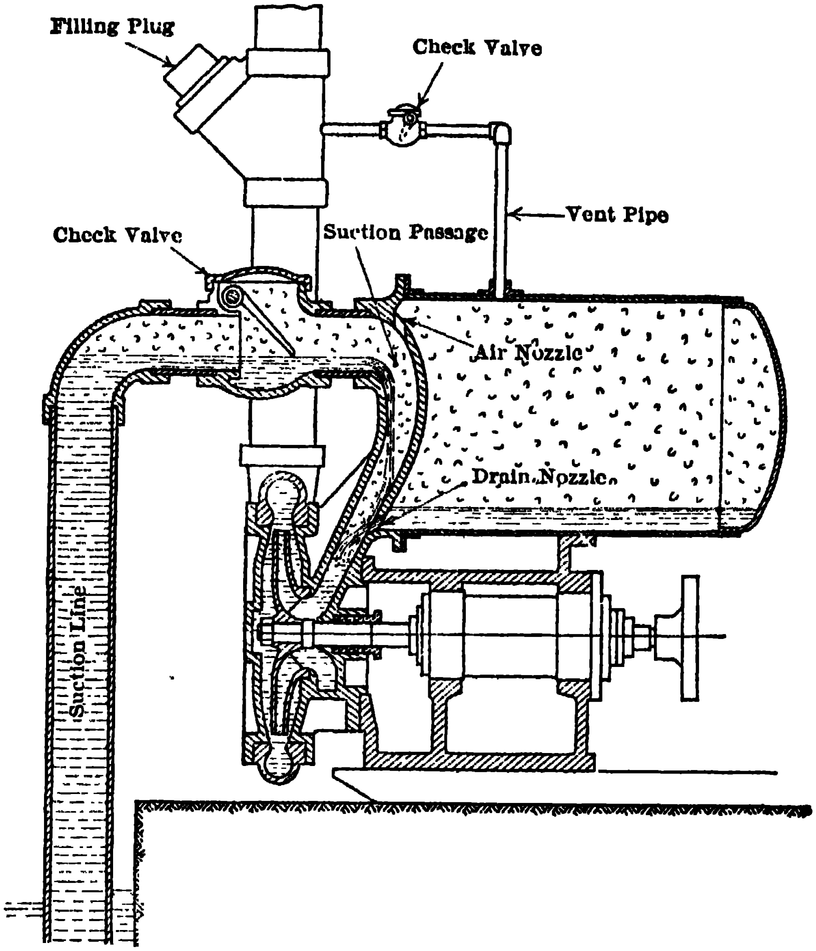

Fig 18. Hasleton Auto Station Pump

Foundations. For station pumps, solid concrete foundations are well worth while. They should be true, of good materials, and only one end of pump bed-frame should be bolted down, the other being left free, to allow for expansion.

Gathering pumps, designed to be moved frequently from place to place, are preferably of the self-priming centrifugal type. Generally, the types capable of pumping continuously a mixture of air and water are less effic and more subject to wear than those pumping water only.

The La Bour pump (Fig 17) is primed by trapping water within the pump and utilizing the veloc of expulsion of pockets of water discharged by the impeller, which entrain air and carry it out of the casing. The pump can handle a mixture of air and water, and draw from several sumps simultaneously.

In the Hasleton Station pump (Fig 18) air is trapped in a vessel connected to the suction line, and pushed directly into the discharge line by a return flow of water caused by stopping the pump. Repeated starts and stops, made automatically, may be required to prime the pump if suction line is long. This pump handles water only and can draw from one sump only. It is started by an electrode (Fig 19), which is suspended over the ditch. When water reaches its high level, contact through the water is established between the electrode and its casing, whereupon the pump starts, and runs until the water is pumped down and air enters the suction line. Then the pump stands idle until the ditch has filled again. Power consumption and wear are thus kept at a minimum.

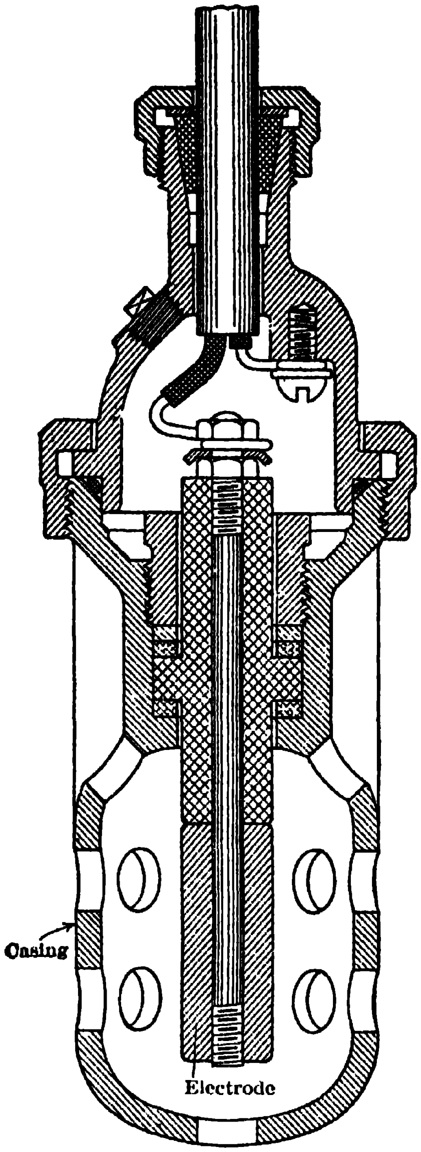

Fig 19. Electrode for Starting Hasleton Pump

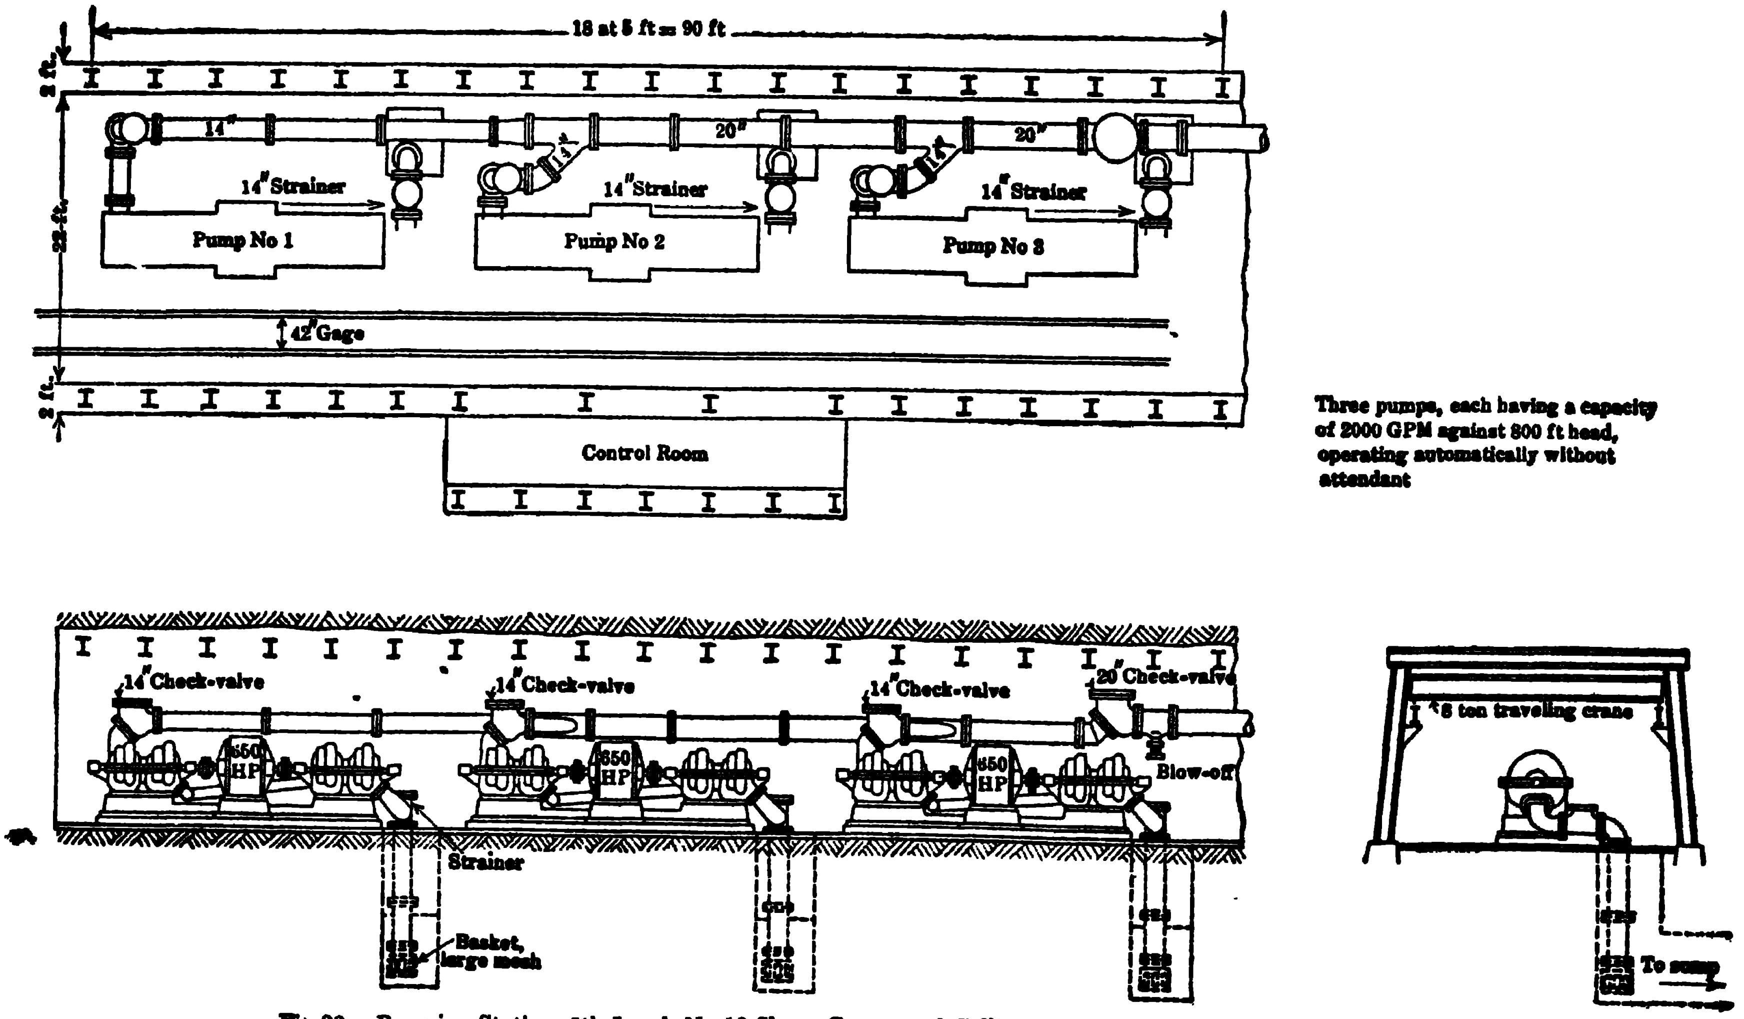
12. CHECK VALVES AND STRAINERS

Check valves should be carefully selected, since their failure may ruin the pump. They are of the single-flap or multiple-flap type. Experience shows that when a single-flap valve is liberally proportioned it will close without shock. Its construction should be simple and all parts exceptionally heavy, as indicated in Fig 21. Noisy seating of a check valve is sometimes caused by breaking (or separating) of the water column in the discharge pipe, when the pump is being shut down. As momentum keeps the water moving in the discharge faster than the pump delivers, the column is broken, resulting



Three pumps, each having a capacity of 2000 GPM against 800 ft head, operating automatically without attendant

Fig 20. Pumping Station, 5th Level, No 12 Slope, Greenwood Colliery, Lehigh Navigation Coal Co, Lansford, Pa

in a water hammer when the flow is reversed. This can be averted by slowing down the motor before cutting off the current entirely. If the motor is of the slip-ring type, a speed reduction of about 10% can be effected, reducing the capac of the pump more than 50%; and if the motor runs for approx 15 seconds at this lower speed the flow in the column pipe will usually be reduced enough to eliminate water hammer.

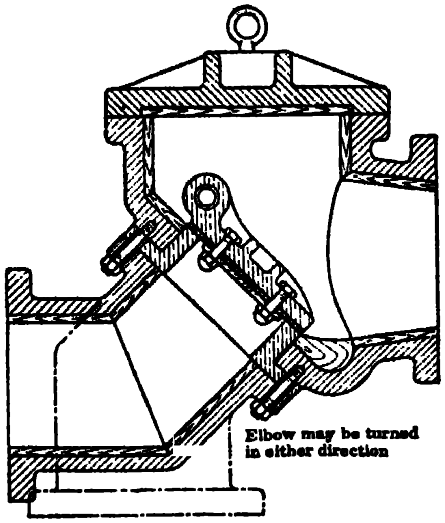


Fig 21. Check Valve, Wood-lined

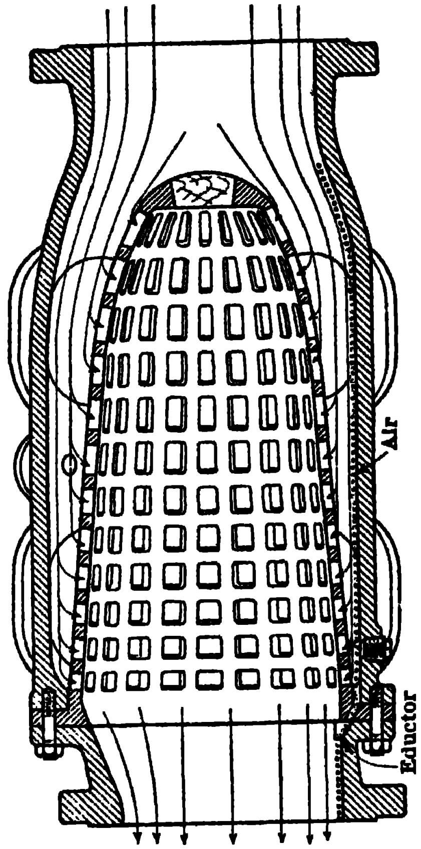

Fig 22. Large-capac Streamlined Strainer

Strainers. A screen should be placed at end of suction line, or in the ditch feeding the sump, to prevent large pieces of wood from entering the pump. A strainer should be installed near the pump, in an easily accessible place, to catch smaller foreign matter which has passed through the screen, and which would block the impeller passages. The strainer should not form an air pocket; the free area of the screen should be approx 4 times as large as the area of suction pipe, and the direction of the flow through the strainer should change only slightly, to avoid disturbance and friction loss.

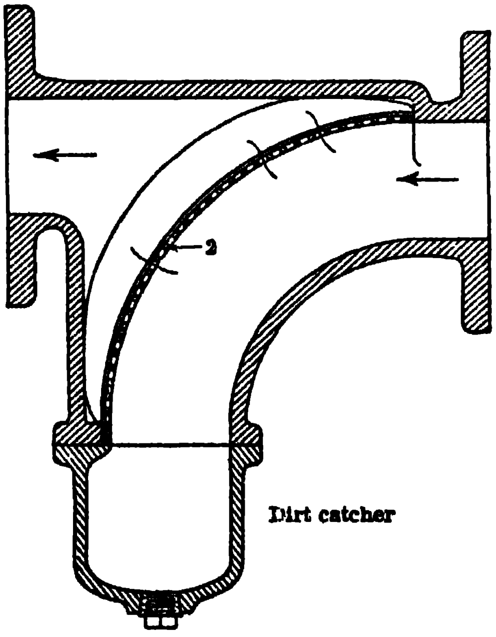

Fig 23. Small-capac Strainer

Fig 22 shows a large capacity (7 000 gal per min), streamlined strainer in which air, separating in upper part of strainer, is automatically withdrawn. Fig 23 shows a small capacity strainer of simple and effic construction. Large particles of foreign matter drop into the dirt catcher; the screen and dirt catcher can readily be removed. Strainers should be inspected and cleaned at regular intervals, to keep frictional resistance at a minimum. Frictional resistance increases the suction lift, which in turn decreases the capac and effic of the pump.

13. AUTOMATIC OPERATION OF CENTRIFUGAL PUMPS

This is rapidly coming into use, and has been so perfected that the largest units can be run with absolute safety without an attendant. Pump runners' wages are thus saved. Automatically controlled pumps keep the water in the sump at a predetermined level; they are protected against accidents caused by loss of water due to air leaks in the suction line, or to choked strainers, and stop automatically in case of breakage of the column.

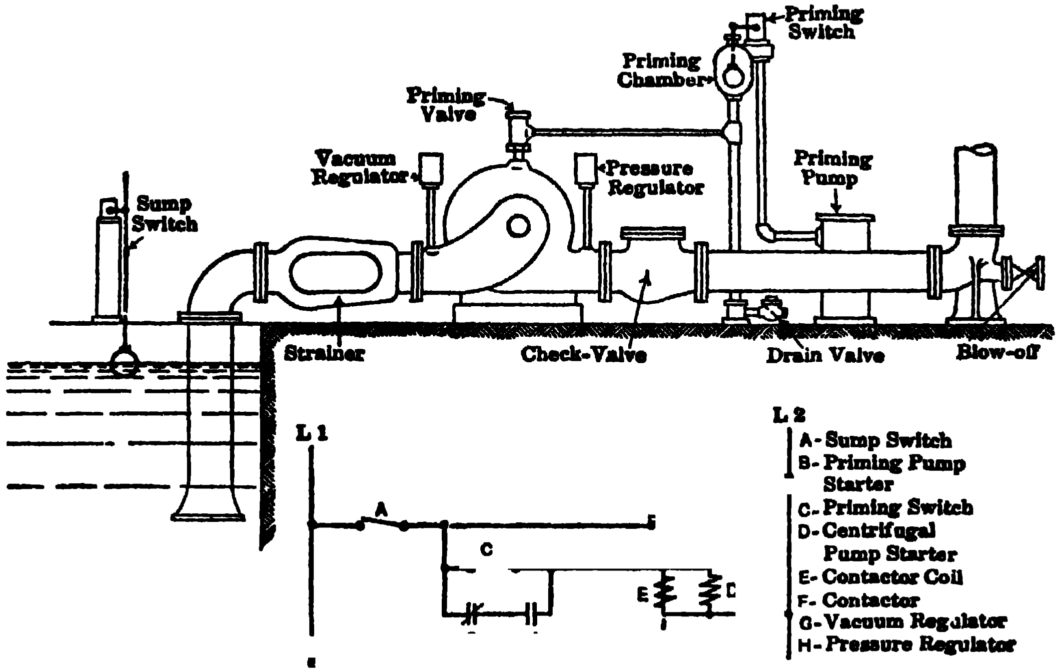

Fig 24. Arrangement of Primer and Accessories for Automatic Control of Centrifugal Pump, with Diagram of Wiring

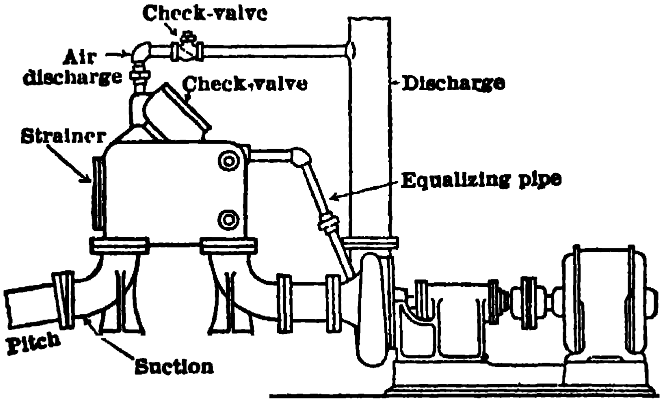

Fig 25. Centrifugal Pump with Suction-line Primer

Priming centrifugal pumps. There are 3 methods: (*a*) installing a foot valve and filling the suction pipe and pump casing with water from the discharge column; (*b*) using a vacuum pump, or other means of exhausting air from the suction line and pump casing, and filling them with water from the sump; (*c*) providing a head on the suction, when a pump takes water from a dam. Foot valves are widely used for small pumps, but are not reliable, as they are apt to leak and wear out rapidly in acid water. A pump with a foot valve will operate automatically with safety, but often fails to start when the valve becomes leaky. Hence, foot valves are not recommended for mine service.

A priming-pump is used for most centrifugals. It is started by a switch operated by a float in the sump, and exhausts the air from the centrifugal, thus drawing water from the sump through the suction pipe and pump casing, and thence through a valve into a priming chamber, which contains a float. When water enters the chamber, the float rises and closes the priming switch, which starts the centrifugal pump motor. The motor having been accelerated a contact is automatically opened, stopping the priming pump. When the centrifugal begins to run, the priming valve is closed by the pressure from the pump, the water from the priming chamber drains out, and the priming switch opens. Protective devices are shunted around the priming switch, and the current flows through them when the switch is open. These devices consist of a vacuum regulator, which opens the circuit if the vacuum exceeds a predetermined value, and a pressure regulator, opening the circuit when the pressure in the discharge line falls below a predetermined pressure. Fig 24 shows arrangement of pumps and accessories, and the elementary wiring diagram.

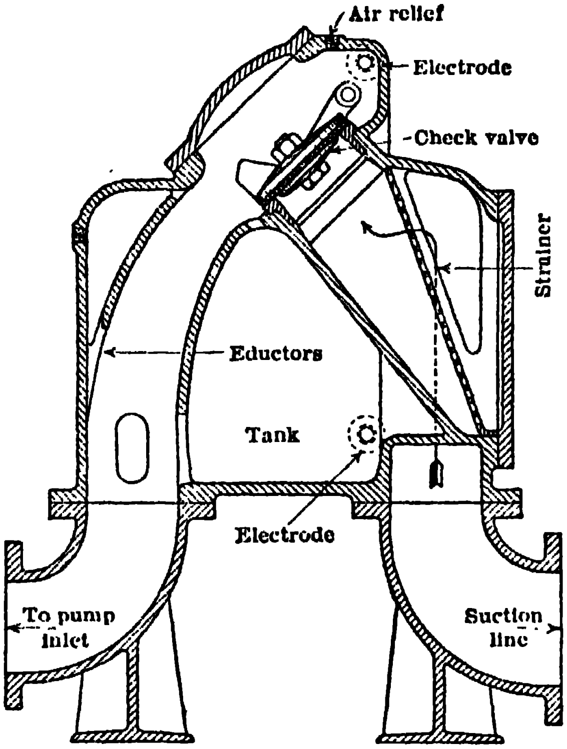

Fig 26. Suction-line Primer

Pumps with capac not exceeding 1 500 gal per min, and working against a head of not more than 250 ft, can be made to work automatically by installing a suction-line primer close to the pump (Fig 25). The primer, shown in Fig 26, combines in one casting a strainer, check valve seat, and air-removing device. To prime the pump, the priming chamber is filled with water and the pump started. It draws the water from the priming tank, and in doing so creates a vacuum in the tank and suction line, which causes water to rise in the suction line and flow through the check valve into the passage leading to the pump inlet, whence it is pumped into the discharge line. The air filling the tank is drawn through eductors into the stream and forced into the discharge line. Repeated starts and stops may be required to prime a long suction line. Starting and stopping may be automatically controlled by an electrode fitted in the tank.

Priming-pumps may be either wet or dry. Wet priming-pumps are in common use, but the water must be clean and free of acid. Dry priming-pumps require less power. A trap must be interposed, to prevent the water from entering the cylinder; a barometric loop serves the same purpose. The most effic trap, widely used with pumps handling acid water, is a chamber in which a float operates an air valve. This valve opens when the water enters the chamber, causing the vacuum to break, thus preventing water from entering the pump. The chamber is placed above the pump and

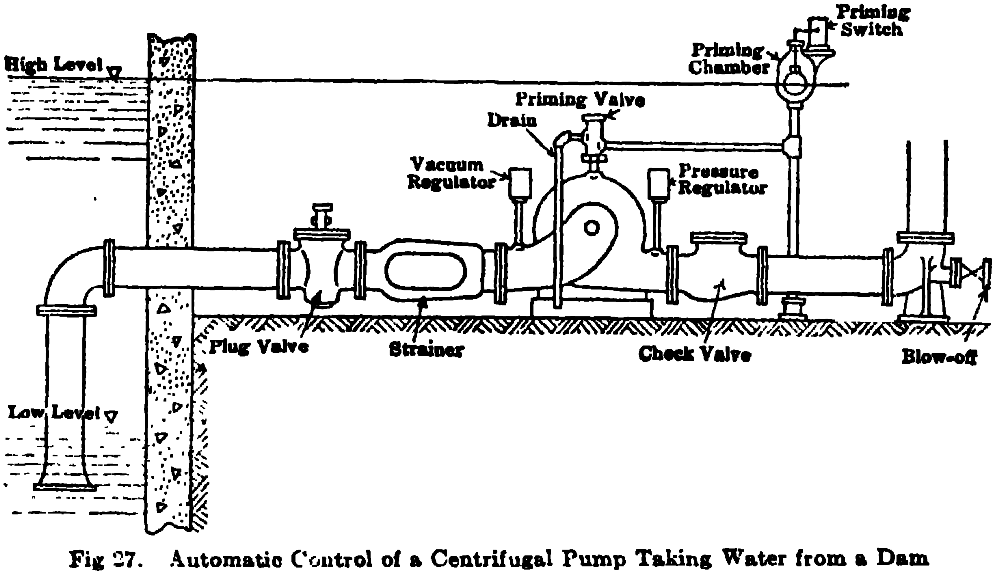

Fig 27. Automatic Control of a Centrifugal Pump Taking Water from a Dam

connected to top of the casing of a single-stage pump, or to top of the first stage of a multi-stage pump. The remaining stages need not be primed.

When a centrifugal takes water from a dam (Fig 27), no priming is required. As the water rises behind the dam, it also rises in the suction line and pump casing, and raises the float in the priming chamber, thus closing the priming switch and starting the pump. The protective devices are shunted as described above. The pump is stopped by the vacuum regulator switch, which opens when the water behind the dam has receded to the low level.

14. NEUTRALIZING ACID MINE WATER (30)

Acid water is sometimes neutralized before pumping, thus avoiding damage to pumps and column pipe. In many mines the quantity of water is so great that it can not be economically neutralized before pumping. Sometimes part of the water used for the preparation of coal is neutralized to prevent rapid wear of the breaker equipment.

A computation based on actual conditions is necessary to determine the advisability of this procedure, dependent as it is on character and quantity of water, type and cost of pumping plant, and price of the alkali required. Milk of lime may be added to sump water in measured quantity at regular intervals, as in coal mines and in metal mines at Butte, Mont, and elsewhere.

MINE VENTILATION

This section treats of the natural and artificial circulation of air currents in mines and tunnels For composition and properties of mine air, and physiological effects of its impurities and variations in physical conditions, see Sec 23.

1. MINE ATMOSPHERE

Ventilation of mines is a form of air conditioning by distribution of air currents in underground openings, in quantities sufficient to maintain working places in safe and healthful condition; it is most elaborately developed in coal mines, because of occurrence of explosive gas and dust. In metal mines it is confined largely to combating effect of high air temp on effic of miners, and effect of rock dusts on health.

Mine air may contain a number of impurities, in addition to normal constituents, and may absorb water vapor and heat in passing through workings (Sec 23, Art 1–4). Major impurities: (*a*) smoke and gases from blasting; (*b*) gases from the strata; (*c*) dust from mining operations. Open lights, breathing of men and animals, and chemical oxidation consume O, and (except oxidation of sulphides) produce CO_2. Minor sources of gaseous impurities are: rotting timber, excretions of men and animals, and smouldering mine fires.

Gases from explosives are dangerous mainly on account of CO, which seldom exceeds 0.3 cu ft per lb of explosive, but is variable and dependent on the oxygen-combustible balance. Gases from strata are most important in coal mines, with CH_4, CO_2, and H_2S in order of occurrence. CO_2 is often found in metal mines, CH_4 and H_2S rarely. Smouldering mine fires may produce CO. DUST in coal mines (other than anthracite) is explosive and therefore dangerous; in metal and anthracite coal mines, it may be a health hazard of importance. MINE AIR TEMP approximates that of the walls of air passages, and, as rock temp increases with depth, deep workings may have hot, high-humidity air conditions (Art 17, 18). Abundant ventilating currents, properly distributed, reduce dangers of gases and dusts and alleviate discomfort due to high-temperature air.

2. VENTILATING SYSTEMS

Definition. Any set of connected underground openings and the forces and appliances that cause flow of air through them constitute a ventilating system. Every mine has its own system, taken as a whole; the similarities occur between separate parts of mines. SYSTEMS: controlled and uncontrolled natural and mechanical ventilation.

Control of ventilating currents is required for their effective use and protection of life and property in case of fire or explosion. Uncontrolled currents may produce good air conditions; but lack of control, resulting in unknown conditions of recirculation, adds to natural hazard. Mechanical systems increase natural hazard from fire or explosion, by causing faster travel of gases.

Uncontrolled natural ventilation. Most small metal mines, a few small coal mines, some large metal mines, and near-surface sections of some large coal mines, are ventilated by uncontrolled natural ventilation (Art 12). Where openings are large and numerous, mines have reached great depths without intentional control of natural air flows. Above the lowest adit connection, mines in mountainous country are generally well ventilated by natural draft.

Controlled natural ventilation. Air flow is often partly controlled by natural conditions, or intentionally. In shallow mines, the driving of openings to the surface at intervals is a form of control. Circulation can be improved and direction of flow controlled by doors and bulkheads (Art 12). In large mines on pitching veins, workings should be divided into sections by barriers extending from surface to top of active zones; as in many Mich copper mines (63), where good natural ventilation exists at depths of 3 000–6 000 ft vert and 4 000–9 000 ft on the dip, below a practically level surface.

Mechanical ventilation. Where natural ventilation is inadequate, circulation is produced by fans (Art 13–16), as at most coal and large metal mines; they are always advisable, if only to provide reversible direction-of-flow for emergencies, and increased flow when the surface temp limits natural flow. In most metal mines, the chief objects of mechanical ventilation are to reduce high air temp in depth and rapidly remove the blasting fumes. Other objectives: better control of air currents in fire areas or for fire protection; dilution and removal of strata gases; reduction in amount of comp air used fo air cooling; reduction of timber decay; and removal of rock dust.

Application of mechanical ventilation. In bedded deposits, as coal, the outlines of the deposit usually are known, and layout of openings is planned in advance for effective ventilation. Most metal mines rely on natural draft until conditions demand more air and better distribution, as supplied by fans. A large multi-seam coal mine is often divided, between seams or at natural barriers, into separately-ventilated sections. A large metal mine is usually ventilated by 2 or more fans operating in parallel or series on the same ventilating system, without division between circuits. Ventilation by one fan is desirable if it can be arranged economically. In planning a mechanical system, the main factors are volume of flow and effect of layout of openings on pressure requirements.

Air quantity requirements (Sec 23, Art 6) for effective ventilation depend on conditions as to gas, dust and rock temp, and vary from 50 to 1 000 cu ft per min per man on largest underground shift employed. In practice, quantities are adjusted until the air in working places seems good. Usual criterions: movement of smoke after blasting in metal mining; presence or absence of gas accumulations in coal mines; and temp and humidity in hot mines. In some U S coal mines, air quality based on routine air analysis is the control used. LEGAL REQUIREMENTS for metal mines or tunnels in the U S are few; N Y regulates siliceous dust concentrations (24). Legal requirements for coal mines (25), based on number of men and animals underground and position of air measurement, are generally exceeded in practice. Abroad, there is a trend to requirements based on max permissible limits of impurities, temp and humidity (26). MINIMUM REQUIREMENTS IN PRACTICE are about 30 cu ft per min ("c f m") per man and 3–5 times as much for a horse (12). For small metal mines, with long intervals between shifts, and blasting at end of shift only, 50 c f m per man may be enough, but, with scattered working places and large openings, requirements approach 100 c f m, the general minimum for coal mines. Blasting during the shift, much timbering, production of gas from the strata or by oxidation, or moderately high temp, increase requirements 50–100 c f m per man. General requirements in undercut-caving, where a veloc of about 100 ft per min is required in grizzly drifts to permit intermittent blasting, are 200–300 c f m per man. Except under extreme gas or high-temp conditions, requirements seldom exceed 500 c f m per man, but may reach 1 000 (9). In Pa non-gaseous anthracite mines the limits are about 100–1 000 c f m; aver, about 300 c f m per man. In Pa gaseous anthracite mines, the limits are about 300–1 000, aver 500 c f m per man (27). In all mines, the quantities necessary for good air conditions are found by trial, but are subject to frequent change.

Total air circulated in gaseous mines often amounts to 10 tons air per ton coal mined; aver, about 6 to 1 (3). In Pa anthracite field, several mines circulate over 1 000 000 cu ft per min; others there and elsewhere, 500 000–900 000 (27); but the aver large mine requires 50 000–250 000 c f m and few exceed 250 000.

Reduction of normal air quantities during idle times, rare in metal mines, is sometimes practiced at intermittently operated coal mines working fairly flat seams, saving much power at moderate sacrifice of safety; usually not practical on pitching seams making much gas, because of gas accumulations.

Pressure requirements. At fixed quantity, power required for circulating air depends on press, which is determined by the airways and their layout. In coal mines, design of airways is usually part of original plan of development (Art 11); in metal mines, it may involve best use of existing openings, with a minimum of "new" work. Press requirements (Art 10, 11) depend on size of airways and how combined in flow circuits; that is, how the flow is split between openings. Main airways, carrying entire flow, demand most attention, as restricted areas or high resistance therein may cripple the whole system. Layout of minor openings, in which split flow occurs, usually has no important effect on press requirements.

Fan pressures at U S metal mines are usually 3–5 in of water gage. In coal mines, economical size of airways is larger and range of fan pressures is usually 0.5–3 in of water. Mine airway conditions may be compared in terms of press required to pass a unit quantity (Art 11). Requirements for 100 000 cu ft per min are: max for small metal mines, 20–30 in; usual for large metal mines, 5–10 in; aver for non-gaseous coal mines, 1–5 in; aver for gaseous mines, 0.2–1.0 in; at a few coal mines, even lower. Aver conditions of fan operation in terms of equivalent orifice (Art 11) are: min for small metal mines, 5–10 sq ft; aver for large metal mines, 15–25; aver for non-gaseous coal mines, 25–40; aver for very gaseous coal mines, 40–90 sq ft.

Major outlines of ventilation systems are determined by the number, size, use and position of shafts, slopes, and adits to surface. DESIRABLE FEATURES: (1) utilization as intakes, or fresh-air outlets, of openings used for transporting men; (2) utilization of all available surface openings, or enough to give low-resistance; (3) coursing of intakes directly to lower levels of active zones, so that currents ascend through them to main outlets, (4) splitting of total flow and uniting separate flows close to surface; (5) minimizing distances traveled; (6) maintaining balanced resistance between main intake and outlet airways, and between separate sections of main airways; (7) minimizing obstructions, as doors and air locks in active openings; (8) avoidance of leakage, recirculation and creation of fog; (9) circulation of air from active zones to caved ground rather than the reverse.

Interventilation of mines is rarely desirable, as cooperation of separate operating staffs is not dependable. It should be a temporary expedient only, except where full control of ventilation in a group of mines is exercised by one official. Connections between adjoining mines are desirable for safety, but should be normally shut off with fire-door air locks.

Exhaust systems of ventilation are preferable, with the fan or fans on the surface at air shafts, slopes or adits; this pays due regard to safety, air is then drawn in and coursed directly to active zones, and the fan is always accessible. Although exhaust systems are general, many blowing systems are in use, especially in eastern U S bituminous mines, except Pa. Main haulage and hoisting openings are then on return air, chiefly to avoid operating inconvenience in cold weather (Art 3).

Location of openings. To decrease distance traveled by air currents, provide safety, and reduce leakage, intake and outlet openings should be so arranged that active workings lie mainly on the line between them. If active workings extend in two or more directions from a downcast shaft, an upcast near the limit of activity in each direction is desirable. If shafts are spaced fairly regularly, as on an extensive pitching vein, alternate shafts should be upcasts and downcasts, to distribute resistances and reach areas that would otherwise receive little flow. Two shafts close together usually serve better when carrying air in the same direction, because few stoppings are required on connections between them, leakage is avoided, and distance traveled by the air is usually minimum.

Ideal lay-out of airways best illustrates desirable major features, as shown in Fig 1 for a typical metal mine. Surface exhaust fans, on outlying and small inactive shafts of a steep vein, draw air in through the centrally located and relatively large operating shaft to the bottom levels, through which it passes to active stopes and thence to less active workings connected to upcast. The foregoing nine desirable conditions are fulfilled and a safe and effic system should result. A similar ideal layout for gaseous coal mine workings on moderate to steep pitches is shown in Fig 2. Here the air is more definitely coursed, and main intakes and returns are close to each other, as generally required for coal mines. The same major conditions are met, as well as the following special objectives for gaseous mines: (1) active sections on separate splits; (2) pillar workings on splits separate from advancing first mining; (3) inactive sections ventilated by returns from active sections; (4) development for ventilation is completed before development for extraction is advanced.

Fig 1. Ideal Layout of Mechanical-ventilation System, Metal Mines (9)

Minor outlines of systems are controlled largely by the individual characteristics of mines, even in quite similar deposits. The more important are: degree of concentration of operations; position of active areas; relative ease or difficulty of maintaining openings; location of sources of heat, dust, or strata gases; position of sealed fire areas or areas liable to spontaneous ignition; condition of abandoned and inaccessible workings; and the precooling of zones of warm rock. These and other special conditions may require modification of the major outlines of the system as a whole, but if the major objectives are observed the system should be effective.

Concentration of working places is important in insuring good air conditions at low cost, for gaseous mines and workings in warm rock, as at great depth. Sections should be cleaned up so they can be abandoned in regular order, thus maintaining a uniform size of active zone. If possible, sections temporarily abandoned should be sealed: timber can be preserved by either sealing or thorough ventilation, whereas insufficient ventilation leads to rapid deterioration of timber and extensive sloughing of rock walls.

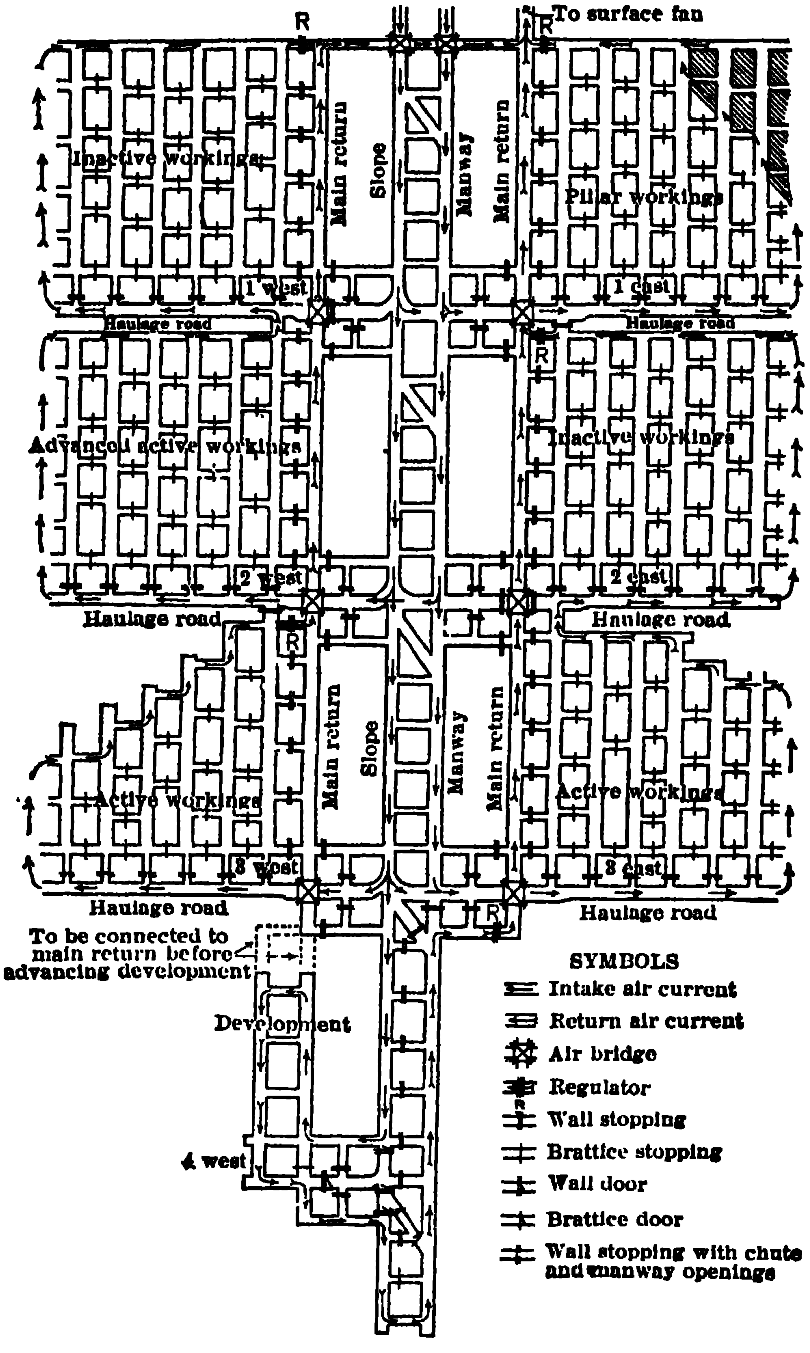

Fig 2. Desirable Method of Ventilating Gaseous Coal Mines on Moderate to Steep Pitches (27)

Extensive operations above the active zone of "first mining," as the reworking of gobbed areas, leasing operations on scattered pillars and lean zones, and retreating pillar extraction, should be on circuits separated from the main circuits below by barriers, natural or artificial. Insistence of mill operators on uniform grade of ore, from sections of non-uniform grade, tends to prevent concentration of active workings in metal mines. Mechanical systems of mining effect this concentration in coal mines.

Local sources of heat, dust, gas, fire hazard, or other conditions interfering with normal arrangement of an otherwise desirable system, are often troublesome and sometimes expensive to handle. A separate intake split usually must be diverted direct to an outlet not used to transport men, or a separate air circuit must be formed. Underground stables in a coal mine require a separate split, as do other possible sources of fire, as elec transformer and pump stations. Sealed fire zones are commonly handled by putting the area under enough press to overcome reverse natural drafts, and providing a small separate split to a main return or to the surface, from a point above the fire zone.

Examples. In the United Verde mine a circulation of 60 000 c f m was planned (1930) for an underground generator and hoist installation (31); in the Village Deep mine, So Af, a split of 75 000 c f m was allocated to a similar installation (81), in the Calumet & Hecla conglomerate mine (Mich), 2 large pumping stations on a return shaft had each a circulation of 30 000 c f m (63); at the Ray undercut-caving mine (Ariz), a separate shaft equipped with a surface exhaust fan connected (1930) with 3 rotary dumps at the ore-hoisting shaft, passed over 40 000 c f m. Auxiliary fan-pipe installations are effective for carrying the return from a local source to a distant airway.

Circulation through caved ground also impairs well-planned ventilation systems. Most common form is leakage through the fill, where the shaft collar extends above the natural ground level; averted by a concrete lining from collar to solid rock, or other tight stratum. In caved ground, circulation depends mainly on how the ground caves. Even though proportion of fine material is large enough to prevent circulation through the mass itself, spaces along the hanging wall and near pillars or solid ground may permit considerable flows. Enough air can pass up through 15–20 ft of coarsely broken ore to ventilate a shrinkage stope, and enough may pass through a 200-ft fill of moderately coarse rock in a raise of large cross-sec to ventilate a small stope (63). In the retreating systems used in Mich copper mines, air circulates freely through caved areas adjacent to active stoping, so that these zones are equivalent to low-resistance return airways.

Pressure systems, under certain conditions, may be desirable to insure that circulation goes from working places to and through caved ground. Where the main system is of the exhaust type, pressure could be maintained locally by booster fans. If pressure ventilation is desirable throughout, it can be adapted to the foregoing major objectives, particularly the rule that openings used for transporting men shall carry intake air. This adaptation usually requires a main fan underground on the intake side; or entrance through an air lock; or use as an intake-air upcast, of the shaft in which men are hoisted. All these methods involve added inconvenience to mining operations or added expense as compared with a straight surface exhaust system.

Ventilation personnel. Ventilation at many metal mines is everybody's business and thus no one's responsibility. Under favorable natural conditions no great harm results, though in case of fire, loss of life or property may be increased by ignorance of the air-distribution system. Under unfavorable conditions, ventilation becomes important, and good results are possible only where lines of authority are strictly drawn. In general, ventilation should be handled solely by: (1) a trained crew to make actual installations of distribution features, (2) a " ventilation foreman " to supervise installation and record the distribution and air conditions; (3) a high official with authority to initiate and control major changes.

Ventilation foreman in a small mine may be an operating official, but in a large mine his position should be independent. Technical ability and knowledge of ventilation theory, though desirable, are less important than mining experience, intimate knowledge of the mine, and ability to work with operating officials. Where natural conditions make good ventilation a matter of prime importance, technical ability and knowledge of ventilation theory are essential to reduce the demands on the higher official.

Official in charge of ventilation should have sole responsibility for the system. In a large organization, some one man often is especially fitted for the work, through knowledge of ventilation theory. For a large mine or group of mines operating under difficult conditions, a mining engineer specializing in ventilation would be the natural selection, with or without other duties of importance. Most large, deep gold mines on the Rand now employ technically-trained ventilation engineers to cope with problems of dust and high temp, and these men contribute much of the current literature on mine ventilation. In coal mines, each grade of official has legal duties and responsibilities in regard to maintenance of ventilation, and systematic layouts can be planned in advance so as to be largely self-extending and foolproof. But, the same need for expert guidance and help exists if operations are to be conducted safely and economically, and the above remarks on metal mining practice apply also to coal mining (3).

Cost of ventilation at many metal mines, where ventilation is wholly " natural," is nil; even where natural circulation is partly controlled, cost is negligible. Mechanical ventilation is expensive and must be effic. Costs vary widely for different operations and conditions, regardless of economy attained or bookkeeping methods used. Few data have been published, particularly for U S coal mines. Briggs (3) estimates that British coal mines circulate about 80 000 000 cu ft of air per min at a cost of about $10 000 000 a year, or 4¢ per ton coal produced, or $122 per year per 1 000 c f m. Davies

(28) gives an aver of about 8.8¢ and a range of 3.2–18.6¢ per ton for 11 So Wales collieries, with power at 2¢ per kw-hr. Cost of ventilation in Northern anthracite field of Pa is estimated (27) as approx $3 500 000 for circulations totaling 25 000 000 c f m, or about 14¢ per ton coal produced. In Western Middle anthracite field of Pa, 10¢ per ton excluding power is said to give good ventilation, 7–8¢ fair, and 4–5¢ poor ventilation. Shallow, easily ventilated, non-gaseous bituminous mines in U S show costs of 1.5–4¢; gaseous operations, 9–14¢ for steady, up to 24¢ per ton for irregular operation. J. A. Saxe estimates that gaseous mines in Pa bituminous fields, of 3 000–5 000 tons per day, with power at 1¢ per kw-hr, should be ventilated for 4¢ per ton; that well-designed new mines could attain 3¢, and new mechanically-operated mines possibly as low as 1.5–2¢ per ton for continuous multiple-shift operation.

Operating and cost data for 14 large metal mines are shown in Table 1, where costs per ton are 0.32–18.7¢, and effect of large-scale concentrated production in reducing per-ton cost can be seen by comparing figures for shallow block-caving operations (first 4 items) with rest of group, which represent normal, deep mine operations.

Distribution of costs between labor, power and supplies depends largely on mine conditions, especially the degree of control of air distribution. With little control, approx percentages are 15–70–15 in the order given; for moderate control, as in the aver deep metal mine or non-gaseous coal mine, 30–50–20; for extensive control, as in gaseous or deep, hot mines, 50–25–25. PERCENT OF TOTAL MINE POWER USED IN VENTILATION at mechanically-ventilated mines is large. For the group shown in Table 1, it is 2–35%; for the small metal mine, it may be 50% or more. A survey of 40 Ill coal mines (29) found an aver of 22.45%. Briggs (3) quotes estimates of 7–40% for British coal mines; probably applicable to U S coal mines, with an aver of roughly 20% for mechanized bituminous and 35% for non-mechanized anthracite mines.

Table 1. Ventilation Costs for Large Metal Mines

3. DISTRIBUTION OF AIR CURRENTS

Control of air currents. Natural distribution of air is almost always inefficient; for effic distribution, both direction and quantity of flow must be controlled. In a large mine, many conflicting factors are involved, and the system should be planned to care for as many factors as possible in order of importance, first with regard to safety, and second, to service (15).

Mine pressure adjustments. General directions of flow are determined by points in the system at which pressures are generated; quantities of flow, by intensity of these pressures. Both direction and quantity can be controlled by modifying the natural resistances to flow in the mine openings, or by artificial airways. Resistance of an airway may be increased by tight stoppings so as to stop the flow entirely, or by loose stoppings to restrict the flow to leakage, or by regulators to provide a flow under quantitative control. Resistance may be decreased by combining airways or changing their physical conditions; or the equivalent effect obtained by a booster fan. A single airway may be divided by a brattice to make 2 separate airways; or an artificial airway may be constructed within an airway (as in auxiliary ventilation by fan-tubing units), or at a junction of airways to permit air currents to pass each other, as by an overcast.

Direction of flow in a mechanically-ventilated mine is primarily determined by position of main fan or fans. Demands of service and safety sometimes coincide, but usually conflict, in whole or in part. With two surface openings available, one in active use for operating purposes and the other inactive, the planning of ventilation distribution involves 3 decisions: what should be the normal direction with respect to the operating opening; should the fan be on the surface or underground; should the general direction be fixed or subject to reversal in emergency? Actual conditions control these decisions, but usually a reasonable regard for safety of life and property requires a primarily-exhausting reversible fan installed on the surface at the non-operating opening, as discussed below.

Operating openings as intakes. In all mines, the important consideration in determining direction of flow is that the means of exit should be on intake air; hence the operating opening should usually be an intake, actuated by an exhaust fan on a non-operating opening. Other effective means are: making the operating opening a fresh-air outlet, or upcast in the case of a shaft, or putting it under pressure with intake air. Most coal and metal mines are so ventilated, including large mines recently equipped. In a gaseous coal mine or deep, hot metal mine, it is almost essential to make the operating opening an intake; in the former, to limit elec haulage to intake airways, and in the latter, to permit direct coursing of surface air to active workings. DISADVANTAGES: in cold climates, formation of ice in the opening, freezing of water lines, and discomfort caused by low temp. These difficulties can be largely overcome at moderate expense. Due to effect of rapidly changing temp and moisture conditions on timber and rock, intake openings are subject to higher maintenance costs near the entrance than the returns with their uniform air conditions; return air currents may not only be highly corrosive to equipment, but may also make openings wet or produce hot, foggy, and smoky air conditions. Where large quantities of dust are raised, on or near an opening that for safety should be an intake, dust should be prevented from entering intake currents.

Location of main fans, in general, should be on the surface, for effic control; legally required for coal mines in some states and in most European countries (26). A fan underground may be wrecked by an explosion or during a fire; the only sure means of control is to cut off the power. However, some normal operating conditions favor underground location, which may actually be more accessible in certain metal-mine layouts than location on surface; but it is then wise to provide also a surface fan for emergencies. Where all surface openings are required for operations, underground location is the usual solution in metal mines; but in English coal mines, location on surface with air locks for passing cars is common. This is relatively expensive where rapid hoisting is done, but operation of main fans underground may be more wasteful of power than is generally realized. Underground installations usually require air locks on main haulage roads that might otherwise be left open; they almost always result in considerable recirculation, dangerous during a mine fire and always undesirable.

Effect of fan location on pressure. In surface installations, greatest press differences between intakes and returns occur in the upper part of the mine, where stoppings can usually be kept in good condition because of infrequent use. In underground installations, greatest press differences are on stoppings and doors in an active zone where, due to frequent use, it is difficult to keep them tight. Surface fans permit air-flow systems of lower resistance than underground fans, as the latter usually must be placed so that flow is confined to less than the full number of airways available.

Arrangement for reversing direction of main flow (Art 13) is required by law for coal mines in some states (25) and in most European countries (26); common at most metal and bituminous coal mines; used at a few mines in the Pa anthracite district. As insurance against emergencies, it should be installed at all mines, regardless of whether its need can be foreseen or not. Lack of reversing arrangements has been held responsible for much loss of life and property in mine-fire disasters. Whether or not to reverse a fan after a mine explosion or during a mine fire is a serious decision, to be made only by the highest officials after consideration of all the factors; the reversing arrangements should therefore be locked unless the attendants are reliable. Time is important, and as it is required to ascertain the need for reversing and make the reversal, not only should smooth operation be insured by occasional trials of the mechanism, but other methods of control should also be planned to effect safe exit of men.

Fireproofing of intake openings is essential. Intake airways usually present a serious fire hazard against which it is difficult or impossible to protect the men underground, except by fireproof construction. But such construction does not overcome the hazard well enough to permit dispensing with the reversible feature of the fan; burning materials in the openings or on stations may give off enough gases to cause danger. Fireproof construction is also desirable in main return airways, though there it is mainly insurance against property loss or interference with operations, since the returns are usually wet throughout.

Fireproofing of installations is customary for main fans; less often for auxiliary fans. These often present fire hazards, particularly the forward-curved-blade centrifugals, which may overload and burn out their motors. Even the backward-curved-blade centrifugals with constant-power characteristic are not entirely safe in this regard, when reversed.

Splitting of the air current. In small mines or sections of a mine, the required quantity of air is best circulated in a single current. In large mines the flow should be split, so that each mine section has its own air current, for effic and safety. The power required for the same circulation is thereby reduced, one section is not necessarily affected by air pollution and hazards of others, and quantities may be adjusted to requirements. For max effic, splits should be taken off the downcast circuit, and returned to the upcast, as close to the surface as possible. Legal requirements as to number of men per split of air make splitting compulsory for all except very small coal mines.

Plan of splitting. In some cases, the main current is divided, say at a shaft bottom, into two or more primary splits, which in turn are divided into two or more secondary splits, and these in turn may be further subdivided. In others, successive splits are taken off the main air current, until it becomes the last split. Splitting should not be carried too far, or veloc of flow will be reduced to ineffectiveness; or, in the case of pitch workings, press may be reduced until natural draft pressures, due to differences in temp or gas content, interfere with circulation.

Natural and controlled splitting. In metal mines, the air generally divides naturally, with minimum regulation, the object being to get as much air as possible through restricted openings. Flow outside the main airways may be through a network of interconnected openings, and little attempt is made to keep the air splits separate. In coal-mining terms, the air is " broadcast " through the active zones of operation. In special cases, a similar procedure is followed at coal mines, but generally the air splits are carefully controlled, with quantities adjusted to requirements by regulators (Art 5). Natural splitting would normally give the least air to the longest working section with the largest requirements. Generally, all splits but one (the " open " split) are throttled by regulators (Art 7).

Average quantities per split vary considerably even for similar mine conditions. Aver figures, to which there are many exceptions, are: 20 000–30 000 cu ft per min for metal mines and longwall coal mines; 10 000–15 000 for flat-pitch room-and-pillar coal mines; and 5 000–10 000 (at higher pressures) for gaseous steep-pitch coal mines.

Booster fans. Control of air currents by regulators is obtained only at expense of increased power requirements, generally accepted as a necessary evil. Where the " open," or unregulated, split has abnormally high resistance, power requirements can be decreased by a booster fan in that circuit, equivalent to reducing circuit resistance. This device is common in metal mines, where irregularity of ore deposits often demands it (Art 13); less often required in coal mines; in gaseous mines, it introduces a hazard and booster fans are prohibited by law in many states and in most European countries, or allowed only for rare conditions (25, 26). Booster fans are also used in special cases to put sections of workings under pressure in mines ventilated by exhaust systems, particularly sealed fire areas or caved areas through which gas or high-temp air would otherwise enter the main circulation.

4. VELOCITY OF AIR CURRENTS

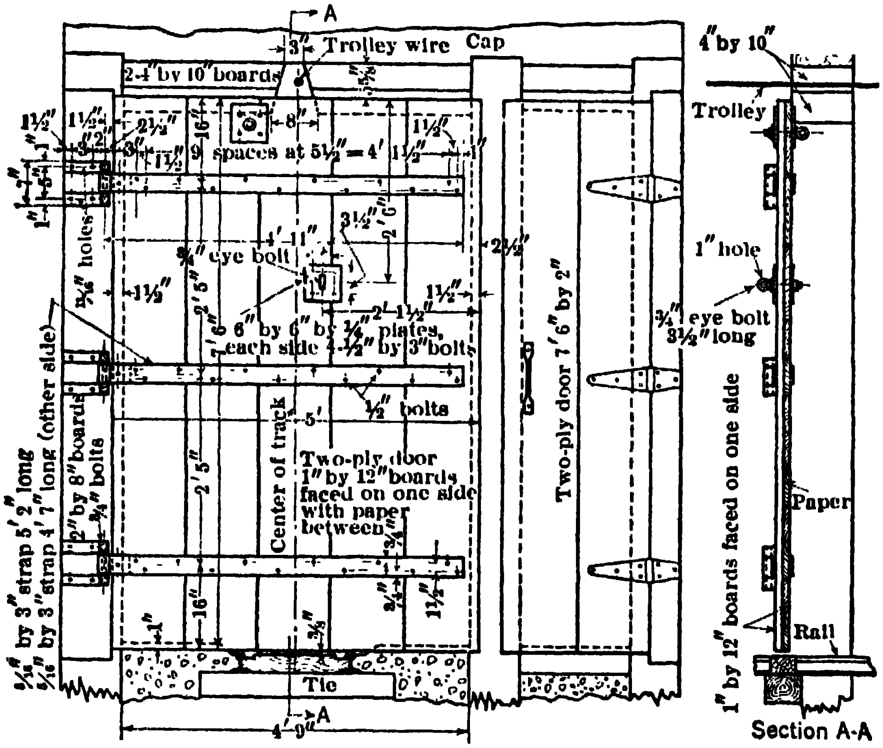
Velocities in passageways. Moderate veloc saves power, by reducing friction and therefore pressure. In airways driven solely for ventilation, veloc should be that for max economy, as determined by balancing construction cost against operating cost (Art 11). In airways for transport and travel, it is limited by considerations of safety and health. High veloc may drive the flame of a safety lamp against the gauze and ignite a surrounding explosive atmosphere (Sec 23). The bonneted, double-gauze lamps now in use are safe to velocities above 2 500 ft per min. Carbide lights can withstand up to about 1 000 ft per min, but for working purposes 500 ft per min should not be exceeded.

In open-light mines, high-veloc exits should be electrically lighted and provided with regulators to permit reducing velocities temporarily in emergency. Max permissible vel in operating shafts in France is 1 500, and in Germany 1 600 ft per min (26). Veloc is not limited in U S coal mines, except occasionally by individual mine inspectors.

Velocities at working faces. In non-gaseous coal mines velocities at working faces are not important. Veloc of 20–30 ft per min moves blasting smoke out of dead ends as a compact cloud. Higher veloc breaks up and diffuses the cloud. In gaseous mines, 100–200 ft per min is sometimes required across faces for rapid dilution of gas emitted. In undercut-caving, 100 ft per min or over is desirable across grizzly levels, to relieve operator of dust from chute-running (31). In hot mines, comfort increases about as the square root of the veloc (Fig 59, Art 17), so that the economy of attempting veloc over 100 f p m in local circulations is debatable. (For veloc distributions in airways, see Art 9; for pipe inlets and discharges, Art 6.)

5. DEVICES FOR CONTROLLING AIR DISTRIBUTION

Stoppings. Almost all devices for controlling distribution by introducing obstructions to flow, or artificial division or deflection walls in airways, may be called " stoppings," since materials and conditions of installation are similar.



Note: Space between frame and rock surfaces filled with concrete

Fig 3. Ventilation Door used on Motor Haulageway in Metal Mine (31)

Permanent stopping is a tight wall across an airway to prevent flow to adjoining openings; usually designated " stopping " in U S bituminous mines, " wall-stopping " in anthracite mines, and " bulkhead " in metal mines; often used in connections between parallel airways in coal mines. While gob stoppings, usually faced with plaster or cement, are still the rule in many older U S coal mines, concrete-block and brick are now preferred in bituminous, and plain concrete in anthracite mines.

A study by Williams (30) of 80-sq ft main-entry stoppings in Ill (1915) shows aver first costs from $7.20 for dry-wall gob type and $7.34 for rough board stoppings, to $11.57 for 8-in concrete and $17.43 for 8-in brick walls; but under specified conditions, annual costs, chiefly of power wasted in leakage, were $1.53 for concrete, $1.91 for brick, $35.93 for dry-wall gob and $76.99 for rough board stoppings. Permanent stoppings in metal mines, chiefly for sealing off abandoned or fire areas, are usually of heavy wood construction, often luted with clay or gunited with cement for tightness, and erected in ground subject to movement. Aver costs per sq ft of gunited stoppings are estimated (1932) as about 40¢ for small and 30¢ for large isolated stoppings, and 20¢ for large jobs or especially large stoppings. Where the ground is " heavy," packs of short timbers laid endwise, or of alternate layers of rock and timbers, give good service by crushing until practically airtight, in circumstances where a reinforced concrete wall would eventually be demolished.

Temporary stoppings. Where waste material is available, and tightness not essential (as in connections between rooms in room-and-pillar work), temporary stoppings are usually of loosely-packed gob. Otherwise, and for extra tightness, they are of light wood, or brattice cloth on a wood frame, usually called " brattices " (bituminous) or " brattice stoppings " (anthracite mines). Temporary stoppings are infrequent in metal mines.

Doors. Where men or traffic must pass through a stopping, it has a door. In coal mines, the resulting hazard keeps the number of doors to a minimum. In metal mines, they are often used where stoppings would be used in coal mines, and transport and travel are thereby facilitated. Where passage of men is infrequent, doors in gaseous coal mines are about 2 by 3 ft, so arranged that they can not be left open. Otherwise doors are almost as large as the stoppings containing them: 6 by 9 ft aver for coal and 5 by 6 ft for metal mines. In metal, but less often in coal mines, a main traffic door, especially if automatically operated, is supplemented by an adjoining narrow door for passage of men (Fig 3). In metal mines doors are often installed in untimbered sections to control air currents in case of fire.

Type of door, commonest in both coal and metal mines, is single, vertically hung and unpainted, made of 2 plies of 1-in boards, with cloth or paper between plies. Practice favors horiz and vert rather than diagonal plies, with vert ply on the "push" side and nails clinched on the "pull" side. Door is set in a timber frame, with posts wedged to roof and floor, and closes flush against the frame rather than on a jamb. Wooden stop blocks are provided at the floor, with clearance for track rails. Doors are swung by long strap hinges on studs, or " hooks " (Fig 4) and arranged to be self closing with the air current, and stay closed against reversed flow. In coal mines, the frame is erected on a slight batter and lower hinge-stud offset about 1.5 in, the door closing by its own weight. In metal mines, the frame is vert, and door is closed by counterweight. Space between frame and walls is filled with concrete; or, in metal mines, it may be boarded over and gunited; in coal mines, filled with " slate " dry-walls faced with mortar. Various devices reduce leakage where tightness is essential (Art 7). For temporary use, or where leakage is not important, light cross-braced single-ply wooden doors, or doors of canvas and wood, set in light wooden frames, are common in coal mines. Metal-covered and all-metal types are rare. Glass reflector buttons are often set in doors to warn motormen of their location, and small glass panels may be inserted in automatic doors to warn men of approaching motor trips.

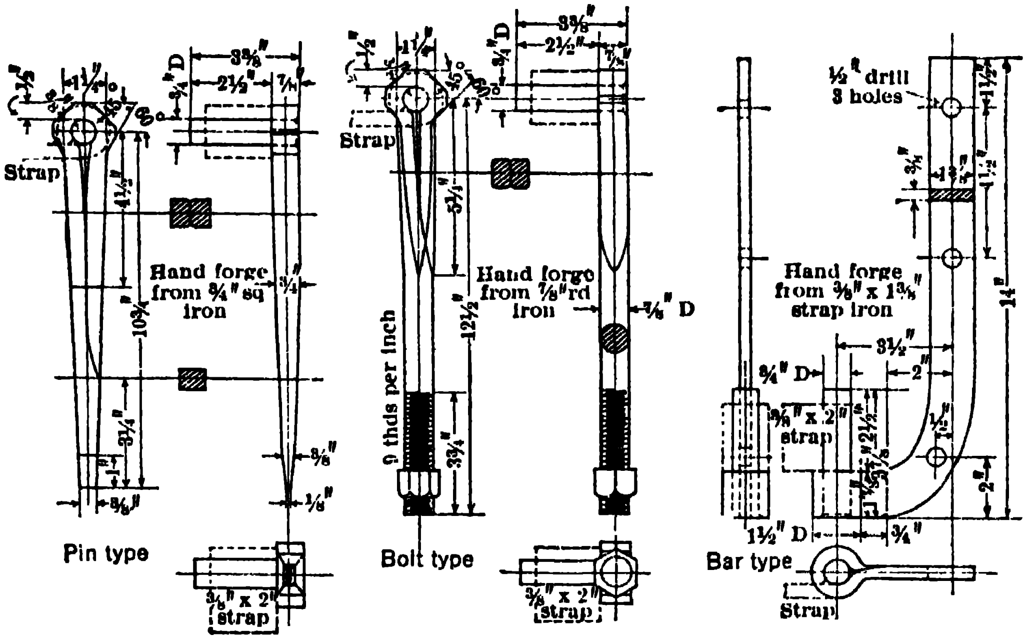


Fig 4. Door Hooks, or Studs, of Strap-type Hinges (27)

Curtains of several narrow, overlapping strips of non-flammable brattice cloth, hung from the roof, often replace doors on entries in bituminous, and on breast manways, in anthracite practice.

Air locks. Where opening a door would seriously interfere with ventilation or create hazard, an air lock is formed of 2 doors, only one of which is opened at a time. Distance between doors is adjusted to the traffic. On main roads in gaseous mines, a third door is often added, to function if either of the others is disabled; required by law in Pa anthracite and some European countries. In metal mines, an air lock is sometimes used where press-difference is high, to facilitate opening the doors, as the net press tends to distribute over both doors. Where the press on air-lock doors makes opening difficult, a small shutter may be inserted in each door, to equalize press before opening.

Automatic doors. In gaseous mines, attendants are required, often by law, at important doors and air locks. Sometimes they may be replaced by an extra man on the motor crew, or by automatic doors operated by bell-crank lever connected to a false rail, depressed by wt of approaching car. Such a device, common in flat and light-pitch coal workings, has been adopted in a few metal mines; not used in steep-pitch coal workings. On main motor roads of metal mines, doors operated by comp air are preferred. A motor-operated door, controlled by trolley-wire contacts, is increasing in use for main motor roads of metal mines.

Remote-control doors. Many metal mines use doors operated from a distance by wires attached to the valve of a comp-air cylinder (Fig 5). The door is opened by the piston, and closed by a counterweight when press is released. Similar designs operate by water press.

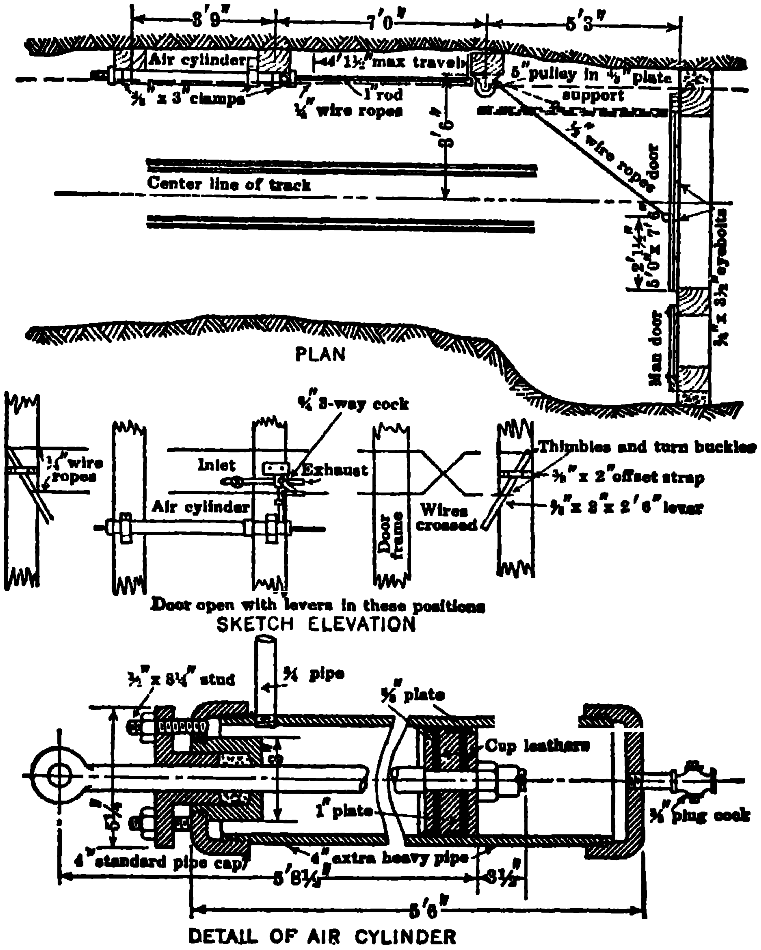

Fig 5. Device for Operating Ventilation Door by Comp Air, Metal Mines (31)

Fire doors and their control. In case of fire the veloc of certain ventilating currents should be immediately reduced without changing directions of flow. As stopping the fans does not stop mine air currents, the only sure means is to shut off all main airways with doors. These are normally blocked open and used only in case of fire. They resemble ventilation doors, except that those installed in timbered sections are usually of fire-proof or at least fire-resistant construction. Best position for the main group of fire doors is on all open airways off the main or operating shafts; many metal mines are so provided and some have installed remote control on sets of doors adjacent to particular shafts, so that all may be closed from one or more positions, particularly from surface. The control utilizes water press, comp air, or elec mechanisms to withdraw a latch, which normally holds the door open against the pull of a counterweight; the device may act by applying press or current, or by removing it. Continual inspection of such mechanisms is important; failures due to ground movement and corrosion are common enough to retard the spread of this useful idea.

Costs of doors. Costs for substantially constructed 4.5 by 6.5-ft doors in Ariz copper mines in 1928 (31) were: door only, $25; door in concrete frame, $50; air-operated door in concrete frame, $175; same, with adjoining narrow man-door, $225. A rail-operated automatic door with adjoining man-door is said to cost approx $300. A temporary type of light wooden door in wooden frame of aver size costs $15–$25.

Line brattice is a lengthwise stopping of light construction (like a temporary stopping), dividing a single opening so as to direct air flow to a gassy working face. It is used in moderately gaseous workings to conduct air from the last crosscut to a development face; also in rooms in very gaseous workings, particularly pitch workings (see Fig 8); usually made of random lengths and widths of 1-in rough boards nailed to each other and to posts of small diam, set on 4 to 6-ft centers; joints are sometimes clayed for tightness. Nonflammable cloth, usually jute but termed " canvas," is often used, especially for room brattices in bituminous mines; it is hung from narrow boards nailed to the posts along roof and floor. Canvas is also used for temporary extensions, and is then hung from small wooden pegs set in roof. Random lengths and widths of light gages of sheet steel " seconds " are used in Ala coal mines at a first cost (comparable to canvas) of 20¢ per sq yd, and last much longer than the 4–5 months aver life of canvas (32). For long extensions of single openings, to make connections in coal mines (" cross-measure tunnels " in Pa anthracite), line brattice is substantial, usually of concrete walls or packed filling between heavy double-plank walls. In rock openings, small pressure-release panels are inserted in the brattice for protection against blasting concussions (27).

Pipe as a substitute for line brattice (common in steep-pitching measures of the Middle Pa anthracite field) is of 24- to 30-in diam, extending to development faces from a board stopping at the last crosscut. This is airtight, and avoids leakage, the major defect of line brattice. In metal mines, auxiliary fan-tubing ventilation replaces line brattice, and is rapidly increasing in coal mines, particularly in deep European mines and U S bituminous mines using mechanical systems of mining (Art 6).

Deflector brattices. A loose stopping for deflecting air current from its normal path is usually termed " deflector brattice " in metal mines, or simply " brattice " or " check " in coal mines. Placed across an airway in a coal mine, it often serves to " hurdle " the air into a high spot in the roof where explosive gas would otherwise collect. Deflector brattices have been tried in metal mines for increasing aver veloc through working zones, by constricting the flow. They are of rough wood construction; canvas brattices are not successful in metal-mine stopes, due to damage by blasting concussions. Deflector brattices are used in hot metal mines to keep convection currents, from dead ends, out of a cooler intake airway, as such currents cause multiple small-temp increases in the cooler air current.

Regulators are stoppings with openings of adjustable size, for adjusting resistance to flow, in series with normal resistance of the airway or mine section, to allow only the vol of flow desired. They should be placed to cause min press-differences on stoppings: on intake side of circuit in a press system, and on return side in an exhaust system. Regulation by adding resistance is common in coal mines, but in most metal mines has been confined to inactive openings, where a small air flow is sufficient to prevent falls or excessive decay of timber. Usually a door is fastened open; if press is high, blocks are placed at both cap and sill to prevent warping. As a regulator is merely an orifice in an airway, its pressure loss and size can be calculated for constant conditions from data on orifice-press losses (Art 10). In practice, the conditions of possible use are largely unknown at time of installation, and a large opening is best, which can be adjusted by trial more accurately than by calculation.

Types of regulator. A door set partly open is sometimes used as a regulator, but the common construction is a stopping with a rectangular opening and adjustable sliding door, often known as a box regulator. Iron slides in concrete stoppings are common on important airways and locked in position; but a wooden slide door in a brattice is more usual, as tightness is not required. The slide is dispensed with on minor airways, and the opening is then adjusted by nailing boards on or ripping them off.

Overcasts. Crossing of air currents without intermingling is effected by overcasts (" air bridges " in Pa anthracite), made by blasting down part of the roof at intersection of airways and building an airtight structure in the space so formed. Although often of wood, more substantial construction is now required; usually of concrete with the floor slab reinforced by old rails (Fig 6). Costs of these range from about $250 where little rock work is required, to $350 for aver flat-pitch bituminous conditions and $500 and over for large structures in moderate to steep-pitch anthracite workings. Undercasts, made by blasting up the floor at intersections, are rarely used on account of the danger of filling with water or debris. Crossings are practically never used in metal mines, as the ordinary layout does not require them. Minor return currents are sometimes passed through intakes in large-diam pipes. Large culvert pipe has been used in coal mines, well as sectional-steel liner plates. Multi-seam coal mines often substitute rock drives to adjoining seams for overcasts (27).

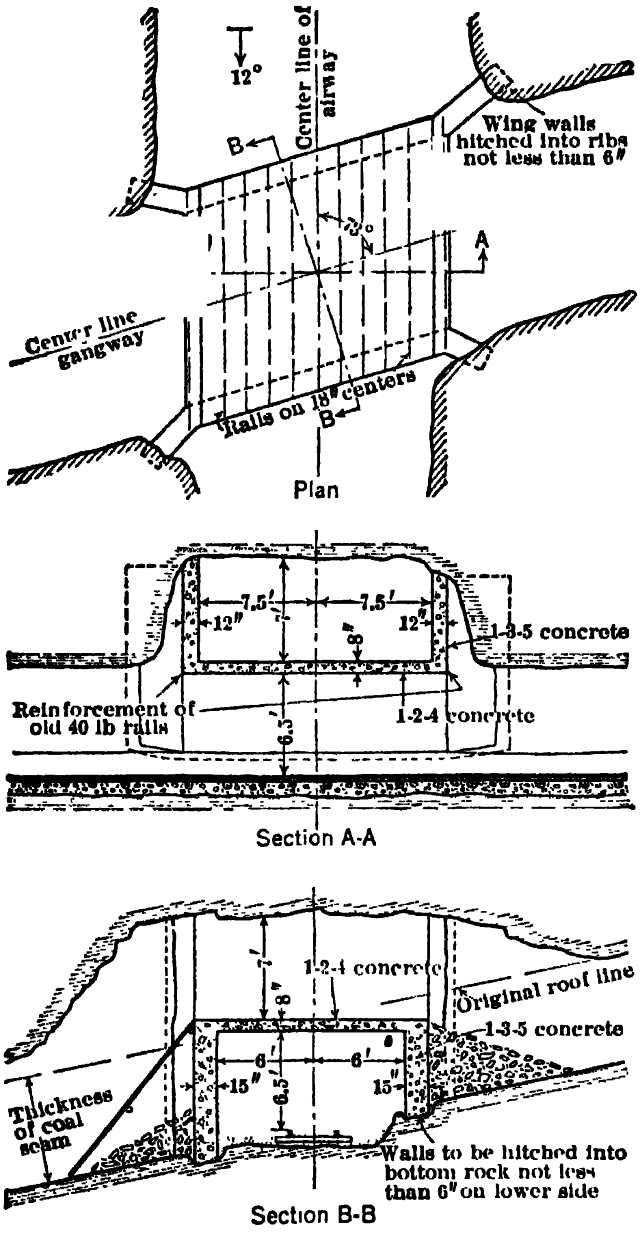

Fig 6. Overcast of Reinforced Concrete (27)

6. AUXILIARY VENTILATION

Fan-pipe installations, whereby air is forced through small-diam pipes to dead-end working faces, or exhausted from them, are common in metal mining and tunnel driving, under conditions of length and high cost of excavation for which line-brattices are not suitable. Although largely used in the Comstock (Nev) mines before 1850 (16), the real development of fan units and piping, particularly canvas pipe (20, 33), started in the U S in Butte about 1915, for combating effects of high temp; then spread to other metal-mining districts with similar problems, and later to coal mines (where permitted), where objectives are reduced leakage due to fewer breakthroughs, and better and cheaper ventilation in mechanized-mining areas. Pipes over 4 miles long have been used in driving tunnels.

Fans of blower type are preferred in both metal and coal mines, because of better cooling effect, better dilution of gases at the face, and in permitting use of canvas tubing. With this type, recirculation should be prevented by placing the fan, or a connection to its inlet, in an intake current at least twice as large as the fan circulation. In coal mining (34), fan inlet should be at least 10 ft from the nearby edge of nearest return current, and fan should not take over 40% of total circulation. Exhaust and reversible fans are preferred in driving long tunnels. Exhaust units discharge blasting smoke, gases, and dust through the pipe, whereas with blower units these return through the tunnel at very low veloc. Reversible units have special dampered ducts at the fan to secure flow in either direction; usual practice is to exhaust for a time after blasting, otherwise to blow. Advantages of both systems are sometimes secured by using 2 blowers: a large unit near the face, discharging to the main circulation or to surface through canvas tubing; and a smaller unit, just outby the larger, blowing part of the tunnel intake air to the face for ventilation (Fig 7). The fans must be far enough from the face to be uninjured by blasting. Differences in ventilating effect between exhaust and blower types depend largely on differences in veloc distribution and convection current effects (Art 12), both of which favor the blower. Air movement is perceptible only a few ft in front of a pipe inlet, but 20–30 ft from a pipe discharge. Actual veloc depends primarily on pipe area at inlet or discharge and is little affected by shape (36, 37). For exhaust units, temp differences between end of pipe-line and face are small, and convection effects negligible. For blower units, temp difference is often large and convection effects important. Anaconda Copper Mining Co (38) uses blower units with narrow-slot discharge, to control direction of discharge so as to produce minimum dust concentration at the breathing level.

Type of fan unit in metal mines is usually the direct-connected motor-driven centrifugal; for elec drive in coal mines, the propeller type. For protection against explosive coal-mine gas, comp-air drive should be used, and fans operated continuously or not at all. Comp-air units are useful auxiliaries at metal mines for emergencies and fire fighting. Comp-air injectors (Art 14) are used for short pipes on temporary jobs; their effic is low, but so also is first cost.

Pipes may be of wood, iron or " canvas," usually jute treated to render it airtight and resistant to fire and decay. Wood-stave pipe and heavy gages of iron pipe are usually limited to long lines in tunnel driving. Canvas tubing and light-gage galvanized iron pipe of 8–16 in diam, occasionally larger, are common in metal mines; 8 in for lines to 250 ft long, 10–12 in to 500 ft, and 16 in to 1 000 ft or more. Canvas is good for temporary installations and where a straight line is impracticable. It comes in 25, 50 and 100-ft lengths with sewed-in couplings, and is attached to a wire fastened to timbers or to rib or roof pegs. It is more easily handled than iron pipe, stands blasting concussions better, but is often torn in service. Iron pipe is good for more lasting installations and for straight lines; press requirements for straight lines are lower than for canvas tubing, in approx ratio of 3 to 5, and joints can be made tighter. Sections are usually about 10 ft long, made up to 12-in diam of single sheets with crimped seams; over 12-in, of 3 sections with all seams riveted-and-soldered, or longit seams crimped. A small swage, or bead, is often formed near ends of separate sheets, used in assembling sections, for extra stiffness; for single-piece sections, ends are swaged and two or more thin iron bands are spot-welded at intermediate positions.

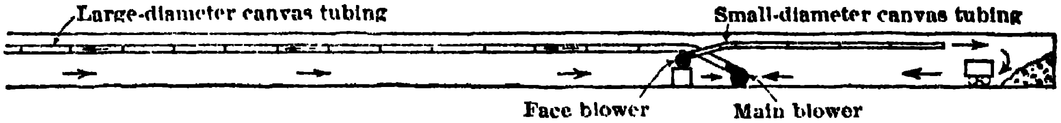

Fig 7. Fan-tubing Installations for Ventilating Long Dead-end Openings with Canvas Tubing (9)

Pipe lines should be as straight as possible and extend to within 15–25 ft of face for max benefit. Depending on type of rock blasted and pipe material, pipe within 25–200 ft of the face must be removed before blasting. To put blasting sections quickly back in service, use of gas masks is recommended for headings; telescopic sections may be used in shafts (12). Blasting gases are usually blown back to the pipe-end with comp air (35).

Joints in canvas tubing usually permit slight leakage which can not be controlled. Slip joints, with male ends pointing downstream, are common for iron pipe, and since pipe ends are easily deformed, large leakages are frequent; remedy is to wrap joints with asphalt-soaked muslin. Joints may be made tight against mine press by using draw-bands over wrapped joints, with pipe ends and bands swaged. Joints in heavy-gage iron pipe used in long tunnels (up to 5 miles) were formerly equipped with expensive flanges, but now are usually welded in place.

Capacities for mine units vary from 500 to 5 000 cu ft per min, occasionally more, depending on size of opening and heat, gas, or dust conditions. For aver conditions in metal mines, roughly approx sizes (51) for 30–50-sq ft openings in warm rock (85–90°) are: 8-in tubing with fan driven by 3-hp motor to give about 1 000 cu ft per min at 4–5-in press for lengths up to 250 ft; 12-in tubing with fan driven by 5-hp motor to give about 2 000 c f m at 5 to 6-in press for lengths up to 500 ft; 16-in tubing with fan driven by 10-hp motor to give about 3 000 c f m at 6 to 8-in press for lengths up to 1 000 ft; and similar fans in series for lengths much over 1 000 ft. If tubing lines are in aver condition, 40–70% of the air passing the fan will be discharged at end of line.

Pipe costs. A 12-in pipe of aver wt, in 10-ft lengths for iron or 50-ft lengths for flexible tubing, costs approx 75¢ per linear ft in small quantities. Costs for other sizes vary roughly with content of material, that is, with diam. For flexible tubing, cost per ft is about 10% lower for 100-ft sections and 10% higher for 25-ft sections. Under aver conditions, cost of installing flexible tubing is about one-third that for iron tubing. Approx aver figures are 2¢ per ft for flexible and 6¢ for iron pipe.

Costs per cu ft of air delivered at or near the working place by fan-tubing methods vary widely, but an approx total of capital return, power cost, and maintenance is 0.2¢ per 1 000 cu ft, against an aver of say 2¢ for comp air released at the face and 0.05¢ for main-fan circulation.

7. LEAKAGE IN VENTILATING SYSTEMS

Effic of distribution. Proportion of entering air that actually passes through working places, is the real criterion of a ventilating system. It is just as important as effic of fan, and much more difficult and expensive to attain, because leakage in solid ground can be minimized only by substantial construction, and in fissured and pervious ground is difficult to control. Leakage losses are generally large and effic of distribution low. Leakage at stoppings, doors, and fan installations are common causes of poor distribution.

Effic in practice. Williams' tests in 16 Ill coal mines (30) showed that the max per cent of the entering air reaching the last crosscuts of splits was 33.5%, aver about 20%, and in 3 instances less than 10%. Davies (28) says that in high-resistance coal mines in So Wales not more than 20% of the air moved by the fan reaches coal faces. In metal mines where all main fans are underground, it is impossible to avoid large recirculation; usually, such fans handle 1.5–3 times the amount of air entering the mine. However, aver practice is much better than these examples indicate. In the aver coal mine, 30–50% of fan air reaches active workings; in the aver metal mine, 50–60%, since fewer stoppings are involved; in both, max is probably about 85 per cent.

Leakage through permanent stoppings. The bane of coal-mine ventilation is leakage through stoppings between adjoining intake and return airways, whereby air is short-circuited without passing through active workings. Leakage is dependent on construction and press-difference p (see Art 11 for effect of leakage on pressure-loss computations), varying directly as p for very small openings in packed material and as $\sqrt{p}$ for ordinary leakages. Williams (30) gives test averages in Ill coal mines, showing range of 6 cu ft per min for 8-in concrete walls, to 171 c f m for faced gob-wall and good board stoppings. Aver press-differences (not given) were probably 0.1–0.2 in of water.

Leakage through doors is an important factor in all mines, and depends on construction and press-difference p, varying as $\sqrt{p}$. At a press of 1 in, common in metal mines, a good door will often pass as much as 3 000 c f m unless precautions are taken, such as covering the edges with canvas strips. Leakage may thus be reduced to about 1 000 c f m on active doors, and to 500 on inactive doors. In coal mines, aver press-difference, where doors are used, rarely exceeds 0.25 in of water, and the above leakages are halved for the same door conditions. However, canvas flaps are less effective at low press and less common in coal mines, and the ordinary " good " door will usually pass 1 000–1 500 c f m. In good Pa anthracite usage, 1 by 6-in boards are set with one edge against the door, when in the normal closed position, and nailed to inside of frame on top and sides. These are adjusted from time to time, as required by warping of the door, or effect of ground movement on the frame (27). Excessive leakage at doors may be due to lack of a tight seal between frame and walls, lack of water-seal on drainage ditches, and excessively large openings for pipes, tracks, and trolley-wires.

Leakage at fan installations, where max press-difference occurs, requires especially tight construction, for which wood is unsuitable for both effic and safety. Under aver conditions of substantial fireproof construction, leakages of 1 000–2 000 cu ft per min for small installations, to 3 000–10 000 for large installations, can be expected on the basis of available data (9).

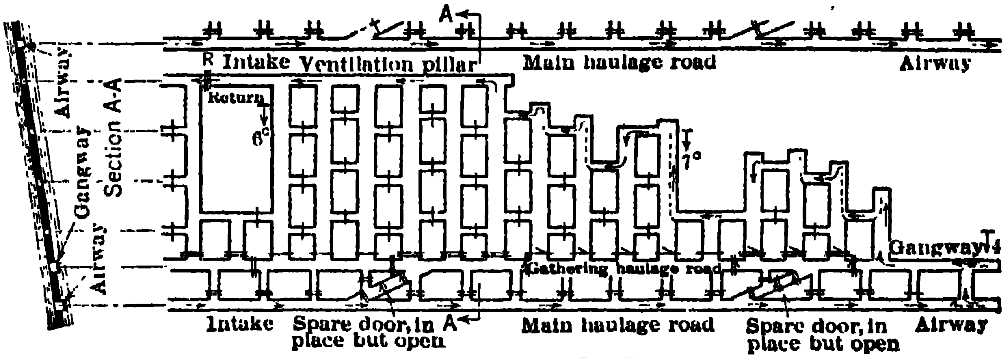
Leakage at fan shafts. Collars of fan shafts and portals of fan drifts should be thoroughly sealed to rock, as by concrete construction, to prevent excessive leakage through ground that may appear tight. Shaft collars of waste from sinking operations will " leak like a sieve " and spoil an otherwise good installation.

Leakage through shaft walls. The practice of carrying intake and return currents in adjoining shaft compartments, though generally regarded as obsolete and forbidden by law in some states and most European countries, is still common at many Ind and Ill mines and anthracite mines in Northern Pa field. In the former, excessive leakages through the curtain wall are common; but in anthracite mines, substantial 16-in brick and concrete walls hitched 2 ft into the side walls practically eliminate leakage unless ground movement is excessive.

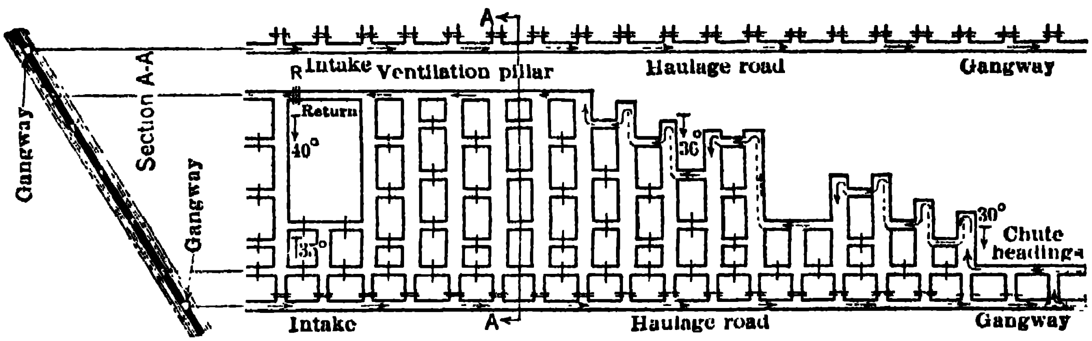
Leakage through strata is normally negligible, but practically always present, as shown by the usual low pressures on fire-area seals even in " good " ground. Where air must be carried through broken, caved, or filled ground, leakages are often amazing: losses of 90% in only 1 000 ft of travel are not uncommon. The usual remedy is new airways through better ground, with air broadcasted through broken ground to similar returns or to surface. In metal mines, booster fans are sometimes used to minimize press-differences at local areas on airways where leakage would otherwise be excessive. Leakage in airways passing through pervious ground may also be reduced by carrying the air through by low-press fans operated in series to minimize press differences.

8. EFFECT OF MINING METHODS ON AIR DISTRIBUTION

General effect of openings on distribution. Exact conditions of distribution at working places where mineral is extracted depend largely on details of mining method, both as to position and type of openings, and time-sequence in driving them. In general, the larger and more numerous the openings, the better the air conditions at working places. However, the prime need for good ventilation is 2 or more openings to all working chambers, to effect through-circulation. To remove blasting smoke to the main flow, for diluting strata gases, or to provide air-motion cooling in warm atmos, quantity of flow usually is less important than veloc. For the same power load, quantity is increased, but veloc decreased, as openings are increased in number and size, whence openings should be of minimum size at working places, and max size elsewhere in the circuits. Exactly the reverse is the normal result of all mining methods, since working places are large openings, and connections much smaller. Low veloc of flow in working places can be increased by attention to details; but for aver conditions velocity requires little consideration, because even very low veloc on through-circuits, with diffusion and convection currents in openings off through-connections, usually suffice. Veloc is important only in gaseous coal mines and for high temp.



A-Workings on Flat Pitches



B-Workings on Moderate Pitches

Fig 8. Methods of Ventilating Gassy Room-and-pillar Workings (27). (Legend as for Fig 2)

Ascensional ventilation. For inclined working places, the relative elevations of connections are important because of natural-draft and convection-current effects. Essential requirement is that connections be made to airways above and below the working openings, so that ascending through-circulation is possible and max advantage is taken of natural-draft press. To utilize available flow in both inclined and flat workings, the rule of next importance is that through-openings be offset with respect to the working openings, so that the actual working place is not a long dead end off a through-opening.

Room-and-pillar methods are practically standard in U S coal mines, and, although details of layouts of workings differ, the essential features in active working sections are shown in Fig 8. Development is by double-entry, employing 2 parallel openings connected by crosscuts 60-100 ft apart.

In steep-pitch workings, air may be distributed as in Fig 8, B, except that "chutes" connecting haulage-road and airway, also the rooms (" breasts "), are partly filled with broken coal, leaving one manway open in the chute and one along each rib in the room

(Fig 9). These manways are bratticed off below the last open crosscuts, and carry air to the face on one side and back to the open crosscut on the other. Manway and airway brattices and chute stoppings have small canvas-covered openings for passage of men. Chute and manway openings in chute stoppings are small, and are sealed off when the chute is no longer used.

In moderate-pitch gaseous workings, the breasts are carried open, and line brattice is used to convey air to the faces; distance from face to end of brattice, and tightness of brattice, depend on gas conditions at the face. Separate lifts, or sections along the pitch, are usually kept separate by ventilation and drainage pillars, and face-ends are connected (Fig 8, B) to avoid gas accumulations in dead ends extending to the rise.

In flat-pitch gaseous workings occurs the extreme of ventilation control, as in Northern Pa anthracite field (Fig 8, A). Air is carried to both development-ends and room ("chamber") faces by line brattice and is practically air-locked all the way. Intake air is carried on the lower road direct to development faces, and main-haulage is on the intake airway. Chambers are doored off while active and walled off when inactive. Upper road is used only as an airway for development and for gathering-haulage service in active sections, and is walled off when no longer thus required. In gaseous bituminous mines and less-gaseous anthracite mines, rooms are generally turned off only one road of a pair of entries. To bring haulage near the rooms through intake air, the intake is sometimes carried in on the room entry, passes through the rooms, then through development faces, and returns on the adjacent entry. Generally, however, most gas occurs in development faces, and air is carried direct to such openings and then through the rooms, with only enough coursing to meet gas conditions; haulage is then on return air, mixed by leakage with intake air. Line brattice is seldom required in rooms in flat bituminous workings. For very gaseous conditions, doors on room necks and brattices in room crosscuts generally suffice. For less gaseous conditions, the latter are not required; the air is forced to travel through the rooms by check curtain brattices on the entry in the active section, sometimes between all room necks (Arkansas).

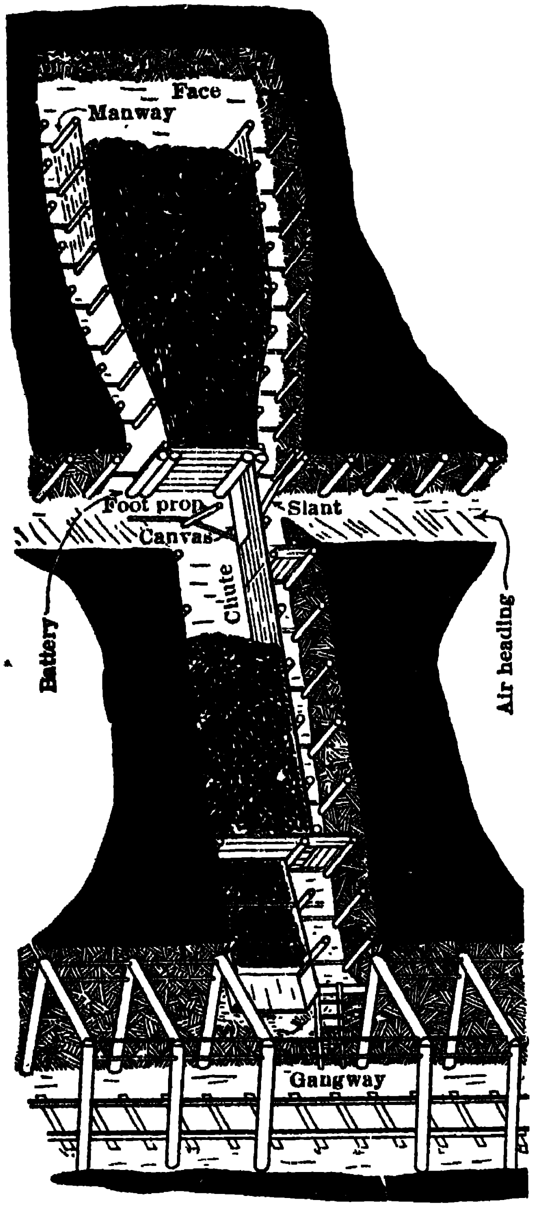


Fig 9. Start of "Full" Breast in Steep-pitch Breast-and-pillar Mining (P & R C & I Co)

Flat non-gaseous workings. In these, only minimum control is needed. A few check curtains on the room entry serve to keep the air "broadcasting" through the rooms. Even these are often omitted, and the only air passing through rooms is that due to natural splitting, occasioned by variable resistances to flow. Interference by cars in entries of small cross-sec forces most of the air to take lower-resistance paths through the rooms and room crosscuts. Rooms are often driven off both entries, so that the intake must necessarily be through one group and the return through another. Often, air requirements are so small that several sections are ventilated by a single split of air, and the return of one section becomes the intake of another, often "sweetened," however, with small additions of intake air direct to each section (see Coal Mining, Sec 10).

Longwall methods used in U S are mostly short-face types with working face comparable to the rib of a room, and air-distribution conditions are like those in room-and-pillar methods. In typical longwall workings (Fig 10) as in Europe, with branching roads from centrally-located downcast and upcast shafts to long working faces, few splits are required and large-volume flows sweep the faces, an important advantage of this system.

Metal mining methods in rare cases are comparable to flat non-gaseous coal mine layouts; usually to multi-seam, steep-pitch, coal operations, but with more variety of mining method. Strict coursing of air currents is not required except to cope with high temp. Larger quantities of explosives are used and blasting smoke is more of a problem than in coal mines.

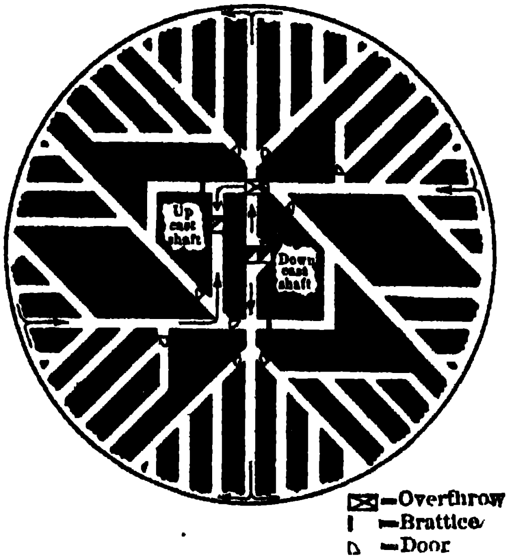

Fig 10. Ventilating System for Longwall Mining

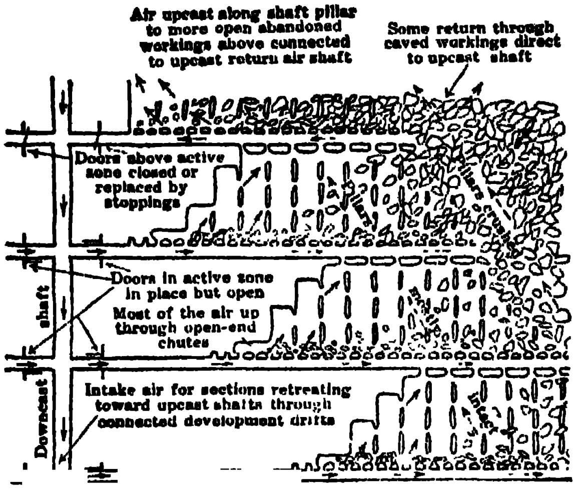
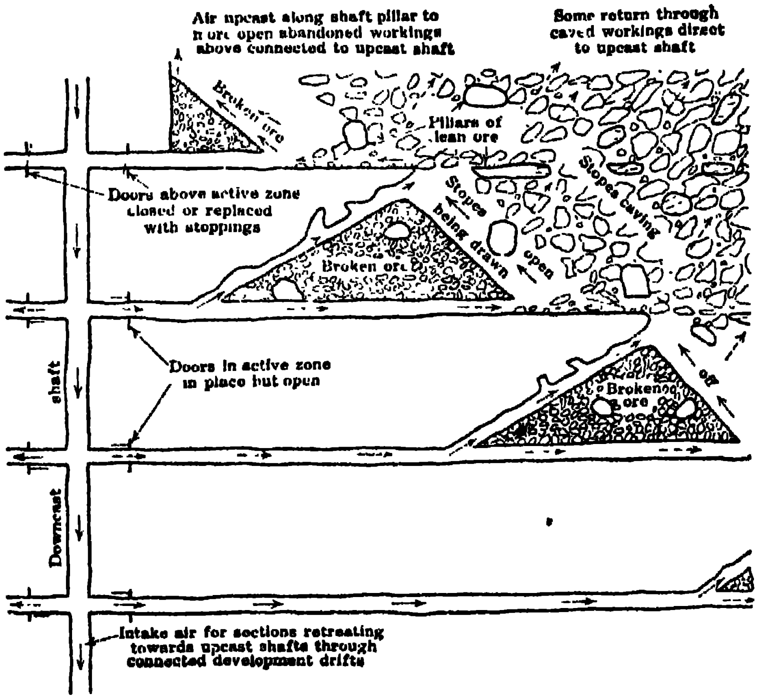


Air upcast along shaft pillar to more open abandoned workings above connected to upcast return air shaft
Some return through caved workings direct to upcast shaft
Doors above active zone closed or replaced by stoppings
Doors in active zone in place but open
Most of the air up through open-end chutes
Intake air for sections retreating toward upcast shafts through connected development drifts
Downcast shaft

Fig 11. Method of Ventilating Retreating Open Stopes (9)

Open-stope workings are usually large and thus easily ventilated, as air requirements are low. There must be at least one opening from each large working place to the level above. Veloc of air travel is usually very low, but blasting smoke and gases have only a short distance to go before reaching inactive workings, where their slow travel is of little importance. Depths of mining which involve high rock temp usually also require changes in mining methods (as from advancing to retreating stoping), and openings cave more readily, automatically diverting air flows to active openings.



Air upcast along shaft pillar to more open abandoned workings above connected to upcast shaft
Some return through caved workings direct to upcast shaft
Broken ore
Pillars of lean ore
Stopes caving
Stopes being drawn open
Doors above active zone closed or replaced with stoppings
Broken ore

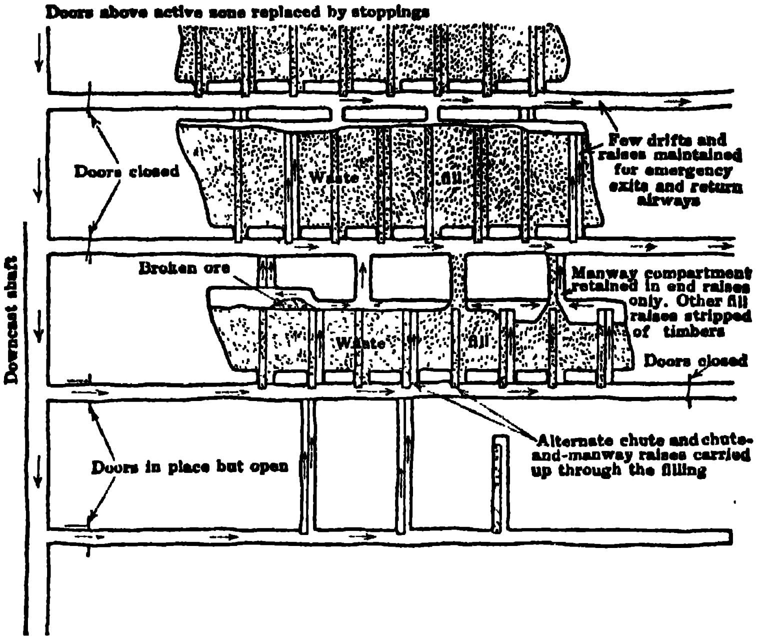
Downcast shaft
Intake air for sections retreating towards upcast shafts through connected development drifts

Fig 12. Method of Ventilating Retreating Shrinkage Stopes (9)

Recently-caved ground near active openings is usually still fairly permeable to flow and constitutes a second opening of low resistance for retreating working faces (Fig 11). Even after caved areas have become compacted, they will usually pass considerable air, chiefly along pillars and solid boundaries. Eventually, with increased depth, special return airways must be provided.

Shrinkage-stope workings. Ground that can be worked by temporary-fill, or shrinkage-stope methods, is also easily ventilated. For safety, each stope should have 2 openings, and for good ventilation these should connect to the levels below and above. The opening at the working face is restricted, and, with blasting confined to end of shift, the small quantities and low veloc of the normal air flow give good ventilation, sometimes permitting blasting of large slabs during the shift, although such blasting is usually confined to the lunch period or end of shift. In continuous shrinkage stoping, connection to the level below is usually provided by the chute-raises driven during advance development; even with a shallow depth of coarsely broken ore, these will often permit enough seepage of air to ventilate the stope. Where a floor pillar is left under the level above, it must be pierced at intervals. A shrinkage stope not connected to an upper level is usually poorly ventilated, particularly where the stope-wall rock is warmer than the air in the airway to which connections are made. Where the wall rock is colder, natural draft may give good ventilation. Often the ventilation of a shrinkage stope, not connected to an upper level, could be improved easily by a loose curtain or canvas door in the lower level, between the end openings into the stope, thus hurdling air to the working face.



Doors above active zone replaced by stoppings
Doors closed
Waste
fill
Few drifts and raises maintained for emergency exits and return airways

fill
Doors closed
Alternate chute and chute-and-manway raises carried up through the filling
Doors in place but open

Fig 13. Method of Ventilating Horiz Cut-and-fill Stopes (9)

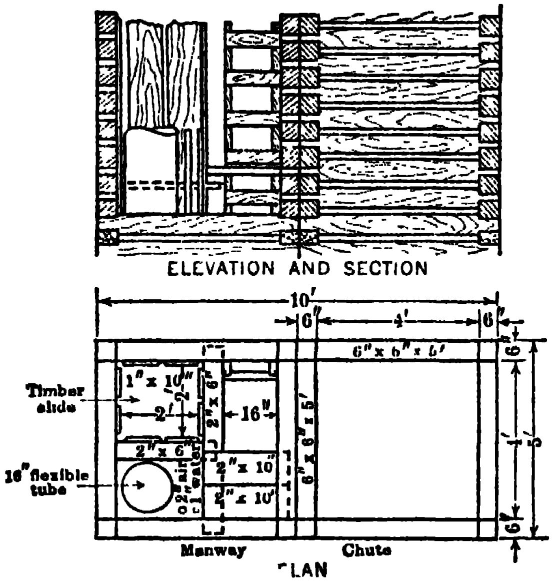

Fig 14. Two-compt Cribbed Raise (9)

Retreating shrinkage stoping on moderate pitches provides good ventilation conditions (Fig 12), as the working chamber is a relatively confined space with large openings to the levels below and above, and the slowly caving ground back of the broken ore makes a low-resistance return. If desired, flow can be confined to the stopes by temporary stoppings or doors inside the last active drawing chute.

Filled-stope workings. Their natural layouts are favorable for ventilation, because they require connections to the levels below and above. However, ground conditions often limit the size of passages, so that air flows are small, even with mechanical ventilation. The larger compartments of raises are usually full of ore or fill, so that circulation depends on the manway compartments, of which two are always kept open for safety. In a stope in its early stage, both manways may lead off the lower level; in later stages the only one maintained may lead to the upper level. Or a single manway may go directly from level to level; stope ventilation then depends largely on eddy currents off this manway. For good air conditions, the layout should provide ascensional flow, with air coursed through the working area (Fig 13). Manway design is important; a good design used in many western metal mines is shown in Fig 14. As veloc must increase in high-temp ground, the cross-sec of openings must be minimized, and filling should closely follow extraction. Rill stoping and filling, especially when retreating, favor stope ventilation.

Top-slicing provides poor natural conditions for ventilation, due to dead-end workings and to heat from decaying crushed timber in the mat. For good results, special openings for air must often be made. There are 3 general methods: "hurdling" from the level below by well-arranged stoppings and doors; connecting each floor in succession to a raise in an adjoining section, connected to the return airway; and connecting, to a return airway, the open space above a thin mat and fill. Miami Copper Co, Ariz (1918), using mechanical ventilation, employed a ventilation level of closely spaced openings, with numerous doors and stoppings to force air through closely spaced raises to large top-slice operations; results were so good that continuous blasting was possible in the stopes. In general, the hurdling method (Fig 15) is applicable to aver top-slice conditions, the other two applying only to special conditions of advancing or retreating methods, or of mining small sections or pillars in ground that stands well.

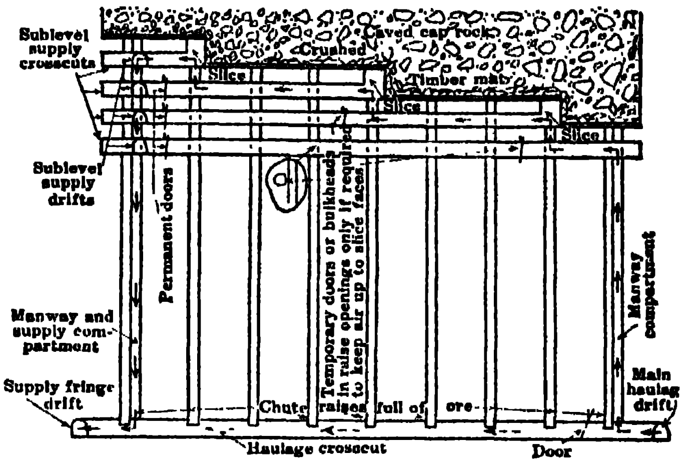

Fig 15. Hurdling Method of Ventilating Top-slice Stopes (9)

Undercut caving involves many development openings without upper connections (unless made to old prospect openings); but the many openings between undercut and grizzly levels usually induce convection currents, with enough circulation for 1-shift work. Mechanical ventilation is always used, and provides quick clearance of smoke from working places and grizzly drifts, where intermittent blasting is required. In general, intake air along the main-haulage level is carried to the grizzly level through raises driven for new development, and passes thence, through active drawing drifts, to fringe-drifts connected to the returns. Due to difficulty of keeping other raises (in drawn and drawing sections) blocked off with waste or ore, control is uncertain, but some control is possible by using doors or stoppings at fringe-drifts, to close all but the active drawing drifts. Actual layouts often preclude simple methods, and in 1929 the Miami mine was considering a special ventilation level for a new section, for better control of ventilation (31). Good ventilation of boundary-caving shrinkage workings usually requires a well-planned system of connected openings.

9. VENTILATION MEASUREMENTS

Quantity of air passing in an airway is expressed in cu ft per min (c f m); not determined directly, but calculated by multiplying the airway area in sq ft by the aver veloc of flow, ft per min.

Measuring current veloc. Usual methods are smoke-clouds for low veloc, anemometers for moderate to high, and pitot-static tubes or special anemometers for very high veloc. Measurements should be made where the cross-sec is regular and preceded by as long a straight section as possible. The observer should not obstruct or disturb the air current, by causing local increases of veloc around his person; his best position is in the plane of measurement at arm's length, or farther, from point of measurement.

Velocity distribution. As veloc is variable over any section, areas must be traversed by multiple readings. One-point observations, if exactly the same point is used, will show relative changes. Max veloc in a straight airway of uniform cross-sec occurs at middle of section and is about 1.2 times the mean veloc. At a constriction in a straight airway, side velocities are increased and mean veloc approaches, or may exceed the center veloc. At an enlargement, side velocities are decreased, and center veloc may be as much as 1.4 times the mean veloc.

Smoke-clouds may be used to determine direction and approx magnitude of flow at velocities below the usual anemometer range. More accurate instruments, including special anemometers and the (dry) kata-thermometer, are available, but their use in mines is limited. Smoke-clouds may be generated with an aspirator bulb blowing puffs of air through a glass tube containing granulated pumice, saturated with anhydrous tin or titanium tetrachloride. Clouds generated to travel at the quarter points of cross-sections give results averaging about 10% high. Variations in flow are easily detected and observations may be limited to periods of normal flow, a decided advantage where velocities are low.

Biram vane anemometer having a range of 150–2 000 ft per min is usual for moderate to high veloc. It is a small windmill (Fig 16) with oblique blades connected through clutch and gearing to one or more dials, which record the velocity of air passing the blades. Observations must therefore be timed: difference between the final and initial readings divided by time in minutes gives veloc in ft per min. Recent designs have a zero reset, giving the total reading directly. Common size is 4-in diam. Side opposite the dial is held against the airflow, usually by hand; but a rod can be attached for more accurate measurements and greater reach.

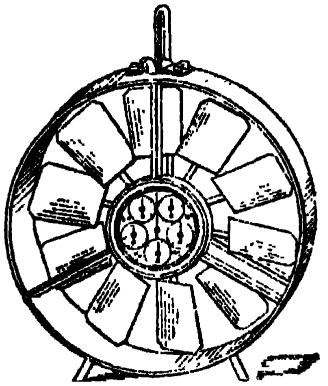

Fig 16. Anemometer

Anemometer calibration. Errors in single readings by Biram anemometer range up to 10%: too high at high veloc, too low at low veloc. Calibration charts or tables are furnished by the maker. Experiment (39) has shown that the relation between registered veloc, V_0, and true veloc, V, can be expressed by the straight-line formula $V = A + BV_0$, in which A and B are constants. A varies as the sq root of density, but values of A being about 30 for common types, the density effect is negligible.

Accuracy of anemometer measurements varies with method of use and with pulsating flow, which causes high readings. Ordinary methods of traversing by hand, without using calibration or method factors, may yield results up to 20% high for high veloc, as in fan ducts. With careful work, relative agreement within 2% is possible for successive readings. Timed hand traversing and use of calibration and method factors (9), give results within 5% under aver flow conditions. In precision traversing, with anemometer shaft guided by a frame, results accurate within about 2% are possible, and relative agreement of successive observations within 0.1% has been obtained (40) when flow is uniform. Holding the instrument by hand increases the reading about 10%.

Other anemometers. HIGH-SPEED INSTRUMENTS of the Biram type usually have half as many blades as the standard, but are otherwise similar. INDICATING ANEMOMETERS, although sensitive and convenient, are little used in mines, because: oscillation of the pointer prevents accuracy; many readings must be averaged to attain accuracy, and observations often involve interference with air currents. Common forms are: windmill types with devices similar to speedometers; and pivoted vanes, indicating veloc by the angle to which the vane is set. VELOMETER is a swinging-vane anemometer, in which the vane is enclosed in a housing with inlet and outlet openings, to which attachments are fitted for measuring veloc and press over a wide range of flow conditions. Impact press of the veloc (and press-differences) cause proportional flow of air through the instrument; and the momentum of this flow actuates the vane. In impact-vane instruments, veloc reading varies directly as the sq root of air density (end of Art).

Pitot tube apparatus is more practicable for measuring very high velocities than are special anemometers, as measurements are often made inside pipes and tubing where an anemometer cannot be used. It consists of a double-walled pitot-static tube (Fig 17) and manometer for measuring difference in press, transmitted through tubing from the two component parts. This press difference is equal to veloc press of the flow (see below). The apparatus is a primary device for air measurement, accurate in most designs to within 1% (39). APPLICATION. With V = veloc in ft per min; H_v = veloc press, in of water; w = wt of 1 cu ft of air (approx 0.075 for usual mine conditions), $V = 1\,098\sqrt{\frac{H_v}{w}}$ or $H_v = \frac{8\,310\,w}{10^{10}}V^2$

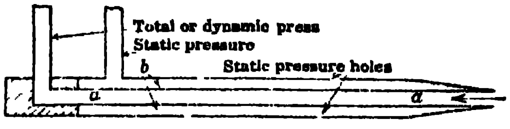

Fig 17. Pitot-static Tube

If $s = \frac{w}{0.075}$ = sp density of air, based on standard wt of 0.075 lb per cu ft,

$$V = 4\,008\sqrt{\frac{H_v}{s}}\text{, and for } s = 1,\ H_v = \left(\frac{V}{4\,008}\right)^2 = \frac{623}{10^{10}}V^2$$

For careful work, aver veloc must be the mean of computed velocities, not that derived from the mean of veloc pressures. Accuracy also requires precision traversing, and, for moderate to low veloc, very sensitive manometers; press is approx 1 in at 4 000, but only 0.25 in at 2 000 ft per min. Under mine conditions of high-veloc flow, the common vert U-tube manometer or "water-gage" is sufficiently accurate, and merely approx methods of traversing are justified.

Other pressure-difference methods, wherein veloc or quantity of flow is measured by the press change caused by an obstruction, such as an orifice plate, or by difference in cross-sec area, as in a venturi-shaped section, are rarely used in mines, although applicable to certain phases, as tests of fan-pipe installations.

Accuracy of air-flow measurements. Considering the normal variations in air quantities in mines, particularly on the split flow, accuracies of individual measurements of the order of 10% for low veloc and 5% for moderate to high veloc are satisfactory. For fan tests, and other purposes where care is justified, accuracy within about 2% is obtainable in absence of marked pulsations. Effect of pulsations in causing high readings can be allowed for if their amplitude and period are known (39); not the case in mine flow. Considering the aver inaccuracy of measurement, the reporting of flows below 20 000 c f m to the nearest 500 c f m, and over 20 000 c f m to the nearest 1 000 c f m, is sufficiently precise.

Absolute pressure of the atmosphere is usually measured by aneroid barometer, chiefly to determine air density (end of Art). Approx values are obtainable from tables of altitudes and temperatures (4), but as the abs press at any point may vary 1 to 2 in of mercury during the year, actual observations are better.

Aneroid barometer is a flat, circular, corrugated vacuum capsule with one side attached to a case and the other to an index mechanism carrying a pointer over graduated circles on front of case. Air pressures distort the capsule and thus actuate the pointer. Best aneroids are compensated for temp by a bar in the linkage, composed of two or more metals. Scales may be graduated to read inches of mercury, or approx equivalent ft of altitude, or both. Mine instruments usually have both, and should always have the mercury scale. For mines at very high altitudes and deep mines at sea level, instruments with special scale ranges are required. Small rugged types are better for mine work than larger and more accurate ones, as they stand sudden and large press and temp changes better without change in calibration. Accurate work requires occasional comparisons with a laboratory-standard vert-tube mercury barometer. With the best instruments there is considerable lag in press and compensation for large changes. PAULIN ANEROID (12) is a special design, in which distortion of the capsule is prevented by changing a spring tension, adjusted by turning a ring on the dial until a secondary pointer comes to zero position, whereupon the main pointer indicates pressure. Several concentric dials are used to indicate very small press changes.

Absolute-pressure surveys. Methods and instruments (41) for measuring abs press closely enough to determine small press-differences due to air flow are in the development stage. Approx results have been secured in main airways of flat-pitch mines, but difficulties in steep-pitch mines have led to a preference (42) for direct press-difference methods. High-precision standard aneroids are popular in England, where a special vert-tube barometer, the "contrabarometer," also finds some use. In Germany, the Askania Statascope (43) is favored; it is an aneroid, in which the base press can be set and small differences from it are measured. In the U S, the Paulin is most used, with graduations in ft of altitude only; and in coal mine practice, density differences are ignored by making direct corrections for differences in altitude, usually without material error. More precise instruments are required for use in minor airways.

Measurement of small pressure differences due to air flow is usually made on liquid manometers (U-tubes partly filled with liquid), by connecting each press to a separate leg of the U and measuring the vert difference in height of liquid due to difference in press. If a liquid other than water is used, its sp gr is determined and press-difference is expressed in inches of water at 60° F; 1 in of water equals 5.2 lb per sq ft or 0.0361 lb per sq in. Kerosene and alcohol are often used in more sensitive types; kerosene in permanent setups, because it does not vaporize or change sp gr; alcohol in the laboratory, as it does not cling to glass nor affect rubber tubing. Toluol is used in some high-precision gages.

Manometers. VERTICAL TYPE (water-gage) is so widely used in mine ventilation that press differences are usually termed "water-gage." Its simplest form is a U-shaped glass tube, partly filled with water and with scale attached. Where mine pressures are separated by a brattice, no tubing connections are needed, the gage being applied as in Fig 18. To facilitate reading differences in level in the two legs, the scale is adjustable to bring an even inch mark opposite one liquid level.

Precautions: (1) connections should be tested for air tightness by observing if the gage will hold a press when the ends are sealed; (2) where differences of elev are involved, composition and temp of air in connections should be the same as in the air current, so that small pressures due to unbalanced air columns do not affect the reading; (3) tube and tubing ends should be in quiet air to avoid small errors due to veloc effects on orifices. Where used in moving air currents, tubing should terminate in a plate or tube, like the static terminal of a pitot tube, having a small burr-less orifice in a surface parallel to the flow. INCLINED MANOMETER, or U-tube with both legs in an inclined plane, magnifies the reading and measures to 0.001 instead of 0.01 in of water; used for greater sensitivity, as in research or with pitot tube. Angle of inclination, accurately known and maintained, is deter-

mined by the magnification desired and sp gr of liquid used; its sine is found by dividing the reciprocal of the sp gr by the magnification ratio, or length (in) of slanting scale for 1 in of vert displacement of water. Instruments with fixed magnification and mounted on a leveled base are usual. For mine work, Weeks (12, 44) has designed a transit-mounted adjustable-slope instrument (Fig 19) suitable for measuring small press changes in short sections of airways. DRAFT GAGE, for fixed positions in power plants, is a manometer with one leg of large and one of small bore, proportioned so that over 95% of the vert displacement of liquid occurs in the smaller tube, which has a graduated scale; readings are made on this leg only. One reading only is required, whereas both levels of a uniform-bore U-tube gage must be read for fluctuating press-diff; but calibrations are required for accuracy. MICROMANOMETERS are precision manometers, for great accuracy, as in measuring low velocities by pitot-tube press methods, and for calibration of ordinary manometers. They resemble draft gages, with micrometer measurements of magnified scale readings and scales set to zero at the level in the large bulb in which, due to large area ratio, only an infinitesimal part of the total displacement occurs. Most types commercially available are of German make, as Prandlt's precision manometer (3) and Askania Minimeter (43). WAHLEN GAGE (45) is a precision manometer of a two-liquid, tilting gage (Chattuck) type, accurate to 0.0001 in of water (Fig 20). It consists of 2 unequal-bore U-tubes half filled with alcohol colored red with aniline, connected by a third U-tube which is inverted and filled with clear kerosene of a sp gr about 0.01 less than the alcohol. In one U-tube the large bulb is movable vertically by a micrometer. Junction of the liquids is in a tube of capillary size. A zero reading is obtained, with both bulbs open to the air, by adjusting height of bulb *A* to bring the junction to an etched mark. Then with the greater press connected to bulb *B*, vert displacement of the junction is neutralized by raising bulb *A*. The difference of final and zero readings measures the press-difference, in inches of alcohol. A scale etched on the capillary is useful where press fluctuates (49). Due to the large amount of exposed glass, this instrument is greatly affected by small temp changes, and can be used properly only under laboratory conditions.

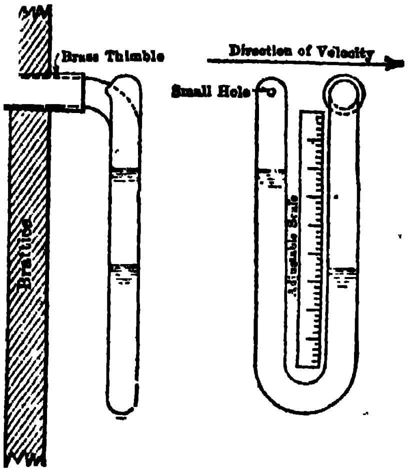

Fig 18. Water Gage

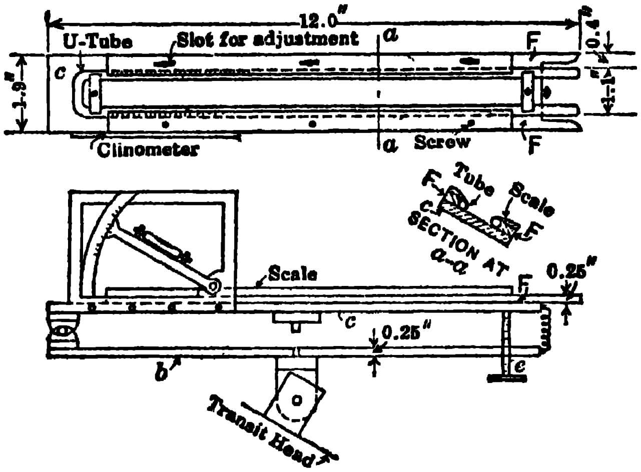

Fig 19. Weeks Manometer (*Min & Met*, Jan, 1923)

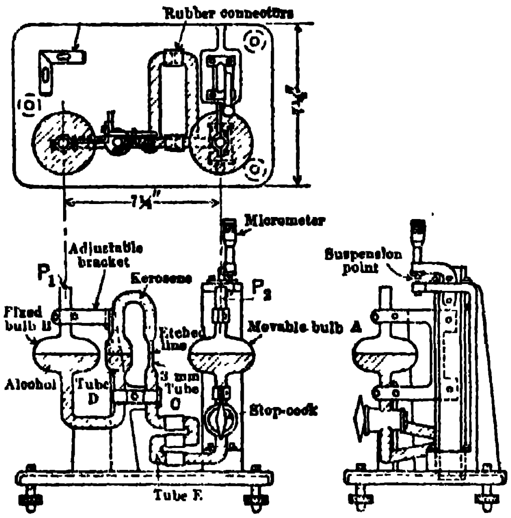

Fig 20. Wahlen Gage (diagrammatic)

Recording pressure gage is useful for continuous records. Common design for fan pressures is like a clock, the face consisting of a 24-hr circular paper chart, with radial hour-lines. An index pen describes a line varying in radial distance according to air press.

Indicating and recording quantity gages are little used in mine ventilation, due to expense and necessity for special calibration. As recording designs are based on measurement of small press differences, the small forces involved require expensive construction. In the BACHARACH QUANTITY RECORDER, veloc press is multiplied by venturi devices 2 to 3 times, and recorded on a drum chart, graduated for quantity if desired. Multiplication of press is not exact and calibration is required.

Power of a ventilating current in ft-lb of work per min = press (including veloc press) in lb per sq ft, × veloc in ft per min, × area of air course in sq ft = $pVa = pQ$, wherein

Q = quantity of flow in cu ft per min. Hp of current = $pQ \div 33\,000$. Example: hp of ventilating current passing 100 000 cu ft per min at press (including veloc press) of 2 in of water = $(100\,000 \times 2 \times 5.2) \div 33\,000 = 31.6$ hp.

Air density (see Sec 23, 39). Press of water vapor is determined by its dew-point (temp) (Sec 23). Both this temp and relative humidity, the ratio of vapor press at dew point to that at dry bulb temp, are determined, from observed wet- and dry-bulb temp and abs press, by psychrometric formulas, tables (57) or charts (9). "Standard atmosphere" is dry air weighing 0.08072 lb per cu ft at 29.922 in barom press at 32° F (at Paris).

Density formulas. Wt of dry air in 1 cu ft of moist air at temp t, barom press b, and press of water vapor f in of mercury, is:

$$w_a = 0.08072\,\frac{491}{459 + t} \cdot \frac{b - f}{29.922} = \frac{1.325}{459 + t}\,(b - f)$$

Wt of water vapor in 1 cu ft, at press f, is: $w_v = 0.622\,\dfrac{1.325}{459 + t}\,f$. Combined wt of air and vapor in 1 cu ft of moist air is:

$$w = w_a + w_v = \frac{1.325}{459 + t}\,(b - 0.378\,f)$$

If relative humidity is r and vapor press corresponding to air temp is F, then $rF = f$. For dry air f = zero, and press = b.

Weight of gaseous mixtures can be computed when proportions of the constituents are known. Wt of moist air is found as above, and the mixture of air and aqueous vapor is treated as a single element; not quite correctly, except when humidity is determined before the air is polluted with mine gases. This is seldom possible, because mine conditions usually increase humidity, but the error is negligible.

Example. To find wt of mine atmos containing 1% CO_2 (sp gr 1.529) and 1% CH_4 (sp gr 0.5545), at 29 in barom, 75% relative humidity and 50° F (at which, press of saturated aqueous vapor is 0.362 in of mercury). Weights per cu ft are as follows:

For moist air, $\dfrac{1.325}{459 + 50}(29 - 0.378 \times 0.75 \times 0.362) = 0.07519$

For CO_2, $1.529\,\dfrac{1.325}{459 + 50}\,29 = 0.1154$

For CH_4, $0.5545\,\dfrac{1.325}{459 + 50}\,29 = 0.0424$

For the mixture:

0.98	cu ft moist air	@ 0.07519	weighs	0.07369 lb
0.01	“ “ CO_2	@ 0.1154	“	0.00115 “
0.01	“ “ CH_4	@ 0.0419	“	0.00042 “
1.00	“ “ of mixture weighs			0.07526 “

10. AIR FLOW IN MINE OPENINGS

Air flow conditions. When air is flowing in a duct, the wall surfaces, and their position with respect to the flow, cause interference of one airstream with another, whereby part of the kinetic energy of flow is converted to heat; hence, to maintain kinetic energy, it must be constantly renewed from total energy of flow. The flow therefore causes continuous decrease in total energy of air current in the direction of flow, and automatically adjusts itself as to quantity, so that total energy used in a circuit equals total energy generated therein. Energy losses occurring in straight ducts of uniform cross-sec are called *friction losses*; those due to deflections and change of cross-sec are *shock losses* (9). Both energy losses and energy gains (as by natural or mechanical means) are evaluated in terms of press.

Pressure forms. Theoretically, total energy of flow is measured by abs static press and velocity press. Abs static press depends on flow and also on difference of elev. But, as changes due to elev are almost balanced in any inclined or vert flow circuit, changes are conventionally considered as though the flow were horiz, and small changes due to unbalanced weights of air columns, as naturally generated press, or " natural draft " (Art 11). The absolute nature of static press is thus ignored, and only changes in absolute press due to flow are considered.

Pressure changes. The sum of static and veloc pressures is the TOTAL PRESS, which remains constant except as depleted by friction and shock. (For positive and negative pressures, see Art 12.) Changes in veloc of flow, due to varying areas of cross-sec, cause corresponding changes in static and veloc pressures, which are mutually convertible; but conversion is always accompanied by some shock loss, depending on abruptness of change in area. Veloc pressures in mine airways usually are so small that practice commonly ignores them and considers only static press, or "water gage," which is usually, but not always, the difference between the abs static pressures in an air stream and in the atmosphere outside.

Pressure losses. Both friction and shock losses depend primarily on dimensions of the airway. Roughness of wall surfaces is a determining factor of friction losses, whereas relative positions of wall surfaces largely determine shock losses. Friction press losses in straight sections of approx uniform cross-sec comprise most of the total press loss in a mine ventilation system. In deep metal mines, main airways alone often account for 70 to 90% of the total press requirement.

Friction formulas. The generally-accepted formula, or law, for press required for flow in mine airways, as developed (12) from an old hydraulic formula for turbulent flow, is

$$p = \frac{kPLV^2}{A} = \frac{kSV^2}{A}$$

where p = difference in total press between ends of airway, lb per sq ft; k = experimental factor (Table 2); S = rubbing surface, sq ft = P, perimeter, ft, × L, length, ft; V = veloc, ft per min; A = aver cross-sec, sq ft. A more convenient form for direct application is

$$H_F = \frac{kPLQ^2}{5.2\,A^3}$$

where H_F = press difference due to friction losses, in of water; Q = cu ft per min.

Laws of proportion. Proportional changes in press requirements due to variations in airway and air-flow conditions are deduced from the basic formulas above, using the first for constant-veloc assumptions, the second for constant-quantity assumptions, which are of more practical importance. For constant quantity through similarly-shaped airways, press difference varies as the 5th power of a side or diam.

Effect of shape of cross-sec on pressure requirements, for same quantity and area (9), can also be deduced from the formula. Multiply the value for circular cross-sec by: 1.13 for a square, 1.15 for a 1 to 1.5 rectangle, 1.20 for a 1 to 2 rectangle, 1.30 for a 1 to 3 rectangle; in shafts with square compts by 1.60 for a 2-compt, 1.95 for a 3-compt and 2.26 for a 4-compt shaft; in shafts with rectangular compts, with 1 : 2 ratio of sides, by 1.69 for 2-compt, 2.07 for 3-compt, and 2.39 for 4-compt shaft.

Value of friction factor *k* depends chiefly on character (roughness) of sides of airway, and varies directly with air density (Art 9); also affected to a lesser extent by size, and possibly form, of cross-sec and veloc of air current; and may be adjusted to include minor shock losses due to curvature, sinuosity, or obstruction. Formulas, based on experiments on pipes and small ducts, have been developed for effect of size and veloc on k for straight, unobstructed, smooth-lined ducts; but not for rough-surfaced ducts, as mine airways, where these effects are relatively unimportant for usual sizes and velocities, in comparison with character of walls, irregularity of section, curvature and obstructions. Table 2, based on existing data and original experiments in coal and metal mines by the Bureau of Mines, applies to velocities of 300–2 000 ft per min, and values of $A \div P$ between 1 and 2 ft.

Table 2. Friction Factors for Mine Airways (40) (9)

Type of airway		Values of $k \times 10^{10}$ for air at 0.075 lb per cu ft *					
		Straight		Slightly sinuous or curved		Highly sinuous or curved	
		Clean	Moderately obstructed	Clean	Moderately obstructed	Clean	Moderately obstructed
Smooth lined	Min.	10	25	20	35	35	50
	Max.	20	35	30	45	45	60
Sedimentary rock	Min.	30	45	40	55	55	70
	Max.	70	85	80	95	95	110
Timbered	Min.	80	95	90	105	105	120
	Max	105	120	115	130	130	145
Igneous rock	Min.	90	105	100	115	115	130
	Max	195	210	205	220	220	235

* For air density w (other than 0.075 per cu ft) corrected value $k' = kw + 0.075$.

Mean radius of duct, $r = A \div P$ (used in some air-flow formulas), is a term borrowed from hydraulics to designate comparative sizes of cross-sec.

Effect on k **of included shock losses.** Investigation (40) has shown that intermittent shock losses, due to sinuosity and crookedness of airways and minor obstructions in them, may be computed as friction losses by adding constants to friction factors. Values of increments depend on value of r. Thus, in Table 2, the factors for clean, straight airways are base values; increments, based on $r = 1.5$ ft, are 10 for slightly curved, 25 for highly curved, and 15 for moderately obstructed airways.

Effect on k **of both veloc and mean radius.** Experimental data on smooth ducts have been correlated (50) in terms of a dimensionless constant, the " Reynolds Criterion," or diam × velocity × density ÷ viscosity, largely restricted to interpreting results of tests on models (Sec 38). Experimental results are often expressed by formulas including a constant k, but with fractional exponents for diam, r, or V; facility in application then requires use of special charts. It is better to maintain the general form of the friction-loss equation and relate variations in k to r and V, as done by Goodenough for tests on smooth concrete ducts for the N Y–N J Vehicular Tunnel Commission (48). His formula for frictional resistance for veloc of 1 000–6 000 ft per min is: $p = w\left[B + \frac{C}{v^2r^2}\right]\frac{Sv^2}{2gA}$ wherein for smooth ducts, $B = 0.0035$ and $C = 0.02867$; v = velocity in ft per sec; other notation as before. Value of k, deduced from the above for $g = 32.16$ and $w = 0.075$, is:

$$k \times 10^{10} = 11.337 + \frac{334\,300}{r^2V^2}$$

If multiplied by 3, to allow for variation in roughness, results by this formula agree closely with those of the Bur Mines (49) on a 6.2 by 9.2-ft straight butt-heading in a coal mine: value of $k \times 10^{10}$ at 300 ft per min by formula and by the Bureau, 37.3; at 900 ft per min, 35.1 by formula, 34.9 by the Bureau. Hence, the formula seems of wide utility.

Friction factors for fan pipes. Tests by Bur Mines (51) on straight sheet metal and canvas tubing, 8–16 in diam, showed aver values of $k \times 10^{10}$, at velocities of 1 000–4 000 ft per min, of 15 for sheet metal and 20–23 for canvas; for aver mine conditions of " straight " lines, values of 20 for metal pipes and 25 for canvas are recommended. Leakage usually prevents accurate application of these factors (Art 11)

General formula for shock losses. Bends, changes in area of cross-sec, and obstructions cause changes in area of air flow; the resulting press losses are independent of roughness of walls, and bear a practically constant ratio to veloc-press of mean veloc of flow. General formula is:

$$H_s = XH_v$$

where H_s = shock press loss due to change of veloc, in any units; X = empirical factor; H_v = veloc press at mean veloc, in same units as H_s, or $\frac{V}{4\,008}$ in of water at $w = 0.075$, varying directly as w.

Shock losses expressed as equivalent friction losses, that is, in terms of equivalent lengths in ft or diameters, or as increments to friction factors, are commonly used in reporting and applying experimental results, especially on bends. Equating shock loss to friction loss (53); Equivalent length in ft $= \frac{3\,240}{k \times 10^{10}}\frac{A}{P}X$; equivalent length in diam $= \frac{810}{k \times 10^{10}}X$; increment for $k \times 10^{10} = 3\,240\,\frac{A}{P} \cdot \frac{X}{L}$. *Example.* For $k \times 10^{10} = 20$, $A \div P = 1.5$, and $X = 1$, equiv length is 243 ft or 40.5 diameters; increment for $k \times 10^{10}$ ($X = 1$ per 1 000 ft) is 4.86.

Characteristics and types of bends. General flow conditions at bends or deflections of air current are as shown in Fig 21. Experiments indicate (53, 9) that press loss is due to abrupt one-sided expansion from the contracted area at departure end, to full area beyond. Characteristics used in specifying bends are shown in Fig 22, and designations of the more common types in Fig 23.

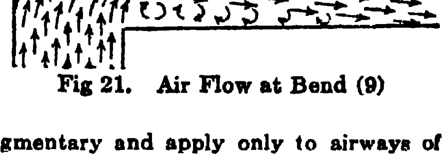

Fig 21. Air Flow at Bend (9)

Shock-loss factor X **for bends** (53, 9). Data are fragmentary and apply only to airways of uniform area before and after bend. There is no general formula for areas not thus uniform, nor are effects of V, $A \div P$, or roughness of lining known. Approx shock factor X for a NORMAL BEND (Fig 23A), with notation as in Fig 22, is $X = \frac{0.25}{r^2a^{1/2}}\left(\frac{i}{90}\right)^2$. When $i = 90°$, $X = 0.25 + r^2a^{1/2}$ for rectangular airway and $X = 0.25 + r^2$ for round or square airway; max $X = 1$ for square inner corner ($r = 0.5$); there is no practical advantage in exceeding $r = 2$, for which $X = 0.06$. For a SQUARE BEND (Fig 23B), $X = \frac{0.60}{ra^{1/2}}\left(\frac{i}{90}\right)^2$. When $i = 90°$, $X = 0.60 + ra^{1/2}$ for rectangular airway and

$x = 0.00 + r$ for round or square airway; max $X = 1.20$ for square inner corner ($r = 0.5$); low values of X practically require changing to a normal bend by rounding outer corner. For other bends, calculation of X is less precise. For a CROWDED BEND (Fig 23C), X for a similar normal bend is arbitrarily increased: e g, by 40 per cent when outer radius at bend = 0.75 of the normal. INNER BEVEL and SEGMENTAL BENDS (Fig 23D, E) may be treated as normal bends with radii circumscribing the segments; but X for a segmental bend is slightly increased to allow for " crowding " on the outer radius. VENTURI BENDS (Fig 23F) may be treated as normal bends with $r = 0.8$ to 0.9. For a BLADE BEND (Fig 23G), X may be taken as for one of the equal sections only, with a small increase for excess rubbing surface. RADIAL VANES divide bends into sections having different values of r and a. Aver factor is determined by weighting factors of separate sections according to area, and increasing result slightly for edge effect and excess rubbing surface. Best position for single vane is about 1/3 width from inner corner. Straight extensions beyond radius in either direction cause increased press loss and should not be used.

Special bend conditions. Bends discharging directly to atmos involve 50–80% more loss than interior bends, due to greater differences in veloc involved in shock loss. Tests on CLOSELY SPACED BENDS show that close spacing affects press losses, probably by its effect on veloc distributions, but data are meagre.

Fig 22. Bend Characteristics

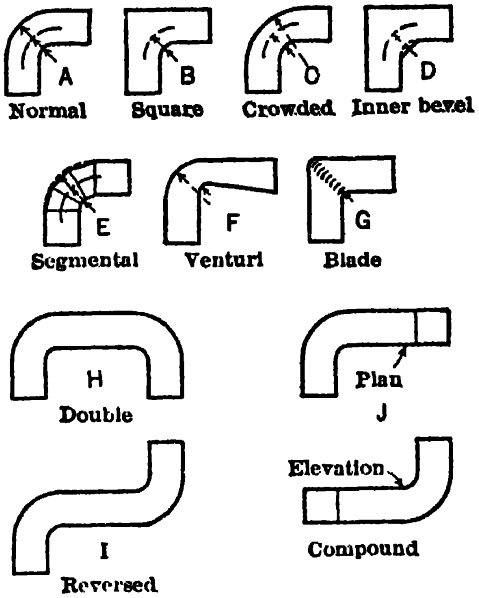

Fig 23. Types of Right-angle Bends (9)

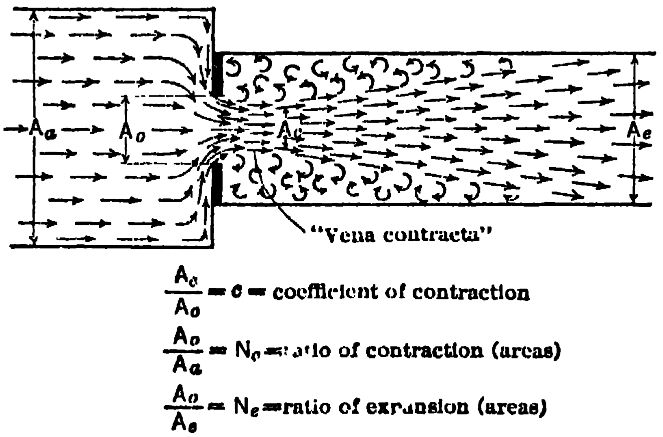
Sinuous and crooked airways. Airways often have bends and curves, wherein shock losses are too small for calculation individually, though a rough approx of total shock loss is desired. Tests by Bur Mines in metal mines (40, 9) gave following range: For a large-radius curve, or sharp bend of about 15°, or a wall line close to center line, not oftener than once every 100 ft; or a small-radius curve, or sharp bend of about 30°, or a wall line crossing center line not oftener than once every 200 ft, $X = 0.2$ per 100 ft. For a continuous large-radius curve, or continuous curve of repeated small deflections of 10°–15° every 20–30 ft, or bends of 20°–30° every 50–100 ft, or a wall line crossing center line about every 50 ft, $X = 0.5$ per 100 ft.

Splits and junctions of air currents cause shock losses due to bends and area changes, for which exact data are lacking. Split loss may be approximated as a bend loss based on veloc of diverted stream. Junction loss is (very roughly) 1.5 times bend loss based on veloc of entering stream.



A_a
A_o
A_c
A_e
"Vena contracta"
$\frac{A_c}{A_o} = c$ = coefficient of contraction
$\frac{A_o}{A_a} = N_c$=ratio of contraction (areas)
$\frac{A_o}{A_e} = N_e$=ratio of expansion (areas)

Fig 24. Flow Conditions and Characteristics of Expansion and Contraction (9)

Characteristics and types of area changes and general conditions of flow thereat are shown in Fig 24. Contraction of the flow to pass a smaller opening causes it to occupy a still smaller area immediately beyond the opening, the so-called "vena contracta."

Pressure losses are primarily shock losses due to abrupt expansion from a smaller section and higher veloc (that of the "vena contracta," where contraction precedes expansion) to a larger section and lower veloc. Types of area changes common to airways and ducts are shown in Fig 25.

Shock-loss formulas for abrupt expansion. Carnot-Borda equation or Borda formula (56) shows that loss of head, due to abrupt expansion of a faster to a slower stream, is equivalent to the veloc press corresponding to difference of aver veloc involved; or loss of head h in ft of air $= (v_1 - v_2)^2 + 2g$, velocities being in ft per sec. At $w = 0.075$ lb per cu ft, with velocities V_1 and V_2 in ft per min, loss H_s, in of water $= \left(\frac{V_1 - V_2}{4\,008}\right)^2$. Since $Q = A_1V_1 = A_2V_2$, $V_1 = (A_2 + A_1)V_2$, and $H_s = \left(\frac{A_2}{A_1} - 1\right)\left(\frac{V_2}{4\,008}\right)^2 = \left(\frac{A_2}{A_1} - 1\right) H_{v_2} = X_2H_{v_2}$. Similarly, $H_s = X_1H_{v_1}$, where X_1 and X_2 are shock factors, or loss in terms of ratios of veloc press, corresponding to veloc before and after expansion respectively; H_{v_1} and H_{v_2} are veloc heads, in of water. In cases of contracted flow, shock loss is due to expansion from the "vena contracta," whose area is c times the actual area preceding expansion, where c (Fig 24) is termed the "coeff of contraction." Where c is known, V_1 can be determined from $c \times A_1$ and applied directly in the preceding formulas.

Shock factors for expansion and contraction (53, 9). More generalized formulas, using the notation of Fig 24, are the following:

$$X_o = \left(\frac{1}{c} - N_e\right)^2;\quad X_e = \frac{\left(\frac{1}{c} - N_e\right)^2}{N_e^2};\quad \text{and}\quad X_a = \frac{\left(\frac{1}{c} - N_e\right)^2}{N_c^2}$$

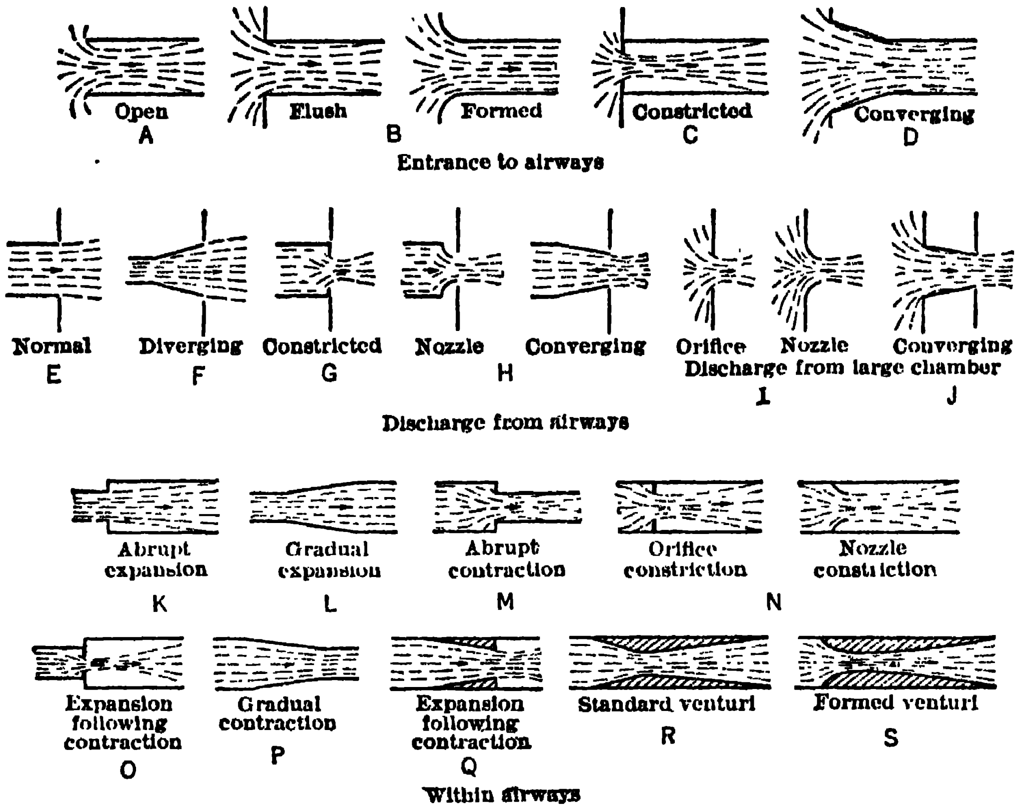


Fig 25. Common Types of Area Changes in Airways (9)

In particular cases, c, N_e or N_c may be equal to 1 or 0, simplifying the formulas. References cited contain tabulated values and charts for graphical determination.

Coeff of contraction c depends on: N_c, or ratio of contraction of areas (Fig 24); the edge condition at contraction, represented by "contraction factor" Z; and conditions of symmetry. A sufficiently accurate relation for c and Z for symmetrical conditions is: $c = \sqrt{\frac{1}{Z - ZN_c^2 + N_c^2}}$ as plotted in Fig 26.

Value of contraction factor, Z. If contraction occurs symmetrically against wall surfaces (normal condition), Z is approx 1.05 for a bell-mouth, 1.5 for a round edge like a mine timber, 2.0 for a smooth edge, as of thin sheet-iron, 2.5 for square edges common to mine forms, 2.8 for very sharp thin edges as in orifice plates for air measurement, and 3.8 for free contraction to a sharp edge (as at entrance to a pipe). Meager data on obstructions in airways, as mine cars or timbers, where contraction occurs along the perimeter of the obstruction, indicate that normal contraction factors should be about doubled; that is, 5.0 for square edges, 3.0 for round edges. For unsymmetrical contraction in ducts (56), press losses and values of c are much greater than for same ratio of symmetrical contraction.

Abrupt expansion. For discharge to atmosphere (Fig 25E), $X = 1$. For expansion in airway (Fig 25K), $c = 1$ and $A_o = A_a$ (Fig 24). Table 3 gives shock loss factor X_a, and change $H_{v_a} - H_{v_e}$ in veloc press, in terms of veloc press H_{v_a} before expansion; also the ratio of these quantities.

Table 3. Constants for Abrupt Expansion in Airways

$N_e = A_a/A_e$	0.9	0.8	0.7	0 6	0.5	0.4	0.3	0.2	0.1
X_a	0.01	0.04	0.09	0.16	0.25	0.36	0.49	0.64	0.81
$\dfrac{H_{v_a} - H_{v_e}}{H_{v_a}}$	0.19	0.36	0.51	0.64	0.75	0.84	0.91	0.96	0.99
Ratio of X_a to $\dfrac{H_{v_a} - H_{v_e}}{H_{v_a}}$	0.05	0.11	0.18	0.25	0.33	0.43	0.54	0.67	0.82

Gradual expansion diminishes shock loss by a constant ratio y, depending on included angle; $X' = yX$, where X' is the shock factor for gradual, and X for abrupt expansion. Test values of y are conflicting (53, 9, 56); apparently, practical minimum is approx 0.25 for 7°; angles exceeding 30° offer no material advantage over abrupt expansion. For gradual expansion in airway (Fig 25L), values of X_a in Table 3 are multiplied by proper value of y. EVASÉ DISCHARGE (gradual expansion at discharge to atmos, Fig 25F) involves both loss due to expansion, yX_a, and loss at discharge, $X_e = 1$. In practice, it is seldom economical to make N less than 0.25; that is, $A_e \div A_a$ more than 4 (Art 14).

Abrupt contraction in airways is a common condition (Fig 25M). Here $N_e = 1$, $X_e = \left(\frac{1}{c} - 1\right)^2$, and $X_a = X_e \div N_c^2$ (Table 4).

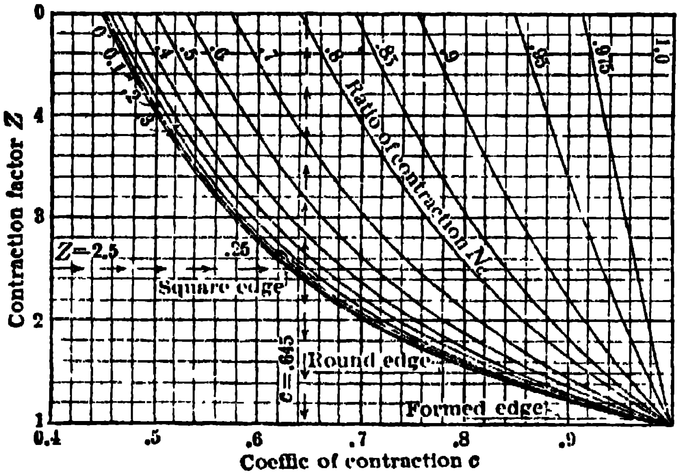

Fig 26. Relation of Coefficient of Contraction c to Contraction Factor Z (19)

Table 4. Constants for Abrupt Contraction in Airways

$N_c = A_a/A_e$		0 9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
Square edge....	X_a	0.022	0.091	0.220	0 446	0.839	1.59	3.21	7 92	33.2
	X_e	0.018	0.058	0.108	0.161	0.210	0.254	0.289	0.317	0.33
Round edge....	X_a	0.003	0.012	0.030	0.061	0.120	0.230	0.471	1.18	4.96
	X_e	0 002	0 007	0 015	0.022	0 030	0.037	0.042	0.047	0.05

Most mine airways represent something between square- and round-edge conditions. Values for rough conditions are difficult to select.

Inlets. For pipe and airway inlets (Fig 25A), $N_c = 0$ and $N_e = 1$. For the PIPE INLET, $Z = 3.8$ and $X_c = 0.95$. For the AIRWAY INLET, X_e is approx 0.34 for square edge, 0.05 for round or beveled, and 0.0006 for a formed or bell-mouth opening (Fig 25B). CONVERGING INLET (Fig 25D) is also a low-loss type, but has both abrupt and gradual contraction. For a RESTRICTED INLET (Fig 25C), $N_c = 0$; then c is 0 633, 0.817 and 0 976 for square, round and formed edges, in the formula for X_e.

Orifices. RESTRICTED DISCHARGE to atmos (Fig 25G, $N_e = 0$) is often used in fan testing with square-edged orifice plates, for which Z = approx 2.5. For FLOW THROUGH A SMALL HOLE in thin wall (Fig 25I), $N_e = 0$ and $N_c = 0$; then $X_a = Z = 2.5$, 1.5 and 1.05 for square, round and formed edge respectively. CONSTRICTION IN AIRWAY (Fig 25N) involves abrupt contraction followed by abrupt expansion. General formulas apply, but in duct or airway of uniform area, $N_c = N_e = N$. Edge of orifice plates used for air measurement approximates $Z = 2.8$.

Regulator is a restrictive device to cause shock loss. Solution by trial and error of $X = \left(\frac{1}{c} - N\right)^2 \div N^2$, or use of chart (55), is required for N greater than 0.2; N = ratio of regulator- to airway-area; X is desired press loss divided by veloc press in airway; c is selected from Fig 26 for $Z = 2.5$ and corresponding value of N. In practice, N is usually less than 0.2, and value of c practically constant; hence approx size can be found by $N = \dfrac{1.6}{\sqrt{X} + 1}$ (approx for $N > 0.2$). Solutions by "equivalent orifice" formula, $A = 0.0004\,Q \div \sqrt{H_s}$, are 10% too high for $N = 0.1$, to 30% too high for $N = 0.3$.

Example. For $Q = 10\,000$ c f m, required area of regulator in a 50-sq ft entry to cause press loss H_s of 0.25 in of water: $V = \frac{10\,000}{50} = 200$ ft per min; veloc press $= \left(\frac{200}{4\,000}\right)^2 = 0.0025$ in; $X = \frac{0.25}{0.0025} = 100$; $\sqrt{X} = 10$; $N = \frac{1.6}{11} = 0.145$; regulator area $= 50 \times 0.145$ or approx 7.3 sq ft. Regulator would be made at least 2 by 4 ft and have a slide. Same solution can be used for size of opening in a door-regulator, but results are less reliable.

Gradual contraction in an airway (Fig 25P) is followed by abrupt expansion from the " vena contracta " to the area following contraction; $N_e = 1$. Values of Z and c are influenced by the included angle and edge condition. Univ of Ill found values equivalent to $Z = 1.51$ for 60° and 1.34 for 30° smooth edges, approximating $Z = 2$ in abrupt contraction (56). Shock losses for included angles less than 30° are practically negligible. Gradual contraction followed by abrupt expansion (Fig 25Q) presents the same flow conditions, except that N_e is less than 1. Converging discharge from an airway has the special condition that $N_e = 0$. Converging inlet (Fig 25D) and converging discharge from a large chamber (Fig 25J) involve both abrupt and gradual contraction and require special test values to find press loss.

Contraction followed by gradual expansion, the contraction being either abrupt or gradual: multiply factors for abrupt expansion by y (see gradual expansion). Venturi orifice, or nozzle (Fig 25R) is a common form of gradual contraction followed by gradual expansion, designed to give large press change with small press loss. The general formulas, with appropriate values of y and Z, are required for solution. With a formed entrance, as in the " standard " orifice, Z may be 1.05, and c determined from Fig 26.

Obstructions in airways cause shock losses due to contraction of flow along the perimeter, followed by abrupt expansion. Bur Mines tests (9) show Z = approx 5 for square edges of timbers and cars, so that Z factors for wall contraction should be doubled for aver conditions of contraction against perimeter of an obstruction. Mine cars cause shock losses at front and rear and increased friction loss. Abrupt contraction at front end, and expansion at rear, may be computed from foregoing data, using $Z = 5$. Friction loss in constricted area is approx $(2 - N) \div N^3$ times normal loss. For area ratio of $N = 0.2$, resistance of car = approx 100 ft of coal-mine entry or 40 ft of rough rock drift; for $N = 0.4$, these values are 400 and 160 ft (9). Closely spaced cars do not allow length required for full expansion downstream and shock loss is less than the above. A trip of cars is therefore treated as a single obstruction.

Intermittent obstructions, causing minor losses, too small or irregular for separate calculation, may be estimated per unit of length. Tests by Bur Mines (40) gave following range: for trolley box, water box, large flanged pipe, occasional falls of roof, hangers and props, $X = 0.1$ per 100 ft; for combinations of the above, large roof falls, piles of timber or pipe, closely set crossbars, props or constrictions, $X = 1.0$ per 100 ft.

11. MINE RESISTANCE

Mine pressure. Total press to circulate air through a system of mine openings is press required to overcome all friction and shock losses along any continuous path from inlet to outlet, regardless of changes in the distribution of total quantity in different parts of that path. Press for circulating a definite quantity depends on whether natural or controlled splitting is used.

Controlled splitting. General procedure in coal mines is to regulate, or add resistance artificially to, all paths from inlet to outlet except one, this being termed the " open split " throughout the section occupied by divided flow. In calculating mine press, quantities are assigned to the various branch splits and press requirements are calculated for each. The path of highest resistance is then determined and the summation of its press losses, from inlet to outlet, is the press required for the total quantity. Regulators placed in all splits and branch splits, other than the open split, bring their press requirements for assigned quantities up to that for the corresponding part of the open split.

Mine characteristics. If press required to circulate one quantity Q is known, press required to circulate any other quantity Q' is easily calculated, since press varies as $(Q' \div Q)^2$, whether for a single airway, or system of airways. Corresponding values of press and quantity may be plotted to show the press-quantity relation, or characteristic, of the airway or mine (Art 12, 15).

Pressure-quantity relation (1) may be expressed as $H = rQ^2$, or as $Q = c\sqrt{H}$, where H is press, and r and c constants; because both friction and shock losses vary directly as the square of veloc, or quantity, for constant airway conditions. For unit quantity, $H = r$, so r is a constant designating specific resistance to flow. For unit press, $Q = c$, so c is a constant designating specific capac for flow. Many expressions equivalent to these, as " equivalent orifice," " press potential," and "Atkinson," are in use.

Equivalent orifice. Since flow through an orifice follows the same law as flow through a mine, the resistance through a mine or a fan may be represented by the size of orifice in a thin plate, that would pass same amount of air with same press loss (for a fan, "orifice of passage") (10). The usual formula is $a = 0.0004Q \div \sqrt{H}$, where a is area of orifice in sq ft. Its derivation (55) assumes constant density, a coeff of contraction of 0.625 (or 0.65 if coeff of Q is 0.000385), and that all veloc press in the contracted stream from the orifice is lost. These conditions hold only for a small hole discharging air to atmos from a large chamber, for which the formula gives a close approximation. Although this conductance constant has been widely used, its restricted theoretical application has caused some confusion, especially in calculating size of regulator openings (Art 10). In form, it is equivalent to $Q = c\sqrt{H}$, where $c = a \div 0.0004$.

Pressure potential. The standard friction formula (Art 10) may be transposed to: $Q = \left(A\sqrt{\frac{A}{kS}}\right)\sqrt{p}$, in which $A\sqrt{\frac{A}{kS}}$, termed "pressure potential" by Beard (2), has often been used in solving theoretical problems of natural splitting or parallel flow. With p constant, Q varies directly as the press potential, whence, for splits beginning and ending together, total quantity is divided between splits in proportion to their respective press potentials. The formula is equivalent to $Q = c\sqrt{H}$, where $c = A\sqrt{\frac{A}{kS}} \times \sqrt{5.2}$. But, as it does not provide for shock losses and is not suitable for summations of pressure losses in series, involving variations in A, k or S, it serves only for rough solutions.

"Atkinson." A committee of the Inst Min Engrs, London, recommended use of the form $p = R_A\left(\frac{q}{1\,000}\right)^2$, which is the standard resistance form with press in lb per sq ft and quantity expressed in the "cusec," or 1 000 cu ft per sec, equivalent to 60 000 cu ft per min (3). Hence, an "Atkinson" (commonly used in England) is the press in lb per sq ft required to pass 60 000 cu ft per min $= R_A = \frac{2\,800}{a^2}$, where a is equiv orifice in sq ft.

Resistance factor. Most convenient form, much used in U S and Gt Britain, is $H = R\left(\frac{Q}{100\,000}\right)^2$, wherein the quantity unit is 100 000 cu ft per min. R has been termed (9) "resistance factor," specified as the press required to pass 100 000 cu ft per min. This large quantity unit gives values close to unity for mine circuits and facilitates computations of R involving friction factor k. For problems of small flows in ducts, values of R are large, and a smaller quantity unit is better.

Determination of R for an airway or a mine may be made directly from measurements of press and quantity. As R is affected by air density, values thus derived are corrected to standard density by multiplying by $(0.075 \div w)$. R may be calculated for friction losses, by inspection of friction formula: $R = \frac{k \times 10^{10}\,PL}{5.2\,A^3}$; for shock losses, $H_s = X\,H_v$, where $H_v = \frac{623}{10^{10}}V^2$ for $w = 0.075$ lb per cu ft (Art 9); whence $R = \frac{H_s}{\left(\frac{Q}{10^5}\right)^2} = \frac{10^{10}\,H_s}{Q^2} = \frac{10^{10}\,X\,H_v}{Q^2} = 10^{10}\,X\,\frac{623\,V^2}{10^{10}\,A^2V^2}\,\frac{w}{0.075} = \frac{623\,X}{A^2}\,\frac{w}{0.075}$.

For known equiv orifice, $R = \frac{1\,600}{a^2}$; for known Atkinsons, $R = 0.535\,R_A$.

Series flow. Resistance constant r (any unit), for an airway, is the sum of r-factors for the friction and shock-loss conditions involved; r for a system of airways is the sum of the separate r-factors of successive parts through which the same total quantity flows ($r = r_1 + r_2 + r_3 + \ldots$).

Parallel, or split flow. Where flow occurs in 2 or more splits in parallel, beginning and ending together, press diff H is the same on all paths, and total quantity is the sum of the separate quantities, or $Q = Q_1 + Q_2 + \ldots$. Then by the general equation for resistance, $H = rQ^2$, or $Q = \sqrt{\frac{H}{r}}$, where $\sqrt{\frac{H}{r}} = \sqrt{\frac{H}{r_1}} + \sqrt{\frac{H}{r_2}} + \ldots$ and $\frac{1}{\sqrt{r}} = \frac{1}{\sqrt{r_1}} + \frac{1}{\sqrt{r_2}} + \ldots$; also $\frac{Q_1}{Q} = \frac{\frac{1}{\sqrt{r_1}}}{\frac{1}{\sqrt{r}}} = \frac{\sqrt{r}}{\sqrt{r_1}}$, and $\frac{Q_2}{Q} = \frac{\sqrt{r}}{\sqrt{r_2}}$. That is, the separate quantity through each split bears the same ratio to total quantity as its $1 \div \sqrt{r}$ value bears to the same value for the group in parallel.

Conductance Factor. In the foregoing expression, $1 \div \sqrt{r}$ is a conductance constant, and, in solving problems in free splitting, is conveniently given a separate designation. Since $r = \frac{H}{Q^2}$ and $c = \frac{Q}{\sqrt{H}}$, then $c = \frac{1}{\sqrt{r}} = C$ ("conductance factor") when H is in of water and Q is 100 000 cu ft per min (9). C is quantity of flow resulting from a press difference of one in of water, and measures capac for flow of an airway, or system of airways. It can be determined directly from quantity and press measurements, or calculated separately for friction and shock losses; but, as it does not provide for combining press losses, it is useful only for the specific case of split flow. Hence, it is simpler to derive C values from R values ($C = 1 \div \sqrt{R}$) and use them for deriving R values to represent split flow, or resistance to flow where the total is divided between 2 or more paths.

Laws of parallel or split flow: (1) the conductance constant for a group of splits with ends in common is the sum of the conductance constants of its parts; (2) total quantity is divided between the parts in proportion to their conductance constants.

Natural splitting. In metal mines, air currents are usually allowed to divide naturally, without use of regulators. Calculations of mine press are then less precise, as working zones are usually a network of airways. Approximations can usually be made by ignoring networks and treating main airways as a series of branching splits. A diagram of the usual metal mine, or section of a coal mine, resembles a ladder, somewhat as shown in Fig 27, in which series-flow in main airways often accounts for 80–90% of total resistance. In attempting a summation for split flow, begin at the bottom, or innermost, split. Calculations are made in terms of corresponding resistance and conductance constants, adding resistances for flow in series and conductances for flow in parallel, and converting from one to other as required, until a single resistance value for split flow is obtained; to which are added resistances of airways carrying the total flow, to obtain the mine resistance in terms of r in $h = rQ^2$. Actual mine press is then obtained for any particular quantity of flow. Proportionate distribution remains constant with change in quantity, except as affected by natural draft (Art 12). In computing the resultant resistance for split flow, networks are avoided by ignoring cross connections and approximating resistances for a group of N similar airways as equal to $1 \div N^2$ times that for a single airway. Charts for finding resistance values and converting them to corresponding conductance values facilitate this analysis (9).

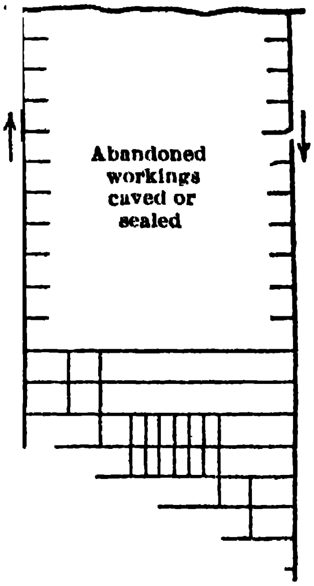

Fig 27. Diagram of Main Airways of a Typical Metal Mine (9)

Networks. Calculation of division of flow in a network of openings is possible, though tedious. The square relation for quantity practically prevents (12) solutions by Kirchoff's laws, as applied to electrical networks, but solutions may be made by trial and error (58).

Allowances for leakage. Indeterminate leakages cause discrepancies between computed and

computation. Where leakage and percolation exist, values of κ or r may be assumed at about 60% of normal values for airtight airways.

Allowances for density changes. Computations are easier if based on standard density for which measured values may be corrected; with final result corrected to aver prevailing density. Minor variations from standard density are usually ignored, as in mines near sea level. For deep mines or at high altitudes, aver density is generally used, without regard to seasonal variation. Change in quantity Q, due to greater density in depth, is usually ignored, although excessive allowances are often made for change due to aver

flow at surface, resistance at depth varies inversely as density, rather than directly. increase with depth at constant temp is between 3 and 4% per 1 000 ft for aver temp and press. If H is press required at 0.075 density, H_f fan press, w_f density at surface fan, and w_m mean density of flow,

$$H_f = H \frac{W_f}{0.075} \frac{W_f}{W_m} \quad \text{and not} \quad H \frac{W_m}{0.075}.$$

The second form is often used, but gives results too high by 2–3% per 1 000 ft of depth for deep mines.

Power-quantity relation. As rQ^2 may be substituted for H in the formula for horsepower (Art 9), hp $= \frac{pQ}{33\,000} = \frac{5.2\,HQ}{33\,000} = \frac{rQ^3}{6\,350}$; that is, for constant mine resistance and constant density, hp required to circulate air varies as Q^3 (Art 14). Since $H = R\,(Q \div 10^5)^2$, above formula in terms of resistance factor R is: hp $= 15.75\,R(Q \div 10^5)^3$.

Economics of air flow. Minimum total cost for air flow depends largely on design of main airways for proper balance between power costs and capital construction charges.

Since power varies as Q^3 for constant resistance, small increases in Q require large increases in power, and large increases in Q are obtained practically only by reducing resistance to flow through physical changes in the airways. Data on friction and shock losses (Art 10) indicate procedure. CHANGES IN AREA A are important, since resistance and power, for constant quantity, vary as $A^{5/2}$ for friction losses, and as A^2 for shock losses. In coal mines, construction of new return airways to permit use of old ones as additional intakes, is a common expedient for increasing area. The large range in possible power costs as affected by quantity and area is indicated in Table 5. CHARACTER OF WALL SURFACE may affect power requirements in the ratio of 10 : 1, as indicated by variation in friction factors. Reducing $k \times 10^{10}$ from 100 to 20, by smooth-lining timbered airshafts, more than doubles resultant flow for same power consumption (20). REDUCTION OF SHOCK LOSSES is a fertile field for reducing power loss. A special case is the top of a fan shaft, where press loss at a right-angle turn is often 0.2–0.3 in of water. Long life justifies a long-radius curve or "blade" bend (Art 10). Short life justifies a short 45° connection, which decreases power loss usually about 1/3 and puts fan out of direct line, as it should be at a coal mine, and as required for emergency hoisting at a metal mine. A "blade" turn in a square bend at such locations is found at a few coal mines, and normally decreases power loss of a plain square bend by 75–80%. SHAPE OF AIRWAY slightly affects power requirements, in a range of 2–1 for normal conditions. Minimum is for circular shape, with octagon and square as close competitors (Art 10).

Table 5. Comparative Power Costs Due to Friction Pressure Losses for 1 000-ft Lengths of Straight Timber-lined Airways

Size of airway, ft	Area of airway, sq ft	Resist factor R, for $k \times 10^{10} = 100$	Air h p for			Annual power cost at 60% overall effic and at 1¢ per kw-hr, for		
			25 000 c f m	50 000 c f m	100 000 c f m	25 000 c f m	50 000 c f m	100 000 c f m
4 by 6	24	27.82	6.85	54.8	438	$746	$5 965	$47 716
5 by 7	35	10.77	2.65	21.2	170	289	2 308	18 472
6 by 8	48	4.87	1.20	9.6	77	131	1 044	8 353
7 by 9	63	2.46	0.61	4.8	39	66	528	4 219
8 by 10	80	1.35	0.33	2.7	21	36	290	2 316

Allowable costs for reducing resistance. Costly changes in airway conditions must be justified by economic advantage, which may be computed with fair accuracy. Comparatively short life involved in mine installations usually justifies crude rather than elaborate types of design. For rough estimates, it is convenient to remember that 100 000 cu ft per min at 1-in press costs $1 000 per year, at overall effic of 51.5% with power charge of 0.5¢ per kw-hr; corrections for specific cases are then a matter of direct proportion. For shock losses, veloc press is approx 1 in at 4 000, 1/4 in at 2 000, and 1/16 in at 1 000 ft per min.

Economic size of airway may be determined by computing capital charges and power costs for a small number of specific sizes and finding the minimum. Careful investigation is justified where large quantities are involved. Weeks (12) cites a case where handling 100 000 cu ft per min through 1 000 ft of 8-ft diam circular shaft for 12 years would represent an increased cost of $57 000 over a 10-ft diam shaft. Mathematical investigation of friction losses in airways (59) shows that $A = Y^{2/7}Q^{6/7}$, where A is area for max economy; Y is resultant of many separate factors, involved in capital charges and power costs. Area for economy is thus mainly a question of Q. Results of one set of computations as above can be solved for $Y^{2/7}$; areas for other quantities may then be determined by the above equation.

Economic velocities. Above equation, confirmed by computation (59), indicates that the range of economic velocities ($V = Q \div A$) is limited. For aver conditions, safe approximations are: 600–1 000 ft per min in unlined airways, 1 000–1 500 in timber-lined, and 2 000–2 500 in smooth-lined airways.

12. NATURAL VENTILATION

Natural draft. Press differences, required to cause air flow, may be produced by natural or mechanical forces. Flow caused by unequal densities, or weights of air columns in or near the openings (due mainly to temp differences) is "natural-draft" flow, and resulting pressure-differences are "natural-draft" pressures. The relatively feeble currents forming complete flow circuits in undivided single openings, also due to unequal densities, are separately termed "convection currents." Many metal mines, and some small coal mines, are ventilated by natural draft alone, which also acts in conjunction with fan pressure in mechanically-ventilated mines; where its importance largely depends on depth of workings and mine resistance (Art 14).

Natural-draft pressures, or density press, are differences in total wt of air columns of unit cross-sec and same difference of elev or vert height. They are computed by assuming the air to move in closed circuit from intake opening, through the mine to the outlet, and thence over the surface at insensible veloc back to the intake. This circuit is divided by its highest and lowest points into 2 columns; and difference in wt of these columns tends to create flow from the heavier to the lighter. Where currents in inclined workings split, each split is a similar complete circuit, which includes the main airways, or 2 connections to surface. Each separate circuit, although it may overlap others, develops its own natural-draft press, which is dissipated by resulting flow in the circuit. Pressures on split-flow circuits in multi-level mines may be opposed in direction; in summer, flow on upper circuit, may be from upcast to downcast, due to temp changes in downcast. Usually one column is partly or entirely outside the mine; for tunnels, both are outside. Surface components are seldom important, because they usually involve only small differences in elev as compared with underground components.

Seasonal and daily changes. Weights of downcast columns and surface components depend largely on surface-air temp. Major effect is usually confined to relatively shallow depth of downcast, depending on veloc of flow. With high veloc, variation in temp at 3 000 ft may be as much as one-tenth the surface variation. Due to seasonal variations in surface-air temp, seasonal reversal of flow, or of press operating in series with fan press, occurs in mines having large surface components, or in relatively shallow mines, or upper parts of deep mines. In the latter, directions of main flows remain constant; seasonal effects are reflected in variations of press and quantity of flow. Where reversal of flow occurs, circulation may be sluggish or lacking for hours, days, or weeks; the time depends largely on elevations of surface openings. In 2 such periods, late spring and late fall, the flow may reverse daily, due to difference between day and night temp.

Currents started artificially in deep mines, when mine atmos is in equilibrium, may determine permanent direction of flow, due to temp changes caused by the flow. In deep naturally-ventilated mines, operating shafts are usually upcast because a slight excess production of heat in them starts feeble upcast flow, which in turn increases temp differences and increases flow. Many, once reversed for a time (as by a fan), would remain so permanently.

Quantity of flow. Except in deep mines, or those having many large openings, natural flows are small because temp differences are small, or act only on short columns; the flow usually ranges from say 5 000 to 20 000 c f m. In deep mines, depending on depth and size and number of openings, flows from 50 000 to 150 000 c f m are found. Aver temp of mine air is higher than that of surface air, due to increase of rock temp with depth (Sec 23). In a naturally-ventilated mine, circulation is normally better in winter than summer; in a mechanically ventilated mine, natural press acting with fan press is normally greater in winter than in summer, causing similar, but smaller, variations in flow.

Intensity of natural pressures in shallow mines usually ranges from a few hundredths to a few tenths inches of water; in deep mechanically-ventilated mines, max is about 1 in for winter and $1/3$ in for summer, per 1 000 ft of column depth underground (9). Max is larger for surface columns: at the 6-mile Moffat Tunnel in Colo. under a 3 000-ft peak, measurements over a year showed max of over 5 in of water in winter and 2 in in summer, with more rapid variation than would occur at mines.

Measurement of natural pressure. If a stopping, or door, can be so placed as to stop the flow on a total-flow circuit temporarily, the press-difference on the stopping approximates the natural press causing the flow (12), as underground temp changes very slowly. If impracticable to stop the flow, a similar procedure may be applied to various splits in a multi-level mine, but analysis of resulting press and flow measurements is involved (60).

Calculation methods. Wt per cu ft of moist air (Art 9) depends on temp, abs press, vapor content, and impurities present, all varying too much to justify precise calculation, which involves logarithmic means for temp (4) and abs press (12). Accuracy within 2–3% is possible by using weighted averages for separate sections of a column of variable temp, to obtain its aver density. Difference in aver densities of the 2 columns gives their aver difference in wt, lb per sq ft; this multiplied by ft of air column gives total press in lb per sq ft, which is divided by 5.2 to obtain press in in of water. The small variations in aver barom press and vapor content are usually neglected except in deep mines. Results within 5–10% are obtainable by the following approximation: $H_n = \dfrac{1.325\,BL}{5.2}\left(\dfrac{1}{T_1} - \dfrac{1}{T_2}\right) = 0.255\,BL\left(\dfrac{1}{T_1} - \dfrac{1}{T_2}\right)$, where H_n is natural-draft press, in of water; B is aver abs press, in of mercury, obtained approx by direct measurement near center of columns, or from measurement at any elev, corrected for difference in elev from center at the rate of 1-in change per 1 000 ft (more closely if rate of change is known); L is vert height of air columns, ft; and T_1 and T_2 are aver abs temps of the columns, deg F, weighted with lengths of separate sections if column temp varies. Natural press may be estimated as 0.03 in of water per 10° F difference per 100 ft difference in elev, at standard air density of 0.075 lb per cu ft.

Application of natural-pressure measurements and calculations. Data on natural drafts and separate components are required to calculate approx changes in quantities and distribution, that would result from changes in either a natural or a mechanical ventilating system. Calculated resistances may be checked against resistances determined by calculated natural drafts and measured flows (60), when installing a fan at a naturally-ventilated mine. Intensities of natural press are necessary to calculate power requirements for changes of fan speed for mechanical ventilation, and for distribution calculations.

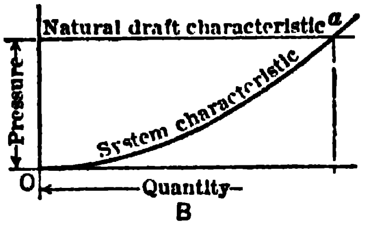

Fig 28. Pressure-quantity Characteristics for Natural-draft Flow (9)

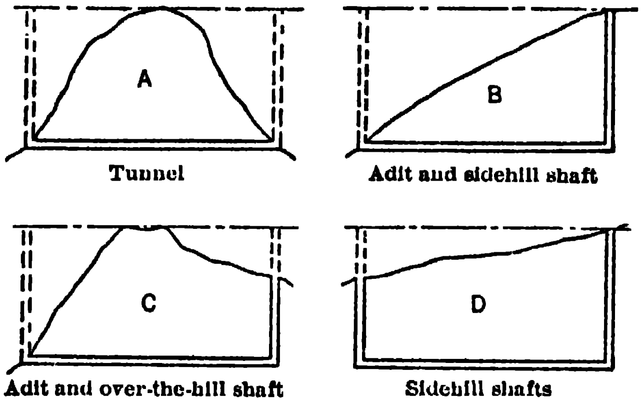

Tunnel

Adit and sidehill shaft

Adit and over-the-hill shaft

Sidehill shafts

Fig 29. Natural-draft Columns for Simple Flow Circuits (9)

Characteristic of natural-draft flow is taken as a straight line, that is, press (at any one time) remains constant with change in quantity, if such change is produced otherwise than by change in natural press. If the natural-draft characteristic (straight line) and mine characteristic (parabola) are plotted to the same scale (Fig 28), the crossing point, a, indicates quantity that will flow.

Natural-draft distribution. Solutions are relatively simple for flat workings with 2 openings to surface, as only one press is involved, which may be considered as a single fan press. With more than 2 openings, separate pressures apply between each individual pair, and the resulting distribution is as though a fan were operating between each pair of openings. For inclined workings, distribution is as though a fan were on each cross-connection. For all except the first condition (fortunately usual in most U S coal mines) distribution calculations as between shafts and levels require either trial-and-error methods or solution of simultaneous equations (61).

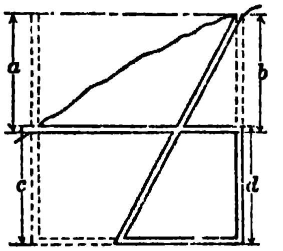

Fig 30. Simple Metal-mine Type of Split-flow Circuits

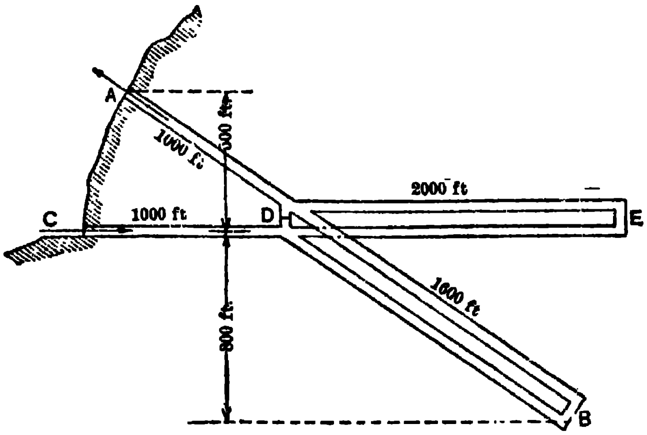

Fig 31. Simple Coal-mine Type of Split-flow Circuits

Simple flow circuits. Natural-draft generation in flat-seam workings may be represented by the simple flow circuits of Fig 29, with 2 columns of equal height. The single horiz connection represents the multiple openings of actual workings. In case A, winds are usually given credit for flow actually caused by the natural press difference of the 2 columns shown by dotted lines.

Split-flow circuit of the simplest type is represented by an interior shaft to surface from a tunnel; equivalent to a fan acting at each portal; here, 1 shaft is better than 2 or more, as flow between interior shafts is practically nil, due to small temp differences. A simple type often found in metal mines is shown in Fig 30, and its counterpart in coal mines in Fig 31. In the usual metal mine there would be no bypass, or separation of currents, at junction of adit and inclined shaft, hence some recirculation would occur on the inside loop. In the coal mine there would be 2 splits, separated by a stopping at *D*.

Example. In Fig 31 let *AB* be a slope, and *CDE* a level, with connecting air courses. Cross-sec of all passages is 6 by 8 ft, and coeff of friction is 0.8 ÷ 10^8. Average barom press between *A* and *B* is 30 in. Temp of outside air, 32° F, and its humidity 50%. Aver temp and humidity of the slope from *A* to *B*, 55° F and 95%. Under these conditions the mine air will be lighter than outside air, and a current will flow in at *C* and out at *A*. Part of the air will pass into the level by first circuit, *CEDAC*, and part by the second circuit *CDBAC*. As *CE* and *DE* are level, the density of the air in them is of no effect. Influence of incoming air makes the aver temp and humidity of slope *DB*, 50° F and 90%. Neglecting impurities, weights of air under these conditions are (Art 9):

At temp 32° F, humidity 50%, barom 30 in, 0.081 lb per cu ft
" " 50° " " 90% " 30 " 0.078 " " " "
" " 55° " " 95% " 30 " 0.077 " " " "

Then for the press of the air columns of the first circuit:

500 ft of outside air @ 0.081 lb per cu ft = 40.5 lb per sq ft
500 " " inside " @ 0.077 " " " " = 38.5 " " " "
Difference = motive press p' = 2.0 " " " "

Similarly, for the second circuit:

500 ft of outside air @ 0.081 lb per cu ft = 40.5 lb per sq ft
800 " " inside " @ 0.078 " " " " = 62.4 " " " "
Total weight of column = 102.9 " " " "
1 300 ft of inside air @ 0.077 lb per cu ft = 100.1 " " " "
Difference = motive press p'' = 2.8 " " " "

If *Q* be total cu ft of air circulating per min, and q' and q'' be the parts in first and second splits, respectively, the velocities are: $Q \div 48$, $q' \div 48$, and $q'' \div 48$. The surface rubbed by total current in *CDA* equals 56 000 sq ft; by air in first split *DED*, 112 000 sq ft, and by air in second split, *DBD*, 89 600 sq ft. If both splits are open (without regulators, Art 5), the simultaneous equations to determine *Q*, q', and q'' are (neglecting velocity head):

$$p' = \Sigma \frac{ksV^2}{a} = \frac{k \times 56\,000}{48} \times \left(\frac{Q}{48}\right)^2 + \frac{k \times 112\,000}{48} \times \left(\frac{q'}{48}\right)^2 = 2.0$$

$$p'' = \Sigma \frac{ksV^2}{a} = \frac{k \times 56\,000}{48} \times \left(\frac{Q}{48}\right)^2 + \frac{k \times 89\,600}{48} \times \left(\frac{q''}{48}\right)^2 = 2.8$$

Putting $k = 0.8 \div 10^8$, these equations reduce to:

$$\begin{aligned} 5.6\,Q^2 + 11.2\,q'^2 &= 2.76 \times 10^9 \\ 5.6\,Q^2 + 8.96\,q''^2 &= 3.86 \times 10^9 \\ Q &= q' + q'' \end{aligned}$$

whence, $Q = 20\,100$, $q' = 6\,700$, and $q'' = 13\,400$ cu ft per min.

The friction press in different parts of mine are:

$$\text{From } C \text{ to } D \text{ (or } D \text{ to } A\text{)}, \ \frac{ksV^2}{a} = \frac{0.8}{10^8} \times \frac{28\,000 \times 17.6 \times 10^4}{48} = 0.82 \text{ lb per sq ft}$$

$$\text{'' } D \text{ to } E \text{ (or } E \text{ to } D\text{)}, \text{ ''} = \frac{0.8}{10^8} \times \frac{56\,000 \times 1.95 \times 10^4}{48} = 0.18 \text{ '' '' '' ''}$$

$$\text{'' } D \text{ to } B \text{ (or } B \text{ to } D\text{)}, \text{ ''} = \frac{0.8}{10^8} \times \frac{44\,800 \times 7.8 \times 10^4}{48} = 0.58 \text{ '' '' '' ''}$$

The head produced by the different densities between *A* and level *CE* = 2.0 lb per sq ft. Of this, the air moving in *CD* and *DA* absorbs 1.64 lb, leaving 0.36 lb per sq ft, equivalent to water gage of 0.069 in, read on an instrument placed in the stopping in the crosscut at *D*. Also, this pressure measures the friction in level *DE* (2 × 0.18 = 0.36 lb per sq ft). The split in the slope is assisted by a difference of density in the two legs, amounting to 0.8 lb per sq ft. As the ventilating press at *D* = 0.36 lb, the total press in *DBD* is 0.36 + 0.8 = 1.16 lb per sq ft, which equals the friction head, 2 × 0.58.

Workings to dip or rise. The essential features of natural ventilation of openings above or below a through current are shown in Fig 32. These may be termed "shunt" circuits, as one branch leaves, and returns to, a main airway, through which the flow is dependent on outside sources. Natural press generated by columns *a* and *b* causes flow far different from that due to natural splitting, without such local natural draft. Temp increases, and addition of lower-density gas, such as CH_4, cause natural draft that opposes flow in a shunt above an airway, and acts with it in one below an airway. Cooling air currents and presence of heavy gases cause the reverse. In developing hot or very gaseous mines, it is often cheaper or safer to drive development openings to the dip rather than the rise, although the latter may otherwise be cheaper and more convenient. Gas-air mixtures in pitch workings are difficult to move down the pitch, as relatively short columns of air and methane-air mixtures generate large natural-draft press.

Multi-level split-flow circuits of common type are shown in Fig 33, where *a* and *b* are vert projections of either slopes or shafts, adjoining or separated. Here there are 4 overlapping circuits, *acb*, *adb*, *aeb*, and *afb*, in each of which the total press losses must equal the difference in wt of the air columns c_1 and c_2, d_1 and d_2, e_1 and e_2, f_1 and f_2, respectively. With resistances and pressures known, quantities are determined by solving simultaneous equations, of which 4 are obtained by equating the natural press for each circuit to the sum of its separate resistances, the first being: $H_c = r_{c_2}Q_{c_2}^2 + r_cQ_c^2 + r_{c_1}Q_{c_1}^2$. Also, total quantity equals the sum of the separate quantities, giving 5 equations. Resistance and conductance factors (Art 11) facilitate calculations, which are very tedious.

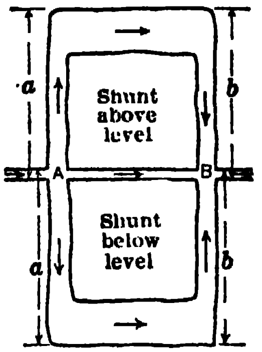

Fig 32. Shunt Type of Split-flow Circuits

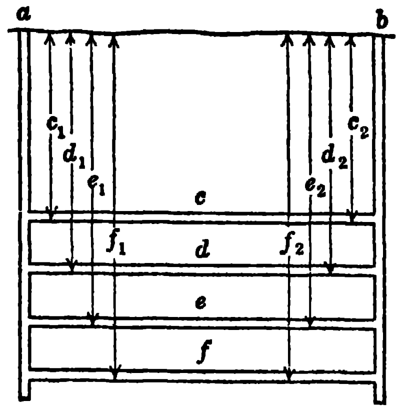

Fig 33. Multi-level Type of Split-flow Circuits

Recirculation due to 2 general conditions may be visualized by referring to Fig 33: (1) high-temp air entering the downcast shaft *a*, but cooling quickly in length *c*, may cause flow in the *c* level opposite to flow in levels below; (2) natural press difference is normally greater in each successive level below; hence, where cross-flow resistances are less than those of the upcast, air is often forced from upcast to downcast rather than to surface. Consequently, large quantities may circulate underground, where only small quantities pass to and from surface (9).

Control of natural ventilation (Art 2). Natural-draft pressures give rise to many variations of flow conditions in both naturally- and mechanically-ventilated mines. In both, however, natural drafts can be partly controlled and used to max advantage permitted by existing conditions. The beneficial effect of a few doors in a typical small metal mine is shown in Fig 34. Seasonal reversal of natural flows is undesirable, both for ventilation, operation, and safety. Reversals are reduced by eliminating large differences in surface elev between inlets and outlets; by coursing intake downcast air at low veloc close to the surface, so that surface-air temp variations affect only a relatively small part of downcast air columns; and by coursing return air at high veloc, to conserve relatively high temp in upcasts. For application of these methods to a medium-sized metal mine in mountainous country, see Fig 35.

Fig 34. Controlled Natural-draft Distribution (9)

Artificial aids to natural draft (62, 6). Before the common use of fans, natural draft was supplemented by furnaces, stacks, air- water- and steam-jets, and falling water. Furnaces are particularly dangerous. All these devices are inefficient and have been displaced by fans, except for remote prospect openings and occasional emergency use in controlling natural draft currents (see 2nd ed of this book, Sec 14, Art 11, 19).

Effect of wind. Wind may exert press on mine openings by impact, or increase pressure losses of a mine system by deflecting discharge currents. On a high-press system, the effects are usually variable and small; becoming important only on low-resistance systems, unless winds are very strong. Not more than 80% of wind-veloc press (measured some distance away) is actually exerted on a building of cubical shape, and the same relation is assumed for effects on mine openings. Deflectors, or wind cowls, on mine openings would be a doubtful economy and hardly practicable.

Convection currents are natural draft currents circulating in a single undivided opening. Unequal densities, as between columns in such openings and those in adjacent atmospheres, generate pressures that are used up by flow to keep abs press everywhere in equilibrium. Such currents, sometimes traveling at insensible veloc and hard to detect even by smoke clouds, sometimes strong enough to be easily perceptible, are the major factors in natural ventilation of "dead-end" openings.

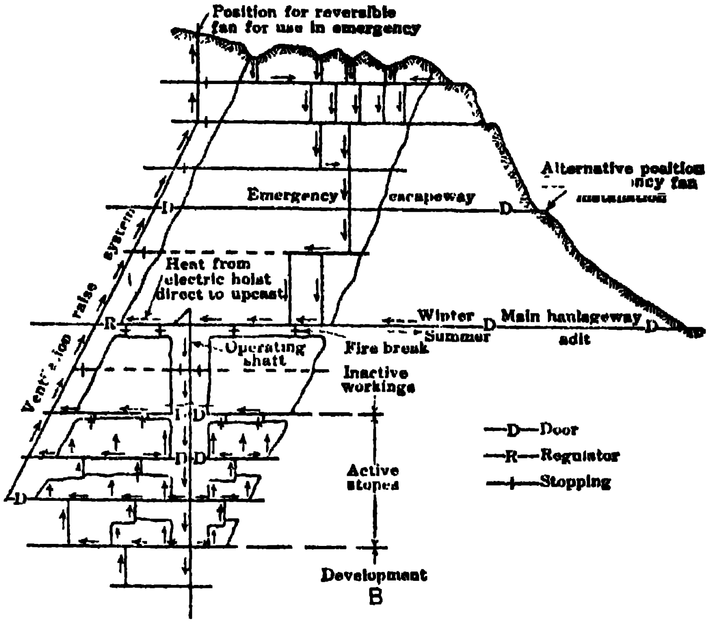

Fig 35 Natural-draft Distribution Controlled to Prevent Seasonal Reversal (9)

In horiz openings, the colder air travels along the floor, the warmer along the roof, with a "neutral" zone between the flows, which expands vertically in the direction of flow until temperatures are finally equalized by action of the wall rock, and flow terminates. In one case, such currents maintained an air temp of 90° F saturated at the face of a 5 by 7-ft crosscut in rock at 115°, and 120 ft from an airway carrying 66° saturated air; in another, a 43° F differential caused currents that could be traced about 1 000 ft (9)

13. MECHANICAL VENTILATION

Definition. Mechanical ventilation produces underground air currents by press differences generated by fans, the pressures acting in conjunction with each other and with natural-draft press. Most coal mines and many metal mines are thus ventilated.

Development of fans. Early types consisted of a rotating drum, with vanes mounted on the open rim and with a central opening in one side, opposite the mine opening, whence air was drawn into the fan and discharged into the atmosphere. With the addition first of a side casing, and later of complete casing with expanding discharge opening, the present centrifugal fan was developed, in which the air is discharged at right angles to direction of entry. Axial-flow fans, in which air is driven axially by the oblique stroke of vanes or blades set at an angle to plane of rotation, have been limited to light duty until quite recently, when propeller designs, suited to all mine service, became available. Positive-displacement machines (Art 14) are used only for ventilating long tunnels. Injectors (Art 14) have a very limited use in fan-pipe auxiliary ventilation.

Designations. Fans are termed "main" fans when they handle the total flow of the mine or of a major circuit; "booster" fans when installed to aid distribution in one section of the workings, "auxiliary" fans when used with pipe or tubing to ventilate single openings. Position of the fan with reference to the airway circuit determines the common designations: "pressure" or "blower fan" for intake position; "exhaust" or "suction fan" for discharge position; and "booster fan" for intermediate positions. Position of fan determines press difference between the atmosphere and a particular point in the air circuit, but does not affect the press difference generated by the fan, or, for the same direction of flow, the press losses due to flow (71) (Art 14).

Centrifugal fan is a low-press large-quantity machine, producing a difference in total press between its inlet and outlet. It is essentially a drum or wheel, composed of a number of blades on a frame keyed on a shaft, inclosed in a casing with parallel sides and gradually-expanding periphery. Air entering at center of one or both sides is caught up by the blades, and given a rotatory motion while being thrown toward the periphery. Centrifugal force is developed, which generates static radial press from center to circumference (12). Also, pressure is developed by impulse effect through conversion of velocity press (in excess of that required at discharge) to static press in the expanding housing. Some of the press developed is lost in the fan itself, by friction against casing and blades, and by shock losses at entrance and in passage through the fan. (See Art 14 for performance, Art 15 for application, and Art 16 for selection of fans.)

Open-running fans have side casings only, discharging freely to atmosphere from the periphery. This type, now represented only by the Waddle (English) (3, 6), can be used only as an exhaust fan. A few were installed at U S coal mines, but are now rarely used.

Guibal fan was the forerunner of closed fans with expanding discharge, from which modern centrifugal fans have developed. At first, the casing was circular and extended to about the three-quarter point (Fig 36) where the expanding outlet or evasé started. Blades were flat, but laid back at about 45° from radial position, and supported on braced bars bolted to parallel "spiders" keyed to fan shaft. At first, all were single-inlet. Later designs included more or less complete expansion scrolls, double inlets and backward-curved blade tips, though with many variants; they are slow-speed fans, of diam up to 40 ft. Many are still operating with fair effic in Pa anthracite mines, and a number in the bituminous districts. A modification of the Guibal, the Walker "Indestructible," is still made in England (3). INTERMEDIATE TYPES of deep-bladed backward-curved radial-vane centrifugals, mostly smaller and of higher speed than Guibals, were installed (1895–1910) in U S bituminous mines, the Capell fan (73, 6) being the best known.

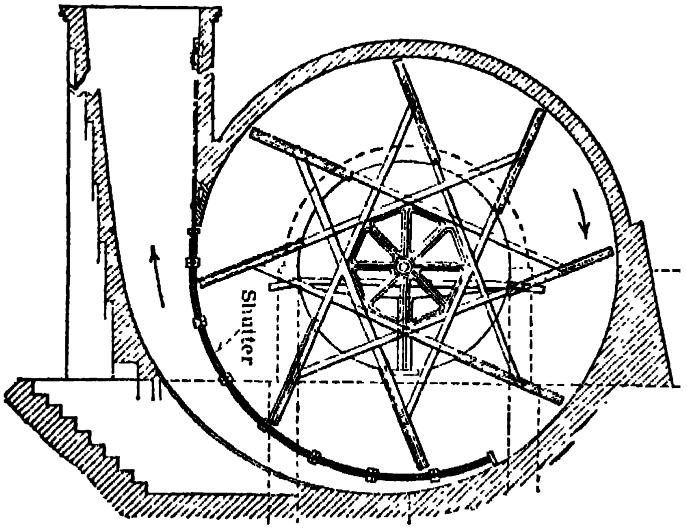

Fig 36. Early Type of Guibal Fan (12)

Multiblade, or " Sirocco," fans. Modern designs in U S are almost all of the multiblade type, wherein the drum-shaped rotor has a large number of shallow blades (the original Davidson or Sirocco had 64, forward-curved blades). Designs differ mainly as to shape and position of blades. Although types with radial, forward-curved, backward-curved and composite-curved blades were developed simultaneously, 1900–1905, the forward-curved blade types, due to greater capac for equal size and speed, have dominated the U S mining field. Practically all main fans at metal mines, most fans at bituminous coal mines, and many at anthracite mines, are of this type.

Fig 37 shows a typical Sirocco fan in an old-style, single-inlet, industrial type of casing. Late designs have a higher cut-off with top of fan discharge about on center-line, thus reducing overall height; mine designs have evasé discharge. Most metal-mine and many coal-mine fans in U S have this type of rotor. A commoner type at coal mines is the Jeffrey stepped multiblade rotor shown in Fig 38. BACKWARD-CURVED MULTIBLADE FANS, on account of certain desirable characteristics for mine use (Art 16), were introduced in a number of designs about 1925. Many have been installed, particularly in metal mines for secondary services, but there are few main-fan installations of this type, probably because of size and speed limitations.

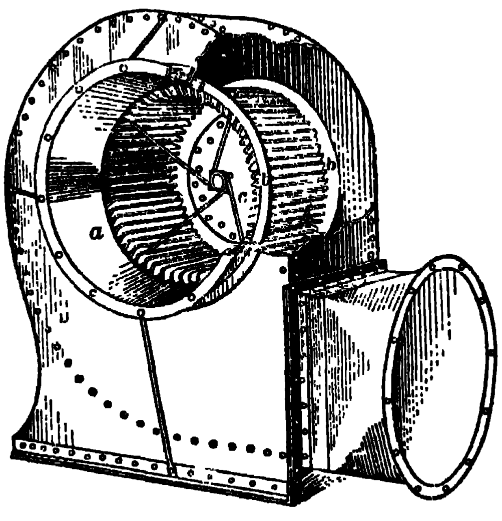

Fig 37. "Troy" Sirocco Fan (6)

Variations in design. Available designs vary in number of inlets, width, degree of completeness of housing, and direction of rotation and discharge. Basic design of standard single-width fan may have single or double inlets. A double-width fan always has

2 inlets and is virtually 2 single-width fans with rotors on a common shaft. Double-width fans are popular as main fans for mines, especially underground, because both fan and installation costs of large units are usually lower than for single-width. The latter generally give lower total costs for small units and sidehill surface locations. The double-width fan passes about twice as much air at same press as the standard single-width of same design. Fans of special width occasionally are used for operating conditions not conveniently met by standard designs. Standard design has a complete metal housing (" full-housed "). The purchaser builds foundations according to plans supplied with the fan; since he must erect a building to house the fan drive and ducts to connect the fan to the mine, he may also build part of the fan housing, for which the maker furnishes plans; the fan is " half-housed " if the buyer builds the lower half, " three-quarter housed " if he builds the lower quarter of the housing. Where the casing extends below ground level, it is important to provide for draining the pit.

Reversing arrangements. Air flow through axial-flow fans is reversed by reversing direction of rotation. In centrifugal fans, direction of rotation is constant, and flow is reversed by reversing the connections of fan to atmosphere and mine respectively, by adjustment of doors in the housing (Fig 39). The doors permit considerable leakage, and resistance to flow through the connections is greater for reversed than for normal flow; hence design should be governed by the primary duty. In a surface installation, the reversing feature represents up to 20% of cost; underground, up to 50%.

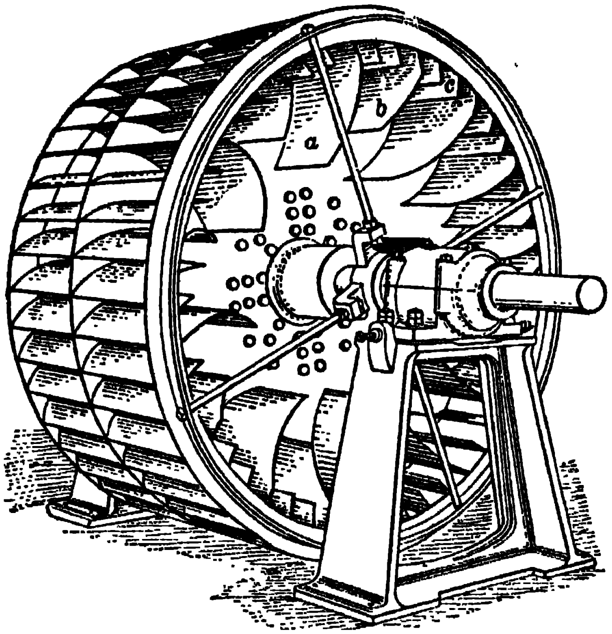

Fig 38. Rotor of Jeffrey Mine Fan (6)

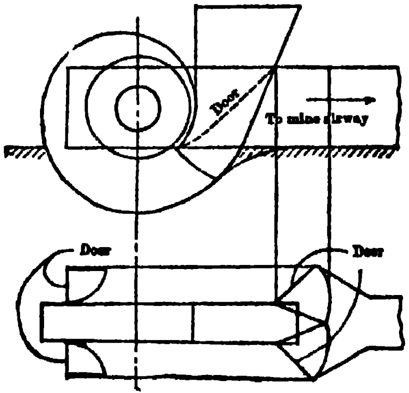

Fig 39. Setting for Reversible Fan

Direction of rotation and discharge. Direction of discharge is designated by the relation of center line of discharge to position of fan shaft, when viewed from the drive side (in a single-inlet fan, the side opposite the inlet, regardless of position of drive). From this viewpoint the normal rotation and discharge are clockwise, and vice versa. If the line of discharge is horiz and above the shaft, the discharge is top horiz; if below the shaft, bottom horiz. If the discharge is vert, it is either upblast or downblast, according to whether above or below the shaft. Discharge in any other direction is angular discharge, and specified in degree as top or bottom angular, up or down discharge.

Disk fan is an axial-flow fan with plane or curved vanes, attached to a shaft through a central hub or disk. It is easily erected, operates at high speeds, is cheaper than a centrifugal for the same duty, permits reversal of flow by simple reversal of rotation, and is only a little less efficient than a centrifugal; but it is adapted only to a low resistance system. Many are installed at coal mines, a few at metal mines. Usual types have iron or steel wheels, 1.5–10 ft diam, with 5–12 vanes with tips at about 30° to plane of rotation, corresponding to a peripheral screw pitch of about 1.8 diam. Casing is cylindrical and serves merely to protect blades and give a surface to seal to. To increase effic by preventing eddies, late designs have the central part, to 0.5 diam, blanked off with a disk or cone. Limiting tip speed is 2 000 ft per min for large, to 12 000 ft for small fans. Pressures rarely exceed 1.5 in water-gage, but greater press is obtainable from especially strong wheels. Larger sizes pass 100 000–150 000 cu ft per min.

Propeller fans (7) of axial-flow type, with propeller-shaped blades attached to a central hub on a shaft, are refined types of disk fans, developed in aeronautical research. They generate high veloc at low press differential, at the same time imparting a spin to the air.

For high effic, an expanding discharge (diffuser or evasé) is required to convert veloc to press, and guide-vanes are required to take the spin out of the air after it leaves the propellers, or to put the proper spin in the air as it enters them (Fig 40). Advantages of modern designs are: cheapness and easy flow-reversal of the disk fan, non-overloading power characteristic (Art 16) of the backward-curved multiblade centrifugal, and higher effic than present-day centrifugals. They are therefore rapidly supplanting centrifugals in mine service, where their chief drawback, noisiness, is rarely important.

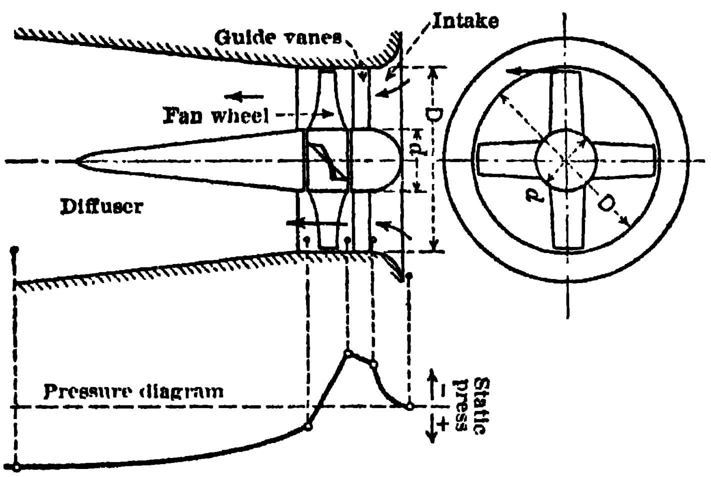

Fig 40. Propeller Fan (7)

An early Coppus design found use in Western metal mines for auxiliary and booster service. Steart in Australia (66) showed that airplane-type propellers, mounted in series on a common shaft, give effic comparable to that of centrifugal fans and can be adjusted to variable duties by changes in number and pitch of blades. A number of Steart fans have been installed in So Africa and in England, where one at the Grange colliery (67) has 14 10-ft diam, 2-bladed propellers. In the Jeffrey Aerovane (1931), 12 airplane-type blades are mounted in a single hub, and 2 stages, or 2 fans in series on a common shaft, are used for press much exceeding 2 in, depending on diam. A later design, the Aerodyne, has 8 blades of typical propeller-fan design, operating in a streamline fairing, and applies to all mine pressures in a single stage. Ladel-Troller fan has 4 blades operating in a shaped central fairing and is also designed for the whole range of mine press in 1 stage, as are 2 similar designs used in Europe and So Africa, the Belgian " Aeroto " and English " Aerex." Experiments are in progress to provide for changing pitch of blade, so as to maintain max effic with changing mine resistance, a feature of the Steart fan omitted in later designs.

Fan bearings. In smaller sizes, shaft bearings are supported by the housing, but in the larger units, the shaft and wheel are supported on pedestals independent of the housing. If foundations settle, as they often do around mine workings, wheel and casing are thrown out of alinement and performance is seriously affected.

Fan drive. Direct-connected steam drive is preferred at gaseous mines, as most dependable and permitting easy change of speed. Belt drive by constant-speed a-c motor is common, with speed adjusted by changing belt pulleys. Variable-speed motors are sometimes advantageous, but seldom used because of higher cost. Direct-connected units are best for auxiliary fans, occasionally for boosters; their speeds are limited by the phase and cycles of the elec current; 3-phase, 60-cycle predominates, but 25-cycle current is sometimes used. Short-center V-belt drives are favored, as flat-belts often give trouble underground. Squirrel-cage induction motors are common, although synchronous motors may be used on large units for power-factor correction, and other types for multiple-speed control. At gaseous mines, either 2 units with different sources of power, or 2 different types or sources of power for a single unit are required for absolutely dependable service. Steam and elec drive for close-in fans, and elec and gasolene-engine drive for outlying fans, constitute good practice in anthracite mines. Auxiliary fans of several types are made for comp-air direct drive by a turbine attached to the fan; small comp-air motors are also obtainable. These are less effic than elec drives, but useful when current fails, as at time of a mine fire, and for temporary service, since comp air is generally available in metal and anthracite mines.

Booster fan position, in active areas underground, requires provision for trips and men to pass without disturbing the flow. If 2 openings exist at desired location, fan is placed to discharge through a stopping in one, with an airlock in the other; if there is only one opening, fan may be placed in a short run-around drift, and the original opening is air-locked. In firm ground it is generally cheaper to widen the opening and provide an airlocked passage alongside the fan (Fig 41). With passage limited to men and single cars, a small fan may be placed at one end of a short air-lock, with the discharge carried through the doorframes in pipe of same area as fan discharge. Installations should be fireproof, or at least fire resistant. Fans with non-overloading power characteristics (Art 16) are best for this duty. Confining flow to one airway in itself increases the normal resistance, which is often further increased by design of installation. Direct drive is preferable to belt for all underground installations.

Cost of fan installations. Total costs of complete main-fan installations (1925-30) range from $5 000 to $15 000; booster fans, $2 000-$5 000; auxiliary fans, $300-$1 000.

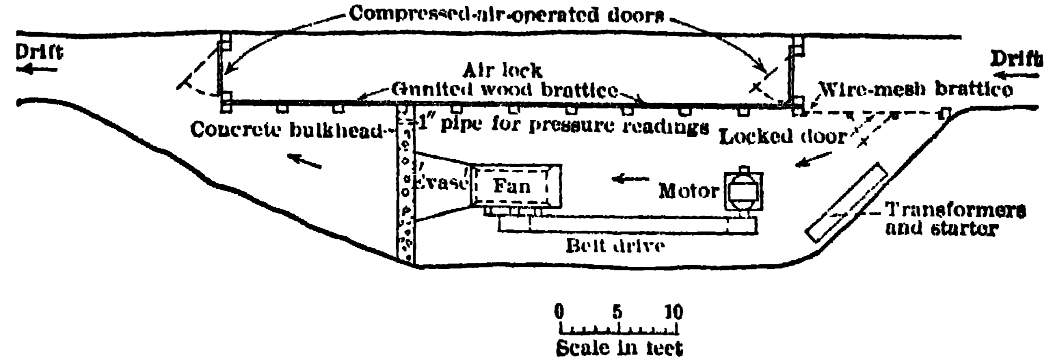

Fig 41. Booster Fan Installation (9)

Cost of centrifugal fans, wheel and casing only (with evasé), f o b factory, is approx 40 D^2 dollars for single-width, single-inlet, non-reversible fans of width 0.5 D; and 60 D^2 for double-width, double-inlet, reversible fans of width D, where D is diam of wheel in ft. Side drifts for reversing add $500-$1 500 for the ordinary large double-inlet, double-width fan, for which shaft hoods aver $500 and airlocks $150 extra. Total costs of non-reversible installations aver about 3 times, and of aver double-width reversible installation about 4 times, the cost of fan alone. Approx costs f o b factory (1936) of centrifugal fan and motor for auxiliary ventilation:

8-in	diam	pipe,	8-in	diam	fan	wheel,	1-hp	motor,	$140
12-in	"	"	16-in	"	"	"	5-hp	"	$320
24-in	"	"	23-in	"	"	"	15-hp	"	$900

Cost of disk fan, without motor, f o b factory in 1936 was approx 80 + 6 D^2 dollars, where D is diam in ft.

Centrifugal compressors are sometimes used for auxiliary ventilation in tunnel driving, where press requirements of long pipe lines are 1-3 lb per sq in. They have same characteristics as centrifugal fans (Art 16), but the large density changes involved at compressor and in the line must be considered (68). For given speed and inlet volume, ratio of abs discharge press to abs inlet press is constant for fixed resistance (12).

Volumetric, or displacement, ventilators. The rotary positive-press blower (Fig 42) is the only one in common use for forcing or exhausting air through long pipe lines under press differences of say 1-3 lb per sq in. Theoretically, they pass a fixed volume per rev; actually some air trapped at each rev leaks from discharge to inlet side ("slip"). The amount of slip depends on press and clearances, and is specified as "slip speed," required to maintain a definite press at no delivery. Variations in air density must be taken into account for pipe line press and blower performance (68).

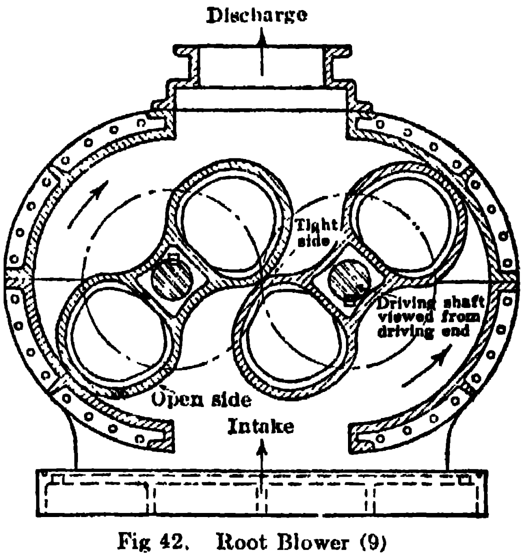

Fig 42. Root Blower (9)

Compressed-air injectors are useful in emergencies; they are cheap and easily installed, but very ineffic. They depend on conversion of the energy of a high-veloc jet into press required for the desired flow. For low-resistance flows, where only discharge veloc is desired, a jet discharging along the axis of a pipe is sufficient. Where flow against resistance is required, venturi designs are used to convert veloc press to static press. Most home-made designs are patterned after the "Modder Deep" (Fig. 43); much used in German and So African, to some extent in U S metal mines, but very little in coal mines. Performance may be closely approximated by theory (69). Effic increases with proper design of venturi, as resistance of line increases and as air press decreases.

Saccardo system uses a low-press injector for ventilating tunnels, by which streams of high-veloc air are discharged from nozzles, or wall openings, at a slight angle to axis of tunnel. Performance (70) varies mainly with ratio of nozzle area to airway area. Effic is max for one condition only, as for fans, and may possibly reach 50%, but overall effic is less than half that of direct fan ventilation, and veloc restricts use to low-resistance (smooth-lined) systems. Example, Liberty vehicular tunnels, Pittsburgh.

Pressures caused by moving objects in air passages assist or retard air flow. Large-vol circulations often are reversed temporarily by movement of skips and cages in shafts.

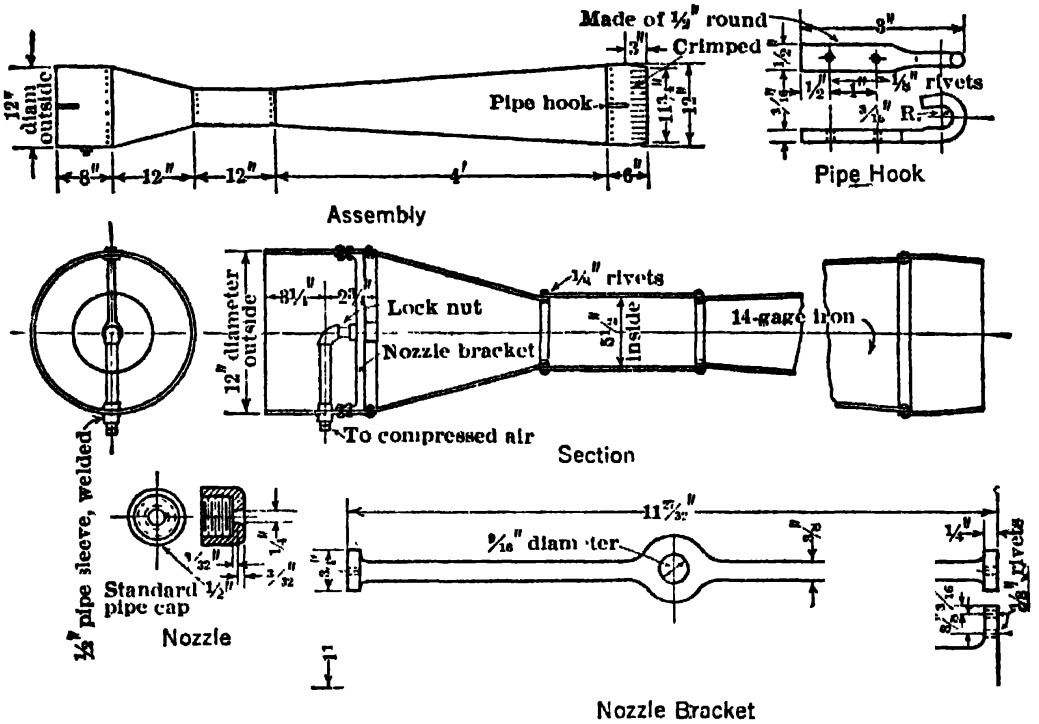

Fig 43. Modder Deep Type of Comp-air Injector (9)

Effect depends mainly on shape of object and ratio of its area to area of airway, and is reduced by decreasing area ratio and by frequent openings between adjoining airways or compartments of multi-compt shafts. No authentic data for computation of effects under mine conditions are available.

14. FAN PERFORMANCE

Performance is determined by test. Theory gives only rough approximations for centrifugal fans (72, 73), and, though more precise for recent propellers (74), offers no simple mathematical relation between vol of flow and press, due to the variable balance between press gains and losses in the fan itself, when operating against varying flow resistance. Formerly, when fans were specially constructed for each mine, largely by rule-of-thumb, the operator's main interest was in design. Now, when construction is left to specialists, and makers offer effic designs in a range of sizes for all requirements, the operator's main interest is in selecting a fan suitable for his needs.

Mine resistance determines fan size. Special sizes (except very large ones) are rarely made. Any one fan will operate at max effic against only one resistance condition, or press-vol relation, and at less than max against all others; but a size may be selected for operation close to max effic against any resistance. Primary condition for effic service is that size of fan must fit the mine, or position of fan in the circuit. Not quantity, but resistance to flow, which practically means size of airways, determines size of fan. Low resistance requires large fans; high resistance, small fans.

Tests. Makers determine performance by laboratory tests, as prescribed by the Standard Test Code of Nat Assoc of Fan Manufacturers and the Amer Soc of Heating and Ventilating Eng (75). Measurements of 5 factors are required: speed, density, quantity, press, and power; repeated, with speed practically constant, for 8 or more different resistance conditions, by varying the resistance added at discharge or inlet end of a test duct. Similar tests are sometimes made on fans in place at a mine, to determine performance, or data on operating conditions and mine resistance. Conditions in field tests are usually unfavorable for accuracy, and results are approx only.

Characteristic curves. Results of tests, corrected to constant speed and standard air density (see below), and plotted against quantity as a base, give a series of " characteristic" curves that specify fan performance (Fig 44). The total-press variation with quantity is the basic characteristic that shows results when the fan is applied to a mine, and is therefore the true "fan characteristic"; point of operation is determined (Art 15) by the intersection of the mine characteristic (Art 11) with the fan total-press characteristic. Point of operation *a* (Fig 44), determines quantity *Q*, and this in turn determines the total press *H*, rated static press *S*, mechanical effic *E*, and power *P*.

Fan laws. Changes in performance have been found by experiment to obey certain laws closely enough to permit general use of the laws over a large range of variation in flow. Hence, from one set of constant-speed tests against variable resistance, fan-performance characteristics can be computed for other speeds and sizes. Actually, a slight increase in effic accompanies increase in speed, but is ignored. Also, fan performance differs slightly, depending on whether the fan takes air at zero veloc, as in the blower position, or at definite veloc, as in exhaust or booster positions, since the shock-press loss in the fan entrance is larger for the first case. With coned or rounded inlets, the difference is negligible. A slight increase in effic also accompanies increase in size of fan, important enough in the smaller sizes to require separate characteristics for different size groups. The larger sizes, for main fans, can usually be placed in one group with little error. With these qualifications "fan laws" are: (1) If speeds of a fan operating against fixed resistance are changed: (*a*) effic remains constant; (*b*) quantity varies directly as *s*; (*c*) press maintained varies directly as s^2; (*d*) power required varies directly as s^3. (2) If geometrically similar fans, with diam in ratio *m*, are operated at the same speed, then, for constant effic: (*a*) quantities vary directly as m^3; (*b*) pressures maintained vary directly as m^2; (*c*) powers required vary directly as m^5. (3) If density of air is changed: (*a*) quantity and effic remain unchanged; (*b*) press and power vary directly as the change in density.

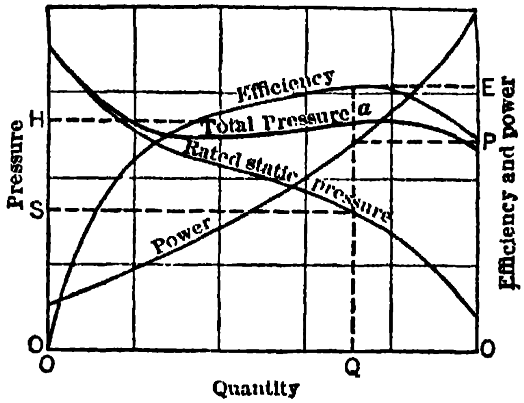

Fig 44. Characteristic Curves of Fan Performance (9)

Pressures and ratings (9) are confusing because press difference, measured directly against atmos press, does not correspond directly to the total-press difference generated by the fan. To avoid confusion, most makers rate their fans on a static-press basis. Fan performance has therefore come to be based almost entirely on static-pressure measurements, to which it has no direct relation, but by which it is approximated closely enough in most cases to obviate serious error, since the veloc press involved in the usual installations is small. Static-press rating must refer to a definite area and operating position. Ordinarily, it is based on area of the discharge connection, and the blower position of operation. Fans for use only for exhaust are sometimes given static-press ratings based on area of inlet connection; then ratings may refer to a fan with free discharge, but usually to a fan having evasé discharge integral in the design.

Pressure graphs (71). The best way to avoid confusion, in correlating field test results to fan ratings, is to chart the press changes, which are changes in abs press, though charted from atmos as a base. Then: (1) difference between aver total press at fan inlet and discharge is the only constant value for all operating positions, and is the value to be used in determining rated static press, which customarily is one discharge-veloc press less; (2) aver total press at any cross-sec of a ventilating system is the algebraic sum of 2 mutually convertible components, static press and aver veloc press, the ratio of which depends only on area of cross-sec; (3) aver total press and static press may be positive or negative in relation to atmos press, but veloc press is always considered positive; (4) aver abs total press always decreases in direction of flow; but (5) is always increased in this direction by a fan. Relations of fan and ventilating-system pressures to atmos are shown graphically in Fig 45 A, B, and C, for 3 fan positions in the same circuit assuming uniform resistance and veloc throughout. In each position, total press developed is the same, and the fan's static-press rating equals this total press, minus veloc press at discharge; that is, it is based on discharge area of the fan operating as a blower. For the exhaust position (Fig 45 B), negative total press at the inlet is equal to static-press rating (blower position) and is independent of area of duct; it is therefore used as an alternative rating for fan in exhaust position. Aver total press over a mine section can be observed directly only by a traverse; hence, is usually computed from measured static press and calculated mean veloc press. Use of such different pressures for rating in different fan positions leads to confusion, increased by still another mode of rating required for a fan in booster position. The basic facts are: position of operation is immaterial; true performance is the total press difference generated; rated static press is an arbitrarily determined figure that has a direct relation to the press generated.

Pressures underground. Where flow for fan in booster position underground is through mine airways, the graph of press change is as in Fig 45 C, but atmos press is not available as a base. Basic measurement is the difference in static press between a point close to the inlet, such as *X*, and a point close to the discharge, such as *Y*. If quantity of flow and the areas at *X*, *Y* (fan inlet and fan outlet) are known, velocity press can be computed and the graph followed to determine the fan total press and rated static press.

Evasé discharge, or gradually expanding section (Art 10) added to fan discharge, increases both total and static (negative) press at inlet of exhaust fan (Fig 45 D), and thus increases proportion of press difference generated that is usefully applied, but without effect on the total press difference. When added to blower-fan discharge, it reduces shock loss at discharge by reducing difference in veloc, which is also its true effect with exhaust or booster fan position. (See paragraph above on "Pressure graphs.") Evasé is really part of the airway system, but is usually supplied by manufacturer to assure effic use of veloc of discharge of fan proper.

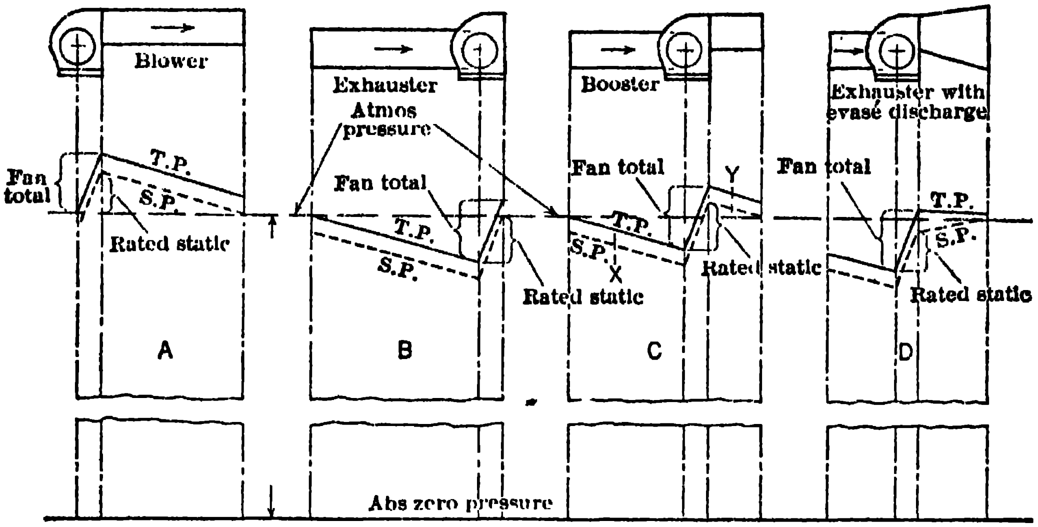

Fig 45. Pressure Changes in Ventilating Systems (71)

Mechanical effic. All of the energy supplied to a fan is not applied to useful work. Part of it, varying with the resistance against the fan, is required for flow through the fan itself; the rest represents useful work, the hp in the air. Useful work per unit of time divided by corresponding power input is the mech effic of the fan. Useful work is computed from total press of the fan and vol of flow. In data on fan performance, " mechanical effic " refers to effic based on total press, even though the fan's press rating is given on a static-press basis. Occasionally, for convenience of application with rated static press, a " static effic " (calculated from rated static press) is given. This bears the same ratio to effic that rated static press does to total press, and can thus be used directly with rated static press to calculate power requirements.

15. APPLICATION OF FANS TO VENTILATING SYSTEMS (12, 9)

Constancy of fan duty. Fans may act singly or in combination with other pressure-generating sources. In a ventilating system there are usually natural-draft pressures acting in series with or against the fan press, and often 2 or more fans acting in series, parallel, or series-parallel combinations with each other and natural-draft press. When a fan is the only pressure source, its required duty is constant, and controlled by the resistance; but when it operates with other pressure sources, all combine to overcome the resistance, and the duty of a fan operating at any one point is variable and determined by its position and by intensity of the other sources acting with it.

Fan as only source of pressure. A fan running at constant speed can produce only the combinations of press and quantity of flow indicated on its characteristic curve (Art 14) for that speed. Press losses in a ventilating system vary with quantity of flow, and the possible combinations are indicated by the characteristic curve of the system (Art 11). Only one combination of press and quantity will satisfy both fan- and system-characteristics; this is indicated graphically by the intersection of fan- and system-characteristics at *a* in Fig 46, which determines press as *H* and quantity as *Q*.

Fan in series with natural-draft press. Except in auxiliary service, fans rarely are the only source of press. Components of natural-draft press always act either with or against fan press. If of small intensity they may be neglected, but in a deep mine they are important in determining both fan duty and quantity of flow. If all workings are on one level, there is but one component of natural draft, developed between the highest surface opening and the level of the workings, and this press acts in series with a fan passing the total flow. In a multi-level mine, the components of natural-draft press act like a group of constant-press fans operating in parallel, and with the resultant of the group operating in series with fans on the main flow. Although problems of distribution require different treatment (Art 12), the resultant of the components acting in series with a main fan may be treated as approx the natural-draft press developed between the highest surface opening and the uppermost mine connection carrying an appreciable part of the total flow. Such pressures developed below the uppermost main cross-connection have little effect on the duty of a fan in the total-flow part of the circuit, but act mainly to change the distribution below this level from that which would result with the fan acting alone (9).

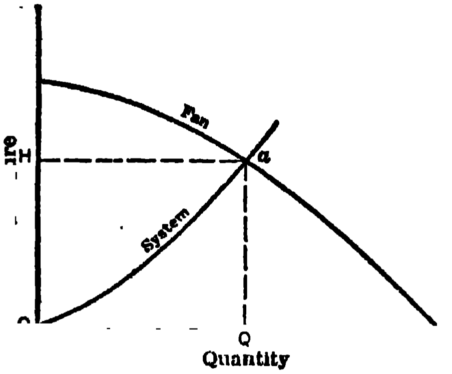

Fig 46. Fan as only Pressure Source (9)

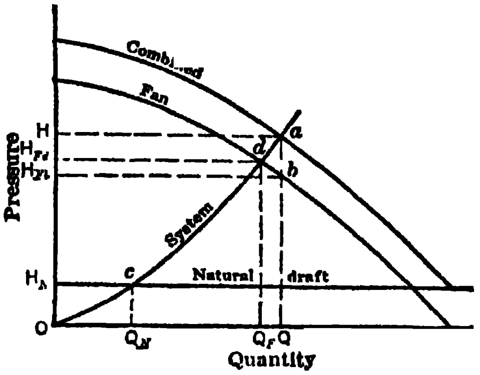

Fig 47. Natural Draft acting with Fan (9)

Natural draft acting with fan (Fig 47). The combined press characteristic of both fan and natural draft is obtained by adding the pressures for equal volumes. Flow conditions are indicated by intersection of the combined press characteristic and the system characteristic at *a*, which determines total press as *H* and quantity as *Q*. The latter determines the operating position of the fan for this condition, as at *b* on its characteristic, and the fan press as H_{F_b}. With natural-draft press H_N acting alone on the system, the intersection of the natural-draft and system characteristics at *c* indicate the quantity of flow as Q_N. With the fan acting alone on the system, the intersection of characteristics at *d* indicates its operating position and determines the pressure as H_{F_d} and quantity of flow as Q_F. Practical result of natural draft acting with the fan is a decrease in resistance and an increase in quantity of flow over what would be produced by the fan acting alone.

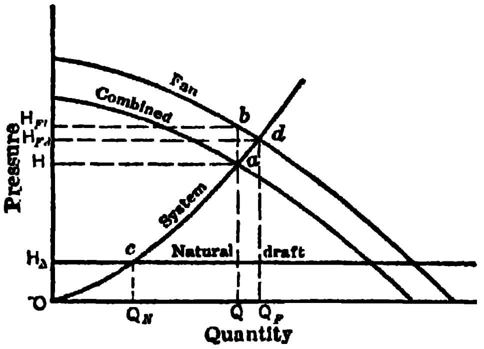

Fig 48. Natural Draft acting against Fan (9)

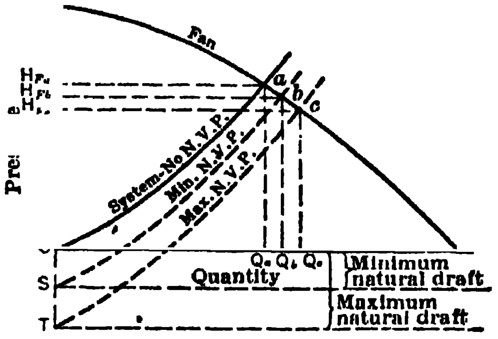

Fig 49. Fan Characteristic used as Combined Characteristic for Fan and Natural Draft (9)

Natural draft acting against fan (Fig 48). The combined characteristic, obtained by subtracting natural-draft press from fan press for the same vol, crosses the system characteristic at *a* and determines press and quantity of flow as *H* and *Q*. *Q* determines the operating position at *b* and the fan press as H_{F_b}. With natural draft H_N acting alone, the characteristics cross at *c* for quantity Q_N, and flow would be in the opposite direction. With the fan acting alone, the characteristics cross at *d*, and quantity would be Q_F, and fan press H_{F_d}. The duty of the fan is changed, through the action of natural draft, from *d* to *b*. Practical result of natural draft acting against the fan is to increase resistance and reduce vol of flow.

Variation in fan duty. If the limits of variation in natural-draft pressures acting in the same or opposite directions are known, combined characteristics can be laid off for each condition, and range of variation in fan duty determined by the quantity intercepts on the fan characteristic, the quantities being determined by intersections of the combined press characteristics with the system characteristic. A more convenient method is to plot the same system characteristics to separate press bases, as at O, S, T (Fig 49), the intercepts OS and OT representing min and max natural-draft pressures on the same scale. The corresponding conditions of fan performance are then determined directly by intercepts of the separate system curves with the fan curve, since the latter, in relation to the proper press base, is equivalent to the combined press curve of Fig 47 or 48. The 3 operating positions of a constant-speed fan, when (1) operating alone, (2) acting in conjunction with minimum natural draft, and (3) with max natural draft, are indicated in Fig 49 by the intersections a, b, and c on the fan characteristic.

Equivalent resistance. When pressures act in combination on all or part of the flow, the characteristics of a fan operating at a particular point are governed by the fan laws, but the operating point is determined both by resistance of the system and by the other pressures acting on the flow. As the major point in mine ventilation is the press-vol relation at the main fan, this relation often is referred to incorrectly as the mine resistance. It is better termed the " equivalent resistance " (9) against which the fan must operate. Since, in a system acted upon by pressures in combination, the equiv resistance for a particular pressure source is determined partly by press losses which do, and press gains which do not, follow a definite law, it can be determined only by direct test or by graphic methods. For known characteristics of press gains and losses, the graphic method may be used. When these are unknown, the press-quantity relations at different fan speeds may be plotted as the characteristic of equiv resistance. Then the particular point of operation of the same or a different fan for the same conditions may be found by using this equiv-resistance characteristic as a system characteristic, and solving graphically for the point of operation, as though the fan were the only press source.

Fans in series. Although generation of press at one point in a system is generally cheaper, sometimes more effic distribution and better operating conditions may be obtained by generating press at more than one point, particularly where resistance to flow is abnormally high or leakage circuits are unavoidable. Fans operate in series when working on the same flow circuit, each handling total circuit flow and each generating part of the total press required. Any number of fans can be so used. Flow conditions are determined by the intersection of the system characteristic and the combined press characteristic of the fans, the latter being the combined fan pressures plotted against quantity.

Series diagram. Fig 50 shows the separate and combined characteristics for 2 fans acting in series on the system. System and combined fan characteristic intersect at c, whence press and quantity of flow are H and Q. As each fan must pass this quantity, its operating position is shown by the intersection of the Q ordinate with the fan characteristic, at d for fan A and at e for fan B, determining the separate pressures as H_A and H_B. If the mine characteristic does not intersect the combined characteristic of the 2 fans, then the larger-capac fan will pass more air alone. Unless fans are properly selected, and operated at proper speeds for the work to be done, they will not work in series at max effic. Where a single fan operates inefficiently, because designed for less than the resistance encountered, a second fan may be installed to operate with it at any point on the total-flow part of the system, and be so selected that both fans will operate at or near max effic.

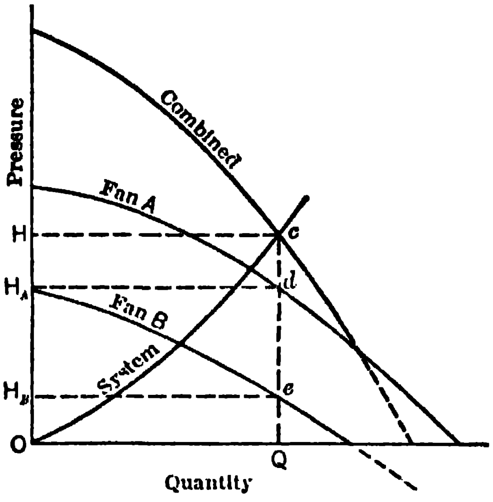

Fig 50. Two Fans acting in Series (9)

Fans in parallel may be used to take full advantage of the layout of airways available, to provide for effic operation within certain limits of change in resistance, or to increase the effic of a fan that by itself would be operating against a resistance lower than that for which it was designed. The fans may be placed to operate on the same or separate airways. Fans on the same airway act together, and a simple graphic solution is available, like that for fans in series. Their combined press characteristic is obtained by plotting pressure against combined quantity. In Fig 51, intersection c of the system and combined fan characteristic determines press H; and, since press must be the same for both fans, the H abscissa determines the relative fan quantities, Q_A and Q_B, by intersections d and e. If the mine characteristic does not intersect the combined characteristic, then the higher-

press fan *A* will pass more air alone than the 2 fans together, and if an attempt is made to operate them in parallel, *A* will blow air back through the lower-press fan *B*. If intersection *c* is at a press higher than any press on the characteristic of fan *B*, the same reversal of flow will occur. Fans having steeply sloping press characteristics act together well in parallel; those that have characteristics combining a comparatively flat part and a steeply sloping part must be operated on the steeply sloping part, at a sacrifice of effic, else a sudden change in the equiv resistance of the system may cause the higher-press fan to take all the load, with danger of burning out a motor. Where forward-curved-blade fans are so installed, various precautions are taken, such as use of fans exactly alike, operated at the same speed or from a common drive shaft; arrangements for speed regulation on one or both fans; or an "equalizing" tube connecting the fan inlets or discharges. FANS ON SEPARATE AIRWAYS constitute the more usual layout for operation in parallel. Where the resistances of the separate airways are comparatively large, very little trouble is experienced, but it is difficult to determine the equiv resistance against which fans so installed must operate for a fixed speed. Resistances of the separate airways, and of the system beyond their junction, must be considered, and flow conditions and fan performances must be solved graphically by trial and error.

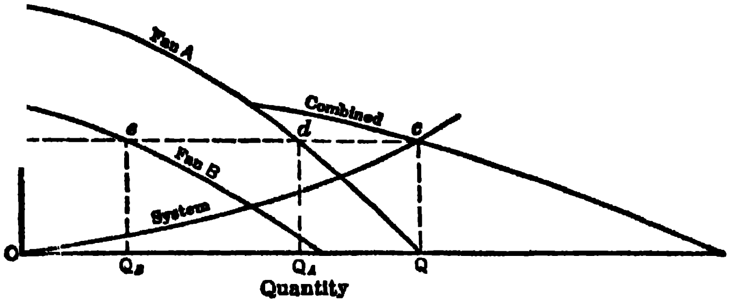

Fig 51. Two Fans acting together in Parallel (9)

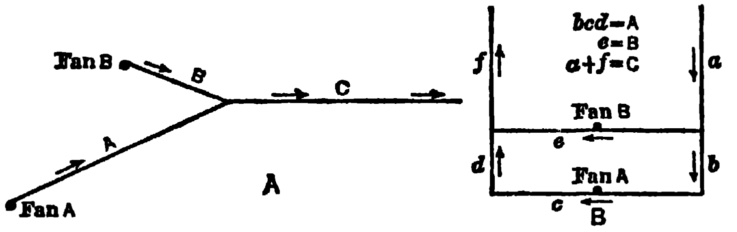

Fig 52. A, Analysis of Flow Conditions for Fans acting in Parallel on Separate Airways; B, Sketch Diagram (9)

Where fans in parallel are the only sources of press, distribution may be represented by fans discharging through separate branches into a common duct (Fig 52 A), although actual conditions might be as in Fig 52 B, where the series resistance $b + c + d$ would be equivalent to *A*, that for *e* equivalent to *B*, and that for $a + f$ equivalent to *C*. Primary condition: vol of flow in each branch must be such that press generated by fan, less pressure-drop between fan and junction, shall equal the common press at the junction, which is the press required to pass the total flow through the rest of the system. Fan characteristics and the 3 mine-section characteristics are plotted in Fig 53, and the flow conditions solved graphically by successive trials. A total quantity of flow, Q_C, is assumed; the intersection of its ordinate with system-characteristic *C* determines press H_C, that would be required in the total-flow section *C* (Fig 52, 53). The excess of each fan press over H_C is available for flow through its respective branch, and the broken curves are special fan characteristics, each based on such excess press (fan press minus H_C); the intersections of these curves with system characteristics *A* and *B* (of the branches) determine the quantities of flow through branches Q_A and Q_B, and the press required as H_A and H_B, under the assumed condition of total quantity Q_C. If $Q_A + Q_B$ is more or less than Q_C, then a larger or smaller total quantity is assumed in the next trial. When quantities are found that agree, the intersections of ordinates Q_A and Q_B with the characteristics of their respective fans (solid curves) indicate the equiv resistances against which the fans must operate and the corresponding pressures H_{FA} and H_{FB}.

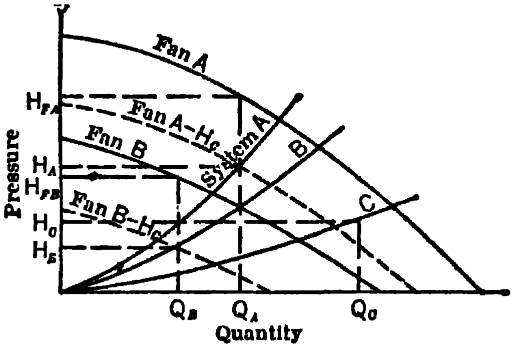

Fig 53. Solution by Trial and Error for Fans acting in Parallel on Separate Airways (9)

Complex combination of pressure sources. In large metal mines fans may operate at various points in conjunction with natural-draft press. The layouts sometimes may be resolved into equivalent simple-flow systems, but often the fan pressures act on only part of the flow in series, parallel, or series-parallel combinations with each other and natural drafts; many leakage circuits are involved, with resultant changes in quantities of flow in addition to those caused by density changes and use of comp air underground. Solutions are therefore complex and only approximate. The important condition is, that the press losses on any complete circuit, regardless of changes in quantity, are equal to the press generated on that circuit, whether by natural draft or fans. If the pressure source may be considered to have a constant-press characteristic, as for natural draft and for limited ranges of operation of forward-curved-blade centrifugal fans, solutions may be aided by mathematics.

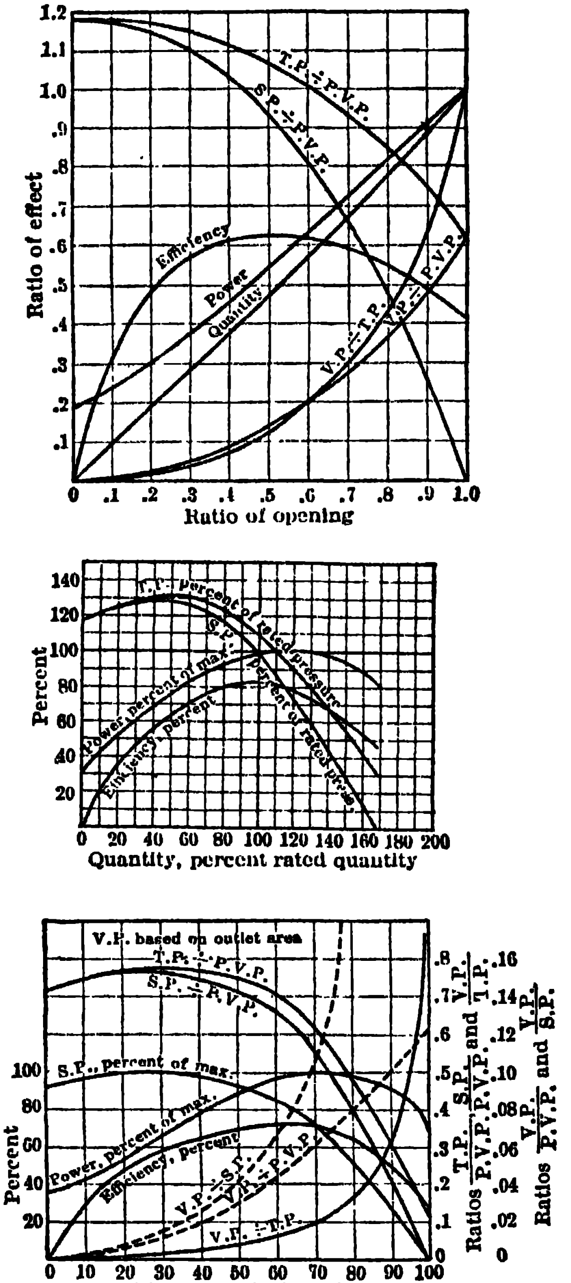

Fig 54. Three Types of Characteristic-ratio Charts

16. SELECTION OF FANS

Performance guarantees. To determine range of duties or resistance conditions, against which a fan must work, is of first importance. The requirements are submitted to one or more makers, who quote on a limited number of sizes and types, from which selection is made on basis of satisfactory performance throughout expected life, at minimum total installation and operating cost. Max effic is not the sole criterion, since, for conditions of limited life, low power requirements, or low power cost, a size smaller than that required for max effic may yield a lower total cost. Makers merely guarantee fans to operate (within the limit of safe peripheral speed) at certain efficiencies in a given range of resistance conditions, without developing mechanical defects. If actual resistance conditions are not as specified, or if they change after the fan is installed, the maker is not responsible for resulting lower effic.

Tables of performance data. For catalog and general use, fan-performance data are tabulated in 3 forms. The first shows rated performance only, for press-quantity combinations that permit max effic; one table represents a complete line of sizes of the same design. In the second and third forms, a separate table gives data for each size over a limited range of high-effic operation: in one of these forms, rated performances are listed in bold-face type; in the other they must be calculated from power, press, and quantity data. Data for performances intermediate between those listed are determined approx by interpolation, or accurately by calculations based on the fan laws (Art 14).

Characteristic-ratio charts. Constant-speed tests against variable resistances on a single size of fan give the maker enough data to determine the operating characteristics of a group of similar fans for any speed. Such characteristics for one size at constant speed (Fig 14) or at a number of speeds, cover the usual service requirements; but in selecting a fan for special requirements, more general methods of representing performance are needed. The basic method is to plot the characteristics as ratios and percentages, rather than actual values; the graphs, in a variety of forms, present a concise conception of the relative changes in performances for the particular design, but their practical use for fan selection is limited. Fig 54 shows 3 types of characteristic-ratio charts.

Constant-effic coefficients. For homologous fans running at constant effic, the fan laws (Art 14) may be combined to show relation of quantity (Q) and press (H) to diam (D) and speed (N), as $Q = k_1ND^3$ and $H = k_2N^2D^2$, where k_1 and k_2 are coefficients. These equations may be combined algebraically to yield many pairs of formulas (76), embracing quantity, press and size, and either quantity or press and peripheral speed, with a coeffic varying with effic in each.

In certain forms the coefficients are dimensionless, that is, independent of the units used (3). Coefficients are plotted against effic in what might be termed effic-coeffic charts, which serve as a base for calculating size and speed requirements for high effic, or for calculating effic for a given size and speed required to pass desired quantity. Coefficients expressing relation of size and speed for max effic only, have had more general use, particularly in the forms: $D = k_3\sqrt{\frac{Q}{\sqrt{H}}}$ for size, and $N = \frac{k_4\sqrt{H}}{D}$ for speed, in rpm, where D = diam in ft, Q = cu ft per min, and H = press in inches of water, either total or rated-static, usually the latter. Values of k_3 and k_4 vary over a limited range; k_3 depends chiefly on ratio of width (W) of wheel to D, whereas k_4 is practically independent of the width ratio. Aver values of k_3 and k_4, based on rated static press, are in Table 6.

Table 6. Size and Speed Coefficients of Fans at Max Effic

	k_3 (size)	k_4 (speed)
Multiblade centrifugals:		
Double-width, $W = D$, forward-curved-blade	0.020	900
Single-width, $W = 0.5\ D$, forward-curved-blade	0.028	900
Single-width, $W = 0.5\ D$, backward-curved-blade	0.031	1 600
Disk fans	0.024	3 500
Late-type Guibals, $W = D + 3$	0.067	1 100
Early-type Guibals, $W = D \div 3$	0.116	1 200

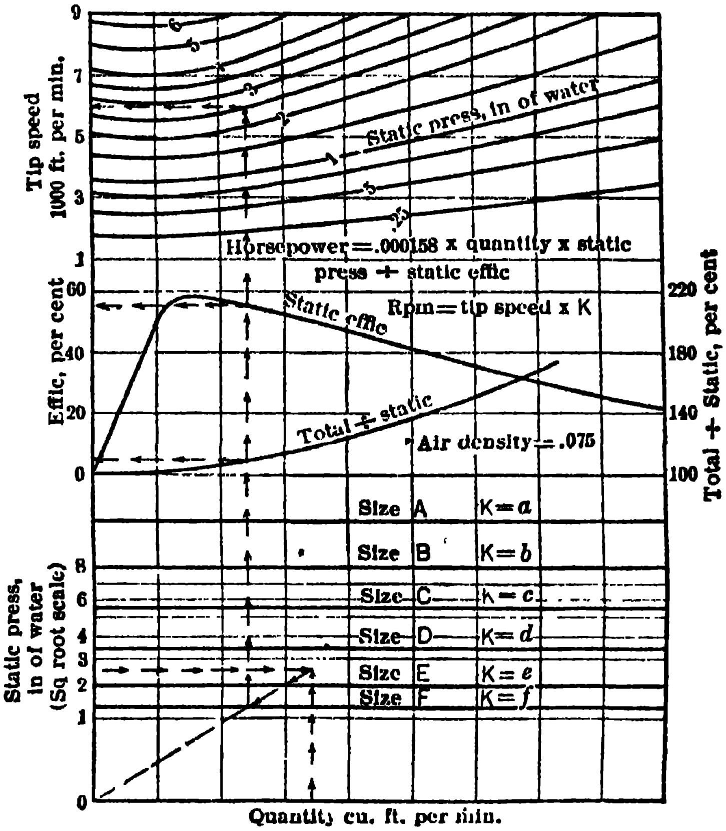

Fig 55. Performance Chart, B. F. Sturtevant Co (9)

Fan-selection charts (76). Properly prepared graphic charts, based on constant-effic coefficients, facilitate fan selection and solution of fan problems, particularly if so constructed that size, effic and speed may be determined directly from quantity and press. Fig 55 shows a simple chart in general use; Fig 56, a proposed, more compact, chart.

Effect of blade shape on performance of fans. General performance characteristics, attributable to blade shape, are shown by the 5 sets of characteristic-ratio curves of Fig 57, 58, representing types rather than particular designs. The characteristics are plotted in terms of resistance to flow, that is, percent r in the general resistance relation $H = rQ^2$ (Art 11), as these are the factors to be coordinated in service. Against percent r, percentage values of power, total press, rated static press, quantity, and effic are plotted for 3 types of centrifugal and for disk fans. Recent propeller designs have characteristics similar to those of the backward-curved-blade centrifugals.

Power characteristics are decisive for mine application. Having power requirements practically constant at, or lower than, the rated power, backward-curved centrifugals and some propeller designs are said to have a "non-overloading" power characteristic and are therefore suitable where resistance fluctuates widely. As both radial- and forward-curved-blade types have rising power characteristics, they are subject to large overloads if resistance is greatly reduced, as by short circuits through doors left open or tubing disconnected from an auxiliary fan. They require motors of excess capac, up to 50%, to guard against possible overloads from fluctuating resistance.

Pressure characteristics have had much attention, being related directly to blade shape. They determine suitability of type for operation in parallel, and where constant

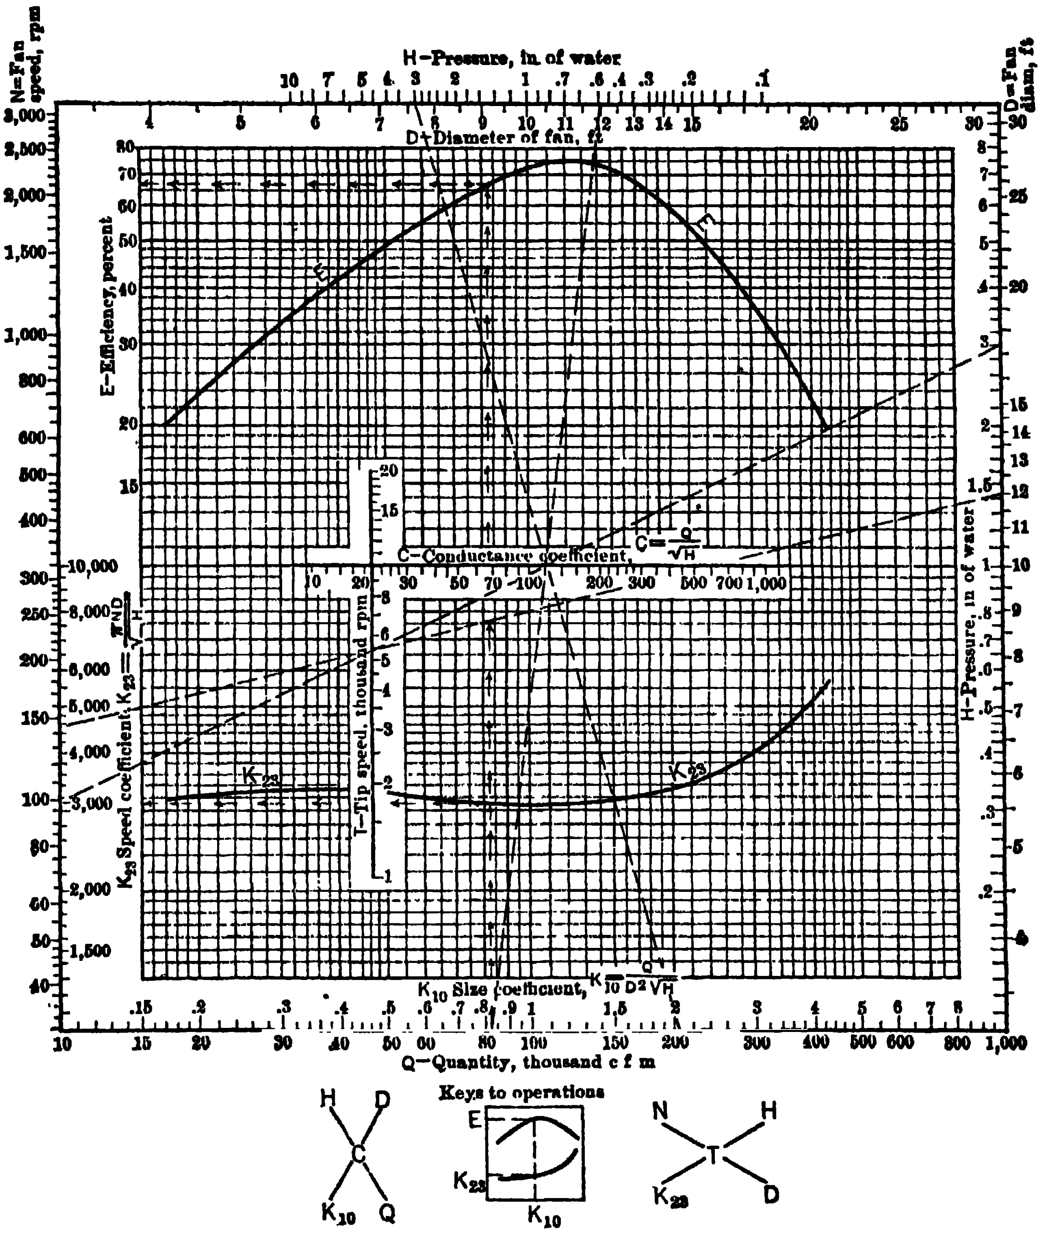

Fig 56. Nomogram Chart for Fan Selection (76)

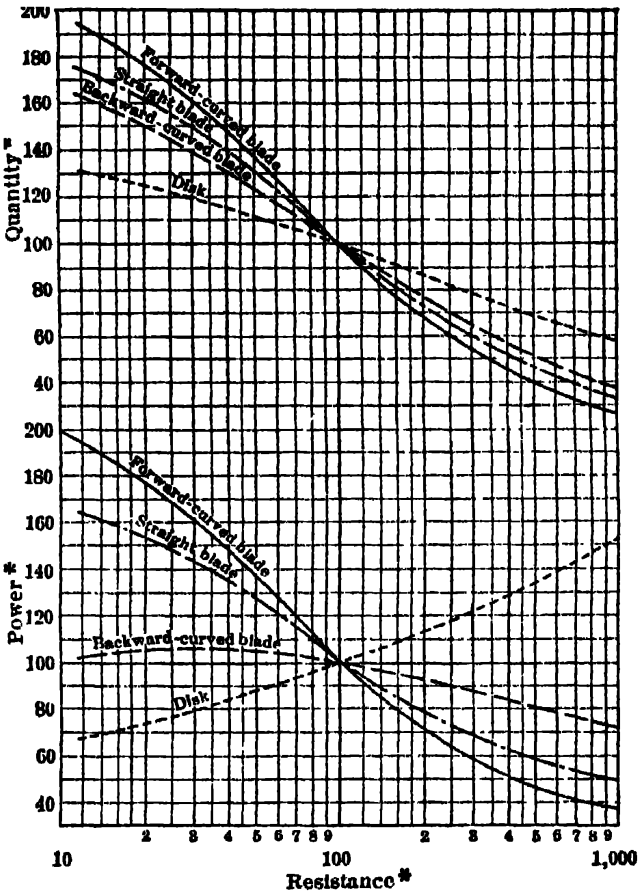
press or constant quantity rather than constant effic is required: backward-curved-blade has a very steep total-press characteristic and is therefore suitable for operation in parallel at max effic; forward-curved-blade has a flat total-press characteristic near max effic and requires large sacrifice in effic for operation on the sloping part of the characteristic, as required when operating in parallel (Art 15); radial-blade has a gently sloping characteristic, requiring only small sacrifice in effic for parallel operation. Press characteristics may be modified by design of housing, as in certain forward-curved-blade types for auxiliary service, which have a steeply sloping press characteristic similar to that of the

backward-curved-blade. Forward-curved-blade types are good for constant-press, and backward-curved-blade for constant-quantity requirements.

Effect of roof falls or short-circuit on water gage. Whether changes in main airway conditions, as a fall of roof or short-circuit, may be inferred from fan press depends on the press characteristics. Water gage for the fan in blower position follows the rated static-press characteristic, and any increase or decrease in it generally indicates change in resistance, though not necessarily the degree of change. Water gage of a fan in exhaust position follows the total-press characteristic (Fig 45); change in press generally indicates a similar change in mine airway and resistance conditions, except for the forward-curved-blade centrifugal, the characteristic for which is so flat over the usual operating range that no such inferences can be made. Most coal- and metal-mine fans have forward-curved-blades, operating in the exhaust position on the flat part of the press characteristic, where water-gage records serve no useful purpose other than to show the constancy of fan speed.

Efficiency characteristics. Economy of operation is not only a question of max effic but also of range of resistance possible at high effic. The flatter the effic characteristic near its max, the more suitable the fan for operation against changing resistance. Effic characteristics in Fig 58 indicate that the backward-curved-blade has a slight advantage over the forward-curved-blade.

Comparative mechanical effic of the various types is fairly well established by consensus of opinion. Virtually all designs can give equally high effic if cost is disregarded, but the designs now on the market have the following comparative ranges of max effic: radial-blade and auxiliary-ventilation centrifugals, and disk fans, 50–60%; forward-curved blade and straight-side backward-curved blade centrifugals, and propeller fans with airplane blades, 60–70%; backward-curved blade centrifugals with coned sides (limited in diam by mechanical design), 70–80%; and late propeller designs, 80–85%. These are actual or total-press efficiencies. Effic based on static press averages about 10% lower. In general, the lower efficiencies apply to smaller, and the higher to larger sizes. Max variation for designs of the same type apparently is limited to about 5%.



*Each scale, Fig 57 and 58, represents values expressed as percentages of value at max effic

Fig 57. Comparative Quantity and Power Characteristics of Mine Fans (9)

Other operating characteristics. For the same resistance, SPEED of rotation (Table 4) of the backward-curved-blade centrifugal is almost double that of the forward-curved-blade, with speed of the radial-blade type intermediate. The speed of the ordinary disk fan is about twice that of the backward-curved-blade centrifugal. High speed is a definite advantage in direct-connected motor-driven units, as high-speed motors cost less than low-speed. QUIETNESS of operation is usually unimportant in mine ventilation. Although conversion of veloc press to static press in the housing is mainly responsible for noise, speed of operation and details of design of both fan and connecting ducts also contribute. Propeller fans are very noisy, forward-curved-blade types of centrifugals moderately, and backward-curved-blade types least noisy. Uniform intensity of noise indicates constancy of performance. Cases of unstable performance are rare; probably caused by turbulence effects at the inlet, due to "wild" turbulence or excessive shock-press losses in inlet passages.

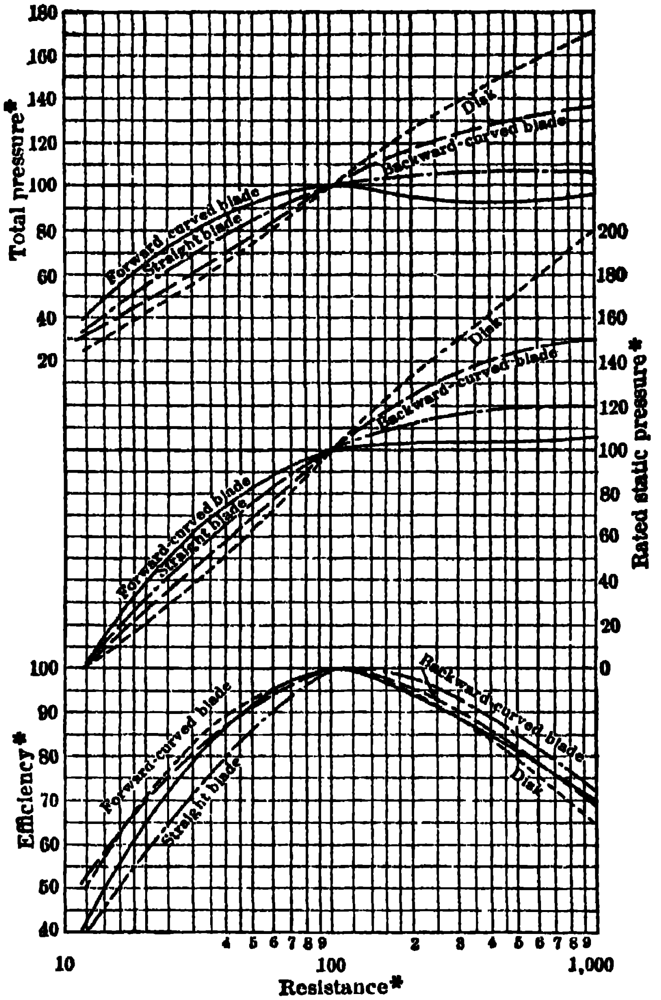


Fig 58. Comparative Pressure and Efficiency Characteristics of Mine Fans (9)

17. CONTROL OF COOLING POWER OF AIR IN HOT MINES

This control is required in many deep-level mines for maintaining effic of manual labor under natural high-temp conditions, and in some cases is of great economic importance. In a few districts, max depth of mining is considered to depend largely on control of air temp, especially on the Rand, So Africa, where a series of deep mines produce about 50 000 000 tons of ore a year, valued at approx $400 000 000, and the recovery of about $3 000 000 000 in gold (77) depends largely on air conditioning at depths of 6 000–12 000 ft. Since 1935, large air-conditioning plants (Art 18) have been installed on the Rand, whence comes much of the literature on the subject.

Limiting air conditions (Sec 23). Comfort depends on rate at which the body loses heat, which in turn depends on wet-bulb temp, air veloc, and dry-bulb temp. Conditions may be compared in terms of kata-thermometer (Sec 23) cooling powers (rate of cooling from 100 to 95° F of large-bulb alcohol thermometer with or without wet sack on bulb) or "effective temp" (temp of still, saturated air that gives same feeling of warmth). Approx empirical relations of Kata cooling powers to temp and air velocity are:

For velocities under 200 ft per min: $K_d = (0.111 + 0.016\sqrt{V})(97.5 - t_d)$ and $K_w = (0.194 + 0.08\sqrt[3]{V})(97.5 - t_w)$. For velocities over 200 ft per min: $K_d = (0.072 + 0.019\sqrt{V})(97.5 - t_d)$ and $K_w = (0.056 + 0.011\sqrt[3]{V})(97.5 - t_w)$, where K_d and K_w are dry and wet Kata cooling powers, in milli-calories per sq cm per sec, t_d and t_w are dry- and wet-bulb temp, and V is veloc in ft per min. Effective temp is determined from charts (Fig 59). Limit of cooling is at effective temp equal to body temp. Effective temp of 85° F (about 7.0 wet-Kata) is about the limit (81) for a fair amount of physical effort by an acclimatized miner stripped to the waist. This corresponds to working face conditions of 87° saturated air with aver veloc of 100 ft per min, and to development face conditions of 93° saturated air with aver veloc of 1 000 ft per min.

Sources of heat underground: (1) heat transmitted from rock to air in workings, and in passage from surface to workings; (2) heat due to auto-compression of downcast air caused by change of abs press; (3) heat from men and machinery underground; (4) heat from oxidation, timber decay and use of explosives; (5) heat due to air passage through fans and friction of air currents; and (6) heat due to ground movement.

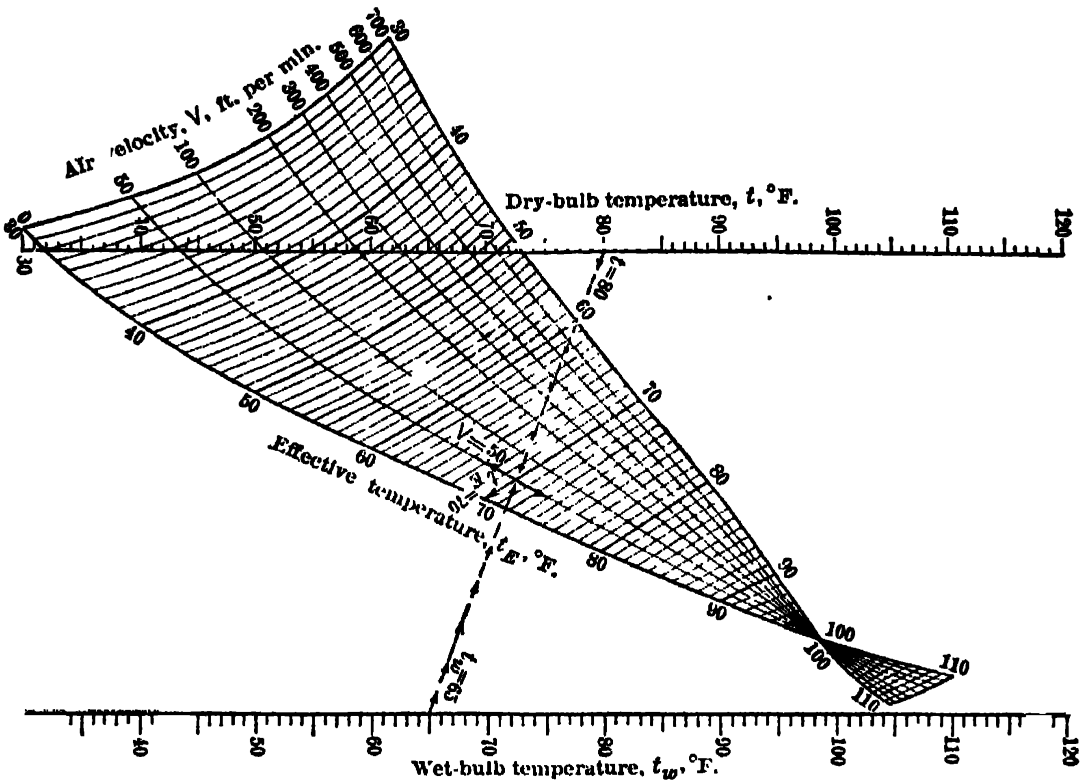

Fig 59. Effective-temp Chart for Men at Rest and Stripped to the Waist (9)

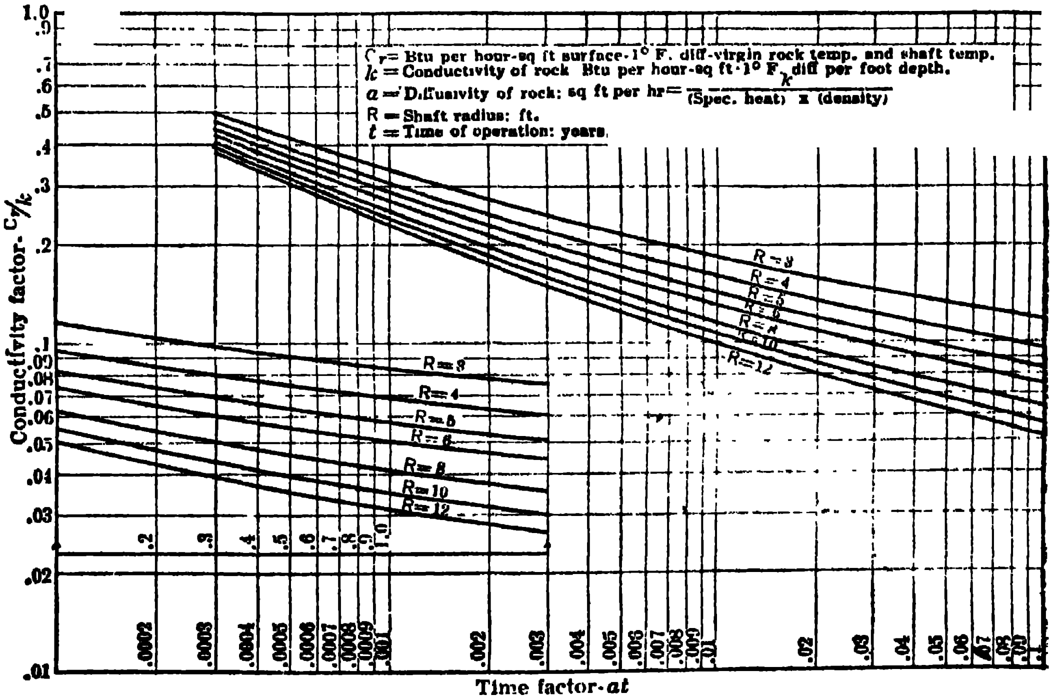

Fig 60. Chart of Heat Flow in Mines (79)

Heat flow from rock. Theoretic computation of heat flow from rock walls into air currents is complex (78), and of qualitative, rather than quantitative interest, due to difficulty of adjusting to actual conditions. Carrier (79) has developed a chart for constant-temp assumptions (Fig 60) from which the heat-transfer coeffic may be determined from time of cooling, and conductivity and

diffusivity coefficients of the rock. The latter, for granite, limestone, sandstone, and slate are much alike (Sec 39); aver for conductivity, in B t u per hr per sq ft per ft of thickness, is about 1.25, and for diffusivity (conductivity ÷ [sp heat × density in lb per cu ft]), about 0.038.

Relation of air temp to rock temp. Estimates of duty of air-conditioning plants have relied on observed data from actual mining, which show that rock walls adjacent to airways tend to assume the aver temp of the air flow, and that the temp gradient in solid rock, inward from the walls, gradually flattens as cooling penetrates farther into the rock. Temperatures in deep boreholes in the walls of intake airways have shown cooling extending inward as much as 350 ft (80). These cooled zones act to insulate airways from rock heat, by reducing temp differential and flow of heat between rock and air at surfaces of contact. Practical differentials depend mainly on veloc of flow, distance of air travel, depth involved, and moisture conditions. Constant flow maintains an almost constant aver differential (81); increasing veloc gradually increases the differential. Aver temp in 1936 in Magma (Ariz) 3 200-level stopes, 500–1 500 ft from downcast shafts, was 84° F wet-bulb and 90° dry-bulb, 43° and 37° respectively below rock temp at that level. Other cases of air temp as much as 30°–40° below virgin rock temp (127°) could be cited, but aver differentials are much lower and range down to zero. Low veloc flow combined with oxidation or timber decay may result in negative differentials, or air temp above rock temp.

Heat of compression. In theory, 1 lb air falling D ft develops D ft-lb of energy, equivalent to ($D \div 778$) B t u, which is sufficient to raise the temp of 1 lb of dry air [$(D \div 778) \div 0.24$ deg F], wherein 0.24 is sp heat of air at constant press. Then theoretical temp rise for 1 000 ft is about 5.4° F, or 1° per 185 ft of depth. Heat added by compression is lost by expansion in an equal height of upcast, hence total heat in mine is unchanged; but change in location of the heat is important for its effect on air conditions in working zones. Increase in wet-bulb temp depends on temp and abs press; approx range for mine shafts is 1.5°–2.5° F per 1 000 ft (see Table 7)

Table 7. Adiabatic Compression in Ideal Shaft, 7 123 ft Deep

	At surface	At foot of shaft
Barometer	25 in	32 in
Corresponding elev above tide	5 059 ft	– 2 064 ft
Temperature: Dry bulb	60.0° F	98.9° F
Wet bulb	55.9	73.6
Humidity	80.0%	28.4%
Water vapor, by volume	1.654%	1.654%
Wt of atmosphere per cu ft	0.0633 lb	0.0755 lb
Wt of water vapor per cu ft of atmos	4.59 grains	5.47 grains
Water vapor per cu ft of atmos, saturated air	5.74 grains	19.22 grains
Added vapor per cu ft required to saturate	1.15 grains	13.75 grains
Latent heat of water required to saturate, per cu ft of atmosphere	0.172 B t u	2.062 B t u
Wet Kata index at wet bulb temp above given, and 125 ft per min veloc	24.5	14.1

Heat from men working at full capac is about 1 000 B t u per man-hr. In hot mines, transfer from man to air is chiefly by evaporation of perspiration, and when evaporation is limited, physical work may become impossible. Effect of veloc of air movement diminishes as body temp is approached, and evaporation ceases when wet-bulb air temp attains body temp (12).

Heat from machinery underground is equivalent to the difference between total energy input and energy absorbed in useful work at 1 hp = 42.4 B t u. Large underground hoisting or pumping units require a separate split for proper ventilation. Quantity for allowable temp rise may be computed for actual conditions; 10 cu ft per min per installed hp is aver figure for elec installations.

Heat from chemical reactions may be calculated from air analyses, if assumptions are made regarding the reactions involved. Heat from oxidation, timber decay and use of explosives is usually of local occurrence and easily controlled by ordinary ventilation. Most cases of heating in mines are due to oxidation of finely disseminated pyrite, occasionally of other sulphides, with absorption of O, but no liberation of CO_2. Timber decay absorbs O and liberates CO_2. Winmill (83) finds 2.1 calories given off per cc of O_2 absorbed by oxidation of coal and 4.3 by oxidation of iron pyrite.

Heat due to fans. Air flowing through fans is heated by compression, change of veloc, and ineffic of fan. Temp rise may be computed for adiabatic compression, with correction for change of veloc, or, with sufficient accuracy, for equiv work required (84). On the latter basis, for 100% effic, using notation of Art 10 with H for total press in in of water: temp rise $= \dfrac{5.19\ HQ}{778 \times 0.24 \times Qw} = \dfrac{0.0278}{w} H$. Due to inefficiency of the fan, actual temp rise is $\dfrac{0.0278}{w} \times \dfrac{H}{\text{effic (as ratio)}}$. For $w = 0.075$, temp rise $= 0.37\ H \div$ effic.

Friction and shock losses in air currents develop heat equivalent to the energy change. Assuming that all the heat enters the air current, derivation is same as above; temp rise is 0.37 H for standard air density and varies inversely as density. Energy changes correspond to total press changes, but may be approximated by using static press, both for temp rise at fan and in air currents. Veloc energy existing at fan discharge is not converted to heat until dissipated in the airway as friction or shock loss, or as shock loss at discharge to the atmos.

Ground movement produces heat, but effects are not important. Local increases in temp have been noted at active faults (85), but in crushed areas the heat can usually be traced to increased rates of oxidation, from increased area of exposure to oxidation.

Effects of circulating air through mine workings, in order of importance, are: (*a*) reduction of natural temp of rock along intake airways and in deep workings; (*b*) reduced humidity, (*c*) increased veloc of air currents. Daily changes in surface air temp and humidity have little effect on downcast air currents except close to the surface, and seasonal effects in slow moving currents at depths of several thousand ft are small. Reduction in amplitude of temp variations largely depends on time of contact: at 10 min only seasonal effects are detectable and at 20 min even these are negligible.

Cooling and drying effects. Downcast air currents absorb heat from warmer rock walls, and absorb water, by evaporation, from walls of intake airways and workings. Cooling power of the air is large in winter, and the lower temp stored in ground near the surface cools warm intake air in summer. Walls of intake airways over a period of years are cooled to great depths, serving to insulate airways from higher-temp rock. Heat and moisture thus absorbed are largely redeposited along upcast airways of deep mines, only a part being discharged to atmos. Where mean cooling power of surface air is limited, or the economic limit of cooling by circulating air currents has been reached, the air must be artificially cooled to permit mining at great depths (Art 18). Continuous absorption of moisture from mine workings by comparatively dry intake air tends to reduce the moisture available, until workings become noticeably drier and relative humidities are decreased. With increased ventilation, mines that were damp to wet have become almost dry in appearance, even though the amount of moisture absorbed in intake shafts and workings remains quite large. Small increases in the normally low veloc of air currents through working places are effective in increasing comfort conditions, even though the same small increase in main-airway veloc would have no detectable effect.

Temperature, heat and moisture changes in air currents involve: dry-bulb, or sensible temp of the air; wet-bulb, or temp of adiabatic saturation; and dew-point, or temp at which condensation would occur upon sufficient cooling. Total heat changes in moist air are measured by changes in: sensible heat of the air, latent heat of the moisture by evaporation or condensation, and sensible heat of the moisture. The latter is negligibly small. Changes in latent heat are most important in air conditioning problems. Dry-bulb temp determines rates of heat transfer, but otherwise represents only the relation of sensible to latent heat in the air. At constant press, the wet-bulb temp represents total heat changes and the dew-point temp changes in absolute moisture content. Both wet-bulb and dew-point temp are affected by changes in abs press. These changes may be ignored in the case of shallow mines at or near sea-level, for which the ordinary constant-press psychrometric charts and tables at 29.92 in of mercury suffice. But, changes in psychrometric characteristics with change of abs press must be taken into account in deep mines, and special charts or tables (86, 79, 9) are required to compute temp change in terms of heat and moisture changes. Also, change in quantity of flow accompanying change in press makes it desirable to use flow rates in terms of lb of air rather than cu ft as in ordinary practice.

Thermal data. Sp heat of air at constant press is 0.2389, usually taken as 0.24. Sensible heat change for 1° F for standard air of 0.075 lb per cu ft is 0.0179 B t u per cu ft. Latent heat of evaporation or condensation is about 1 050 B t u per lb of water, or 0.15 B t u per grain of water (Sec 39). In refrigeration terms, 1 ton refrigeration is 200 B t u per min, or approx 1.05×10^{10} B t u per year.

Cooling with air currents. Within limits, the cheapest way to obtain added cooling at deep levels is by increasing the quantity Q of ventilating air (77, 87); limits are imposed by power cost, since fan hp increases about as Q^3. Increase in airway capac may be gained through additional shafts to depth, but as cost often exceeds $100 per ft, this solution may not be economical, especially as shafts have no salvage value, whereas air-conditioning plants are removable. Thus artificial cooling may give the same result more economically, or produce results not possible with unconditioned surface air. Cooling by ventilating air has been the main reliance of hot deep mines to date, and only a few have supplemented it by artificial cooling.

Effect of increasing veloc of air travel in intakes is to spread the heat and moisture absorbed over more air and thus heat it less. General result is a lowering of aver temp in working zones, accompanied by increases in seasonal effect.

Examples. At Village Deep, So Africa (88), workings were advanced 800 ft in vert depth from about 6 500 ft, to a 3.3° F higher rock temp, without increase of temp in intakes or splits (shaft-to stopes) when air flow was increased approx 50%; but stope temp gradually increased at a somewhat lesser rate than rock temp, as did temp at development faces, except when machines were drilling, at which times approx the same temp existed as at levels 800 ft higher. At the Magma mine, Ariz (31), monthly records of stope temp in the central block adjacent to downcast shafts show little change in mean yearly temp in 8 years, while the lowest stoping zone progressed from the 2 550 to the 3 200 level, where virgin rock temp was approx 10° F higher. During this time air circulated gradually increased 60–70%. However, the seasonal ranges of aver stope temp were increased from about 82–89° F wet-bulb and 86–90° dry-bulb to 79–90° wet-bulb and 85–93° dry-bulb. During this period, the mine workings became perceptibly drier and gradual improvement in comfort was noted, except at the max summer condition, which remained about the same.

Dry *vs* wet shafts. Evaporation of water in downcast intake shafts lowers dry-bulb temp and thus increases the differential between air and virgin rock temp, with more rapid transfer of heat and cooling of walls. But cooling of the walls also reduces rate of heat flow for the same virgin-rock temp differential, and the relative merits of dry and wet shafts have been much debated. Observations (89) indicate that, although wet-bulb temp and total heat are about the same at the bottom of dry or wet deep shafts, dry-bulb temp is much higher in the case of dry shafts, and the air is therefore in better condition to travel from shaft to working place with minimum accession of heat from the walls. As air absorbs moisture, the dry-bulb temp decreases and heat flow into the air is increased. Every effort should therefore be made in hot mines to keep evaporation of moisture at a minimum to the last working place on the circuit, where, however, reduction of the dry-bulb to the wet-bulb temp by evaporation of moisture slightly improves comfort conditions.

Fan-pipe auxiliary ventilation delivers air long distances at high veloc without change in moisture content, and therefore provides optimum conditions for minimum increase in total heat and wet-bulb temp. Final temp of air is largely determined by temp of slow-moving return air along the pipe line, which is reduced as air quantity is increased. In high-temp rock, wet-bulb depression at discharge at development faces is often 15–20° F, but usually is not more than half as much at working faces 10–20 ft from the discharge. Fan-pipe ventilation is practically a method of maintaining the cooling power of mine air, auxiliary to all general methods of cooling, whether by ventilation or air conditioning. Small, hot mines sometimes use fan-pipe ventilation for all working places (9) and secure better working conditions than would be possible for the same layout with general ventilation. McIntyre (90) has proposed that the total intake be carried from surface to depth in a similar air-insulated pipe.

Control of development return air. Currents from fan-pipe-ventilated development faces in hot mines usually have max temp of the mine, often 95° to over 100° wet-bulb. These are usually added to intake currents of active workings and thus increase temp in working zones. Each small current of 2 000–4 000 c f m is equivalent to at least 15–30 tons of refrigeration. An important step in combating high temp, therefore, is to carry return air shafts to the bottom, rather than the top, of active zones, so that development returns can be directly coursed to them without traversing active stopes.

18. AIR CONDITIONING IN MINES

Definition. As generally applied to mines, air conditioning refers to artificial or mechanical cooling of air currents for control of the cooling power of the air. Other forms of air conditioning are applied to mine air (Sec 23), but are not thus specifically designated.

Cooling and drying methods, other than refrigeration, have been proposed for local use in mines, but high costs of production and transport generally rule them out (87), and only a few have been used regardless of cost.

Examples. Use of cool water from surface, sprayed directly on the men at hot faces, has been a last resort in some hot mines. Ice has been used, particularly in So Africa, where the Village Deep used blocks of ice on trays in fan-pipes for development faces, and, by spraying ice-chilled water into stope intake air, secured a 5° reduction in wet-bulb temp. Surface water, run to waste, was used experimentally (1931) at the Mountain Con mine, Butte (91), to determine design data for conditioning plants installed later. Similar smaller plants were occasionally used later at other Butte mines; in the winter of 1938, 6 fan-pipe cooling units were in use and 12 more contemplated, each using 20 gal per min of city water discharged between closely spaced plates in the pipes. In an aver case, wet-bulb temp in a development face was reduced 10° F (A. S. Richardson).

Drying agents, aside from high cost, have the disadvantages of heating the air with latent heat released by change from vapor to liquid, and of requiring heat for regeneration. Silica gel has been proposed (E. C. Holden, 1926) for drying comp air on surface, so as to increase its cooling effect underground when expanded in air drills, but has not been used although devaporizing comp air is now the essence of comp-air refrigeration methods. Absorption materials might be used at the bottom of wet shafts to change latent to sensible heat to condition the air for minimum heat absorption in further travel.

Lowering vapor tension by using solutions of magnesium chloride (92), a cheap waste product, and of calcium chloride has been proposed, to reduce moisture absorbed by air in passing through wet workings. Expected difficulties due to corrosion and effect on milling methods have retarded large-scale trials. In deep Mich copper mines (63), waters in lowest levels are concentrated calcium chloride solutions, and wet-bulb depressions of 3° to 11° F are found in places where depression in similar water-wet workings would not exceed 1°.

Mechanical refrigeration involves both cooling and drying, as changes in heat content are affected by changes of temp and of moisture content. Both air and its vapor are cooled. Vapor cooled to the dew-point temp condenses and drops out, but liberates latent heat of condensation, which is the principal load on a plant dealing with air near saturation, or air cooled through a large range. A refrigeration system merely transfers heat from the cooled medium to some other medium from which it can be dissipated without reaffecting the cooled medium. Safe refrigerants for underground service have been developed in recent years; the major difficulty and cost is in dissipating the heat (93).

General requirements for large-capac plants in commercial service are said to be about 0.2 ton refrigeration per 1 000 c f m per deg wet-bulb cooling, 2 gal condenser water per ton, 2.5 gal spray water per ton, and 1.0 hp per ton of refrigeration. At high-temp level of heat exchange underground, about 0.4 ton refrigeration is required, and estimates of condenser water, spray water, and hp are about 50% higher than above.

Methods for mine air-conditioning have been: (1) vapor refrigeration of air at surface, or underground; (2) cooling of liquids on surface, by evaporative cooling and by vapor refrigeration, both surface and underground, for use in underground heat exchangers; and (3) dehumidification of comp air on surface, by over-compression-and-expansion, for use underground in air motors and drills.

Surface air refrigeration. The largest plants so far installed, Morro Velho (Brazil), Robinson Deep (So Africa), and Kolar (India), are surface vapor-refrigerating plants. Advantages of surface plants: easy disposition of waste heat, absorbed from the air, plus heat due to work performed; max safety, reliability and operating convenience; and increase of summer natural draft to approx winter conditions. Disadvantages: low positional effic (about 0.4 the first year for 7 500 ft on the Rand (77) with probable increase in time to 0.55), due to increased flow of heat from walls of downcast; operation at aver of approx 60% capac, requiring larger plant; and limited capac, due to limited temp range available above freezing, and to lower heat capac of air at lower temp. Reduction of 1° in wet-bulb temp requires about 3 times as many heat units per lb of air at 90° as at 40°.

Morro Velho mine, Brazil, (94) was the first to be artificially cooled. A surface plant was installed in 1920 and an underground plant in 1929. The mine is very dry and in a warm moist climate; surface elev, 2 768 ft. Aver dry-bulb temp (t_d), 68° F; max wet-bulb (t_w) in rainy season, 75°; aver max t_w, 72°. Rock temp increases 1° per 140 ft from surface to 6 400 ft, but 1° per 119 ft from 5 300 to 6 400 ft and is 123° at 7 000 ft. Monthly output from a pitching gold reef by cut-and-fill methods was about 14 000 tons in 1922, with aver of 290 men underground per shift (3 shifts). Stopes are 6–12 ft high, 8 ft wide and over 1 000 ft long; one per level, off 5 active levels spaced 300 ft vertically (active zone of 1 500 ft). Hoisting is in relatively shallow stages through offset interior shafts. Advance in depth per year is approx 150 ft. In 1926 lowest stoping operations were on 24th level, about 7 000 ft (E. Davies).

Surface plant. Ammonia-vapor refrigeration, divided into 6 stages (with provision for 3 more). Reciprocating compressors and rotary-plate water coolers are installed at portal of the 850-ft main adit at elev 2 444 ft. Cooled air is blown in by fans, with pressures adjusted to prevent admixture of surface air, and no airlock is required. A safety door is placed in the adit, with remote control from plant and shaft. Rated capac, 100 600 B t u, or 503 tons refrigeration, equal to reduction of t_w from 72° to 43.2° F for 5 040 lb dry air per min, or 80 000 c f m. (Condition of cooled air approximates aver climatic condition in England.) Design based on reducing moisture of surface air to a content estimated to hold max t_w on 22nd level (12 500 ft of travel) at 81° and max in 21st level stope, 85°. When plant started, an underground fan, in series with the surface fan, doubled the pressure and increased the quantity in circulation 40%. Both together lowered max wet-bulb temp 9.4° during first 16 mo. In the same period, the fatality accident rate was reduced two-thirds and cases of heat cramp three-fourths; and production increased 12% with the same force. In 1926, the lowest stoping level was the 24th, where aver cooling was 8° t_w (Davies). The plant cost $455 000, and expenditures for power supply made total cost about $630 000. Max requirements for 6-stage operation, 700 hp for 21 motors. UNDERGROUND PLANT (95), in series with surface plant on the 5 800-ft level, above the active mining zone and 6 000 ft from lowest stopes, consists of 2 centrifugal compressors using Carrene (CH_2Cl_2) as refrigerant, which boils at 104° (sea level) and permits operation at pressures below atmos. Capac is said to be 150 tons, cooling a shunt circuit (to avoid excessive lowering of t_d) of 50 000 c f m from 75 t_w – 100 t_d to 64 t_w – 74 t_d. This gave an aver temp of 82 t_w – 100 t_d at lowest level. Temp as high as 126° t_d are known, but corresponding t_w is about 80° and men can work at good rate. Condenser water is cooled by spray tower in upcast air of 82 t_w – 102 t_d at plant horizon, with only 0.5% loss by evaporation (79). Added resistance of cooling tower is compensated by increased natural draft.

Turf Shaft, Robinson Deep, So Africa (96, 97) has the second surface installation (1935), the largest of its kind. Mine is dry, except for water to wet down timbered shafts and combat dust hazard; climate warm and dry; surface elev, 5 600 ft. Mean t_d, 60° F; mean t_w, 52.5°. Rock-temp gradient (80) is 1° per 185 ft; temp at 8 000 ft, 101.5° F.

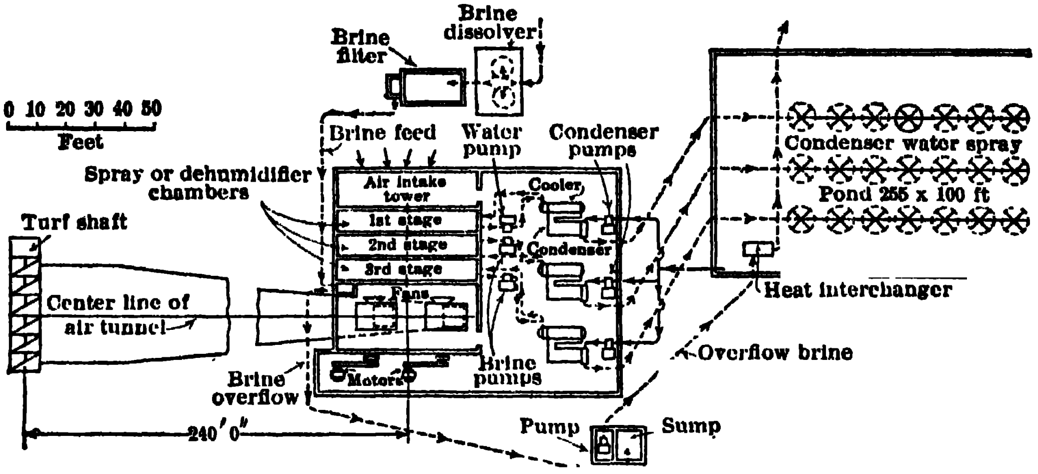

Fig 61. Sketch-plan of Robinson Deep Refrigeration Plant (79)

Monthly output of Turf Shaft section is about 40% of total tonnage. In 1933, with production at 117 000 tons per mo, mine employed aver of 390 whites and 6 100 natives. Uniform-grade, narrow reefs dipping about 33° are mined by cut-and-fill (resuing) methods, with stopes 5-ft high off rock drifts on levels spaced 300 ft along the dip and extending up to 1 mile from shafts. Aver depth of stoping zone was 6 700 ft in 1933; max depth of development, 8 000 ft; advance in depth, about 200 ft per yr. The 7-compt Turf shaft goes to the 4 060-ft level, the 6-compt Main Incline shaft thence to the 6 200 ft level (3 775 ft slope), and two 3-compt sub-inclines 80 ft apart thence to bottom. Max air travel is 2 miles as intake, and 5 miles in all.

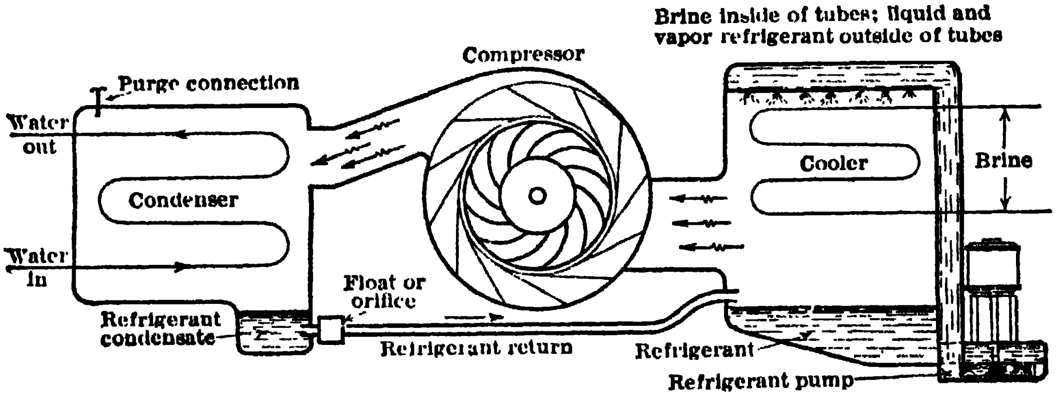

Fig 62. Arrangement of Centrifugal Refrigeration System (79)

Plant (Fig 61, 62) is in separate units, using Carrene No 2 (monofluorotrichloromethane), boiling at 75° at sea level. Each unit has a 750-hp 2-stage centrifugal compressor, shell-and-tube cooler and condenser, 150-hp 2 300-gal per min spray pump and 75-hp 2 000-gal per min condenser pump. Plant rated at approx 2 100 tons refrigeration; designed to cool 407 000 c f m from 65° F t_w to 38°, actually cools approx 360 000 c f m from 65° t_w to 33.5°. Water is used for first stage and brine for others. Cooled air is blown by fans through spray-type dehumidifiers, and through a 12 by 36-ft duct on 27° slope, entering shaft 100 ft below collar. Fan pressures are adjusted to permit small upcast of cooled air to surface. Main fan is on the 33rd level (6 204 ft), between main incline and sub-incline shafts, and downcasts air from surface duct to the lowest levels. Return air is broadcast through old workings to shallow surface shafts. Lack of an upcast shaft was important in deciding on a surface rather than underground plant. First year of operation prevented normal summer rise of 6° t_w in stopes, and summer max t_w was subsequently lowered 8°–9°, or an aver reduction of stope temp of 4°–4.5° t_w (79). Notwithstanding depth and aver distance air has to travel, results are considered satisfactory, and sufficient to warrant deepening of workings at least 1 500 ft beyond 1935 limits. Positional effic at 7 500 ft depth at shaft in 15 mo was 75%. Plant cost approx $500 000, including winze connection to shaft, and requires about 3 000 hp at capacity. Operation is at aver of 55% of capac. Initial operating cost of about $7 320 per month is expected to decrease gradually to aver of $6 200.

Kolar Goldfield, So India (Pryor, 77) has the third large surface air-refrigeration plant, approaching completion on a mine 8 200 ft deep in 1938. Plant, of standard ammonia-compression type using brine in pipe coils, has capac of 1 140 tons refrigeration, to cool 150 000 c f m (10 000 lb) from 73° to 40° F.

Underground air refrigeration. The underground plant at Morro Velho (above), was the first thus installed. A second has been placed in an East Rand mine. Advantages: high positional effic, operation at full capac, and practically unlimited heat capac due to high temp range. Disadvantages: difficulty and cost of disposing of heat abstracted; high cost of required excavation: deduction of heat radiated by machinery from net cooling effect; and no increase of natural ventilation except where condenser water is cooled by heating upcast currents.

East Rand Proprietary Mine, So Africa (95). A Freon vapor refrigerating plant of about 500-ton capac was installed on 46th level, 6 400 ft deep and 1 000 ft below sea level, in 1936. It cooled 157 000–176 000 c f m from 81° t_w – 83° t_d to about 72° and 71° saturated. Heat to condenser water represents about 630 tons actual refrigeration. Mine water is used for condensing and pumped to surface; but an estimated return of 400 000 c f m at about 3 000 ft depth could cool condenser water for 1 400 tons actual refrigeration with increase of 10° t_w.

Surface refrigeration of liquids used underground. Plants for this purpose have been installed at mines in Germany and Butte, Mont. Use of a liquid rather than air to transport cooling has often been advocated in discussions of mine air-conditioning (77), but the heavy piping required to withstand press at great depths, or alternate necessity of stage heat exchangers, has retarded use of this system. Main advantage over surface air refrigeration is less loss in transfer of cooling to working places; hence better positional effic, and smaller space required for transporting same volume of cooling in aver ratio of 1 for water to 3 500 for air. Main disadvantages: cost of piping; finding place for piping in already crowded pipe compts of shafts; and danger in case of pipe failure by corrosion.

Zeche Radbod mine, Ruhr, Germany (81). A small surface ammonia plant was installed about 1923 for temporary cooling of water in pipe radiators on the 3 150-level, pending sinking of another shaft and increase in ventilating quantity. Coal is mined at depths between 2 600 and 3 250 ft. Rock temp gradient, 1° per 50 ft; max rock temp 111° F, expected to reach 136°. At temp above 82.5° t_w, miner works shift of 5 instead of 6 hr. Short shifts increased to 83% and production fell to 0.51 ton per man by June, 1921. Ventilation was increased from 350 000 to 700 000 c f m and by Feb, 1922, short shifts had decreased to zero and production rose to 0.68 ton per man. But in summer of 1922 short shifts were up to 25% and production down to 0.64. A new shaft was sunk to increase ventilation, and trials of cooling were made pending its completion. At first, city water, 61° at surface, cooled 250 000 c f m on 3 150 level, an aver of 1° t_w. Then water was cooled by ammonia plant to 34° at surface, rising to 41° at 3 150 level in 1.5-min travel in insulated pipe, and 22 c f m heated to 61° (138 ton refrigeration) at discharge. Radiator of 340 ft of pipe with 19 000 sq ft surface cooled 250 000 c f m 5.5° t_d (est as approx 2° t_w) from 73° t_d. Plant (second-hand) cost $17 000 to build and $107 per shift to operate, with increase of $170 output per shift.

Mountain Con Mine, Butte, Mont (98) has adopted A. S. Richardson's new method of evaporative cooling of water to a temp about halfway between t_w and dew-point, whereas ordinary cooling in spray towers leaves water 5°–7° above t_w of air. Mine is damp to dry (but damp to wet without intensive ventilation), in exceptionally cool, dry climate. Mean annual temp (1922) at approx 6 000 ft elev, 36.9° F t_d; precipitation 12.8 in; aver temp, Jan 12°, July 62° t_d; aver t_w 10° below t_d for 4 summer months. During warmest part of day, t_w is usually 15–30° lower than t_d, and dew-point 10°–20° lower than t_w; dew-point is often below freezing in hottest months. Rock temp gradient for Butte mines is probably nearer 1° per 55–60 ft, than per 100 ft as usually stated. Rock temp at Mountain Con 3 500-ft level, over 100° F. Ore, copper sulphides in granite country rock; veins dipping 70°–90°. Levels, approx 135 ft apart, extend 1 000–2 000 ft from a downcast shaft carrying 120 000 c f m for approx 100 working places.

Plant (Fig 63): (1) surface plant of fan, low-press heat absorber and spray tower; (2) high-press pipe columns in shaft, carrying sump water and forming closed circuit from surface to underground plants and return; (3) high-press underground heat absorbers on 3 500- and 3 600-ft levels. Shaft

pipe columns, 1 000 gal per min capac, are $8^5/_8$-in steel tubing, tested to withstand 2 000 lb per sq in with safety factor of 4; branch lines, 6-in and smaller; all insulated with 1.5 in of mineral wool. Small pump near surface overcomes friction in balanced circuit. In surface plant, air is blown through an extended surface pipe-coil absorber, which circulates sump-water countercurrently; the cooled exit air, of same vapor content as at entrance, rises through cooling tower against heated sprays from (*a*) same absorber coils, (*b*) underground absorbers. The latter, using sump water piped from cooling tower comprise high-press plain coils with closed-circuit spray water, to wash the air and assist heat transfer; also (3 600-ft level), high-press extended-surface coils of special design that, for equal capac, require only $^1/_{12}$ as much excavation as plain coils with sprays. Of 4 units planned (total capac, 1 200 tons refrigeration), 2 are installed, with shaft piping for four. Water was the cooling medium to 1938, but brine or non-freezing solutions are contemplated. Results have varied with operating conditions and location of working places. The 3 600-level unit lowered t_w of the 14 working places (to 3 800 level) for which it was installed, an aver of 14° (max 30°); in 5 mo, aver temp of 100 working places decreased from 83.7° t_w to 75.3. Seasonal effect being estimated at about 2°, conditioner effect was about 6° plus. Costs of plant and operating cost are low, but have not been revealed.

Underground refrigeration of liquids, although a logical selection, is used in but one plant (Magma). Main advantage over surface cooling of liquids is avoidance of high-press pipe and high-press heat absorbers. Main disadvantages lie in providing condenser water and disposing of heat abstracted, which may require as much pipe as surface cooling. As liquids cooled at a central plant may be used in one or more semi-portable units, positional effic is higher than for cooling air directly.

Magma Copper Co, Ariz (99). Mine, in hot, dry climate, is normally damp, but dried by intensive ventilation. Elev of 500 level (main-operating adits), 3 050 ft. Mean surface t_d, 72.4°; mean t_w, 57.4°; mean relative humidity, 38%. Mean annual precipitation, 18.7 in. Rock temp gradient, 1° per 67 ft; rock temp 140° F at 4 000 ft (lowest level in 1939). Deposit, high-grade copper sulphides in a steep-pitching orebody; also, small bodies of copper and zinc ore. Method, rill cut-and-fill stoping with raises through, before mining, on 105-ft centers; levels 200 ft apart. Advance in depth, about 100 ft per yr. Main orebody is 1 000–1 500 ft long. Production, 1 300 tons a day with about 420 men underground on 3 shifts, 200 on largest shift. Of total ventilation of 240 000 c f m, about 145 000 passes up through main orebody, intaking on bottom levels from vert shafts. Initial development is by footwall drifts between shafts in comparatively dry rock, with mining off drifts in the vein.

Plant: 2 vapor units, with a capacity of 140 tons refrigeration each, are installed in a 20 by 62 by 12-ft chamber on 3 600 level, with space for an additional unit. Rated performance lowers the t_w of 60 000 c f m 12° from 85°, but capac decreases with decrease of exit temp at cooling coils. Refrigerant is Carrene No 2 (as at Robinson Deep). Chilled water is pumped through extended-surface cooling coils, set in crosscuts before 30 000-c f m booster fans; initially placed on 3 600 level near plant and vert above on 3 400 level, but coils can be placed over 1 000 ft below plant if required in future. Water condensed on cooling coils keeps them clean. Condensers heat 400 gal per min of mine water (from distant part of mine on opposite side of orebody) from 90° to 113°; 7 929 ft of pipe, mostly 6-in, was required for these lines, with 2 000 ft of return line, insulated in passing through the footwall drift to a pipe column in intake shaft on opposite side of orebody; 1 650 ft of 4-in pipe was required for cooling-coil connections. A new return shaft in the hanging wall now carries the mine pump column, and possible use of future cross-cuts to this shaft for cooling condenser water were under consideration. Operation of the plant greatly speeded development and start of stoping on the 3 400 and 3 600 levels. Results for only 4 mo of operation have been reported; inconclusive, due to large seasonal range of temp in shaft-stations, stopes and development faces. Aver decreases of 7°–8° t_w on 3 600 and 3 400 levels, and of 1°-2° t_w on 3 200 and 3 000 levels are indicated. Effect on aver stope temp can not be large, as only 43% of ventilation air is cooled not more than 10° t_w aver over the year. But, effect of plant will increase with time, and will be reinforced by connecting development direct to new return shaft, instead of to intakes. Total cost of plant, $86 538, exclusive of fans and crosscuts normally required for ventilation; $24 351 was for condenser pipe lines and pump. In May 1939 (C. B. Foraker), power requirements were 229 646 kw-hr, divided about 62–24–14% between compressors, fans, and condenser pumps (to sump on 3 600 level at new shaft); operating cost, exclusive of power, $547. Plant is operated 6 days a week. For development of 4 000 level, a 25-ton vapor-refrigeration plant was installed there in Jan, 1938, for conditioning the air intake of 2 fan-pipe units.

Use of devaporized compressed-air. One large group of mines on the Rand has installed (and on order) a number of special compressors for producing practically dry air, which greatly increases coldness of exhaust (to −80° F) of underground machinery without freezing troubles. This method has max positional effic, max flexibility in use, permits gradual expansion of plant, introduces no new factor into mine operations, and the main plant is on surface. Chief objection is cost, estimated to be at least twice that of vapor refrigeration. Also, capac is limited unless all machinery underground is converted to comp-air drive.

Anglo-American Corpn, Rand, So Africa (77) had devaporizing compressors of 10 000–20 000 c f m free air capac installed at 6 mines in 1938, and four 20 000-c f m machines on order, a total capac of 198 000. Those on order are elec driven, with over-compression and expansion stages built in. Earlier types have separate devaporizing units, or, in case of steam turbine drive, extra stages mounted on same shaft.

Devaporizing method is shown diagrammatically in Fig 64. Normal comp air at 90 lb is over-compressed to 130 lb, cooled (in cooler and heat-exchanger), expanded back to normal press and 32° F, and then restored to normal temp in heat exchanger, where cooling is transferred to over-compressed air before expansion. Water is removed between stages, so that final product is dried to moisture content at normal press and 32° F. Control of temp in expansion stage is either automatic or manual. For producing similar results at lower cost, a regenerative system (100) has been proposed, but not yet applied.

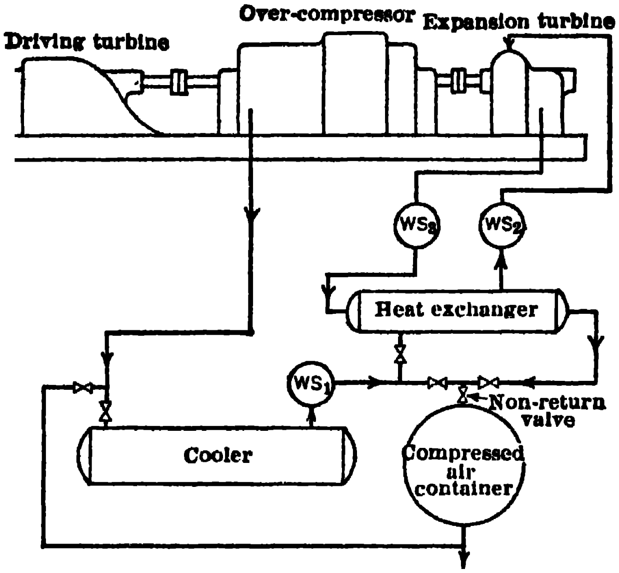

Fig 64. Devaporization Method for Comp Air (77)

Comparative costs of cooling B t u's (87, 90). Aver cost by ventilation, where feasible, is 0.00001–0.00002¢ per B t u. McIntyre estimates cost of piping air from surface at about 0.000025¢. With capital charge of 10%, and power at 1¢ per kw-hr, comparative costs per B t u for full-capac operation of cooling plants may be calculated from available data as approx 0.00018¢ for Morro Velho (surface plant only), 0.00013¢ for Robinson Deep, and 0.00015¢ for Magma (without charge for pumping condenser water from 3 600 level). On the same basis, the cost of Richardson's system is estimated not to exceed 0.00005¢ at Butte, though impracticable for most mining districts. Actual costs would be reduced by lower power rates and increased by under-capac operation (surface plants). Actual cost for 1st-yr operation at Robinson Deep, at less than $^1/_3$ capac (97), was about 0.00019¢ on basis of 10% capital charge. Estimates for devaporized comp air are usually 0.0001–0.0002¢, and for free discharge of comp air from nozzle 0.001–0.002¢. Minimum for ice, with ice at 5¢ per 100 lb, is 0.003¢ plus transport; and for liquid air at 1.7¢ per lb, 0.008¢ plus handling charges.

Boulders in drift mines 10–609
  in hydraulic mining 10–553
  in shaft-sinking 8–02
Boundary caving drifts 10–352
  crooked **17–33**
Box elevator, hydraulic mining 10–574
Boxes for drill cores 10–53
Box-head type of tramway **26–40**
  mono-cable tramways **26–42**
Box-type scraper **27–12**
Bracket, surveying **18–04**
Braden mine, block-caving 10–361
  combined method 10–383
  drift lagging 10–108
  hand stoping 10–126
  pilot raises 10–109
  stoping method 10–131
Bradford coal breaker **35–05, 35–08**
  oil field, water-flooding **44–22, 44–23**
Brake engine for hoists 12–16
  horsepower **39–05**
Brakes, hoisting-drum 12–14
  mine-car 11-13
  tramway **26–26**
Brakpan mine, Rand, development 10–90
Branch pipes, calculation of **38–16**
Branched chutes, block-caving 10–346
  raises, sub-level caving 10–335
Branch-raise caving 10–357
Bratt resuscitator **23–57**
Brattice cloth for rescue work **23–58**
  mining 14–13
Braun sample grinder **29–07**
Brazilian iron ore 2–22
Breakage of anthracite **34–31**
Breaker, anthracite, ideal **34–05**
  products **34–03**
  refuse **34–06**
    for flushing 10–516
  rolls, anthracite **34–17**
  structures **34–14**
Breaking character of rocks **5–02**
  coal at strippings 10–467
  ground in coal mines 10–511
    flat-back stopes 10–256
    Malayan tin mines 10–625
    in open-cuts 10–430
    Rand 10–146
    in stopes 10–124, *et seq*
  load **43–02**
  parts, jaw-crusher **28–04**
Breast stoping 10–124, 10–133 *et seq*
  Boleo mine 10–417
Breasting in drift mines 10–607
Breasts, coal mine 10–481
Breathing apparatus, portable **23–55**
  oxygen consumed **23–15**
Breccia 2–03, 2–07

Breccia fault 2-13
  fillings 10-16
Brecciated ground, Tri-State distr, 10-137, 10-141
Breeze, coke **35-30**
Brick masonry **43-10**
  from shale 2-28
  varieties **43-10**
Bricked chute, Black Rock mine 10-406
  Frood mine 10-204
Bridge, timber **43-40**
  trusses **43-25**
Bridges, structural-steel **43-51**
Briggs clinophone 9-67
  gate **27-35**
  mine, underhand square-setting 10-210
Bright, Victoria, dredging 10-598
Brine wells 10-398
Bristol plotting device **18-27**
  recording gage **38-28**
Britannia Beach, payroll system **22-10**
Britannia mine, deviation of boreholes 9-63
  hand sorting **28-17**
  machine loading 10-104
  scraper loading 6-16
  tunneling 6-17
Britannia Min & Sm Co, bonus system **22-07**
British coal mining 10-496
  rope drive **41-09**
  thermal unit **39-20**
British Columbia, hand stoping 10-126
  mining law **24-33**
  Nickel Co, tunneling 6-17, 6-24, 6-26
  placer drilling 9-42
Broaching of rocks 5-24
Broken Hill mines, comp-air ventilation, **15-54**
Broken Hill South mine, chutes 10-404
  shaft-plumbing bucket **18-20**
  survey spads **18-03**
  underhand square-set stope 10-210
Broken stone, quarrying 5-25
Brown cyanide tank **33-17**
  hematite ore 2-21
  process paper **17-11**
Brown & Mills oxygen apparatus **23-56**
Brown & Sharpe wire gauge **42-05, 42-06**
Brucite, tests for 1-50
Brunton magnetometer 10-A-08
  pocket transit **17-06, 18-05, 18-13**
  samplers **29-06**
  sampling shovel **29-07**
Brushing in coal mines 10-474
Bryant crosshead 12-97
Buck Mt coal seam, headings in 10-511 *et seq*
Buckboard for assay samples **30-03**
Bucket conveyers **27-31**
  effic of dragline excavators 10-455
  elevators **27-32**
  hooks 12-94
Bucket-ladder dredges 10-577 *et seq*
Buckets, dredge 10-582
  for elevators **27-32**
  for hand windlass 12-57
  hoisting 12-91 *et seq*
  for whim hoisting 12-58
Bucyrus-Armstrong churn drill 9-43
Buda-Hubron well digger 9-08
Buffalo mine, methods 10-278
Buggy breast 10-481
Buhler shaking-screen drive **35-06**
Building stones, occurrence of 2-28
Buildings, structural-steel **43-52**
Bulkheads against mud runs 10-526
  for flushing 10-517
Bulkheads, hydraulic-mine 10-563
  timber 10-223
Bullard's Bar dam 10-552
Bulldozers, excavating with 3-07, 3-14
Bulldozing chamber 10-293, 10-409
  Fresnillo 10-462
Bullion, melting **33-05**
Bullwheel, oil-well rig 9-10
Bulolo, New Guinea, dredging 10-597
Bulowat Syndicate undercurrents 10-570
Bultfontein diamond mine 10-392
Bumpers, mine-car 11-08
Bumps in coal mines **23-53**
  in mines 10-521
Bunch blasting 6-14
Bunker Hill & Sullivan, accounts **21-23** *et seq*
  carbon consumption 9-55
  diamond drilling 9-59
  filled square-sets 10-209
  shaft, cost 7-24
  trolley locos 11-40
Bunkers, suspended 12-128, 12-133
Bunting's rules for mine cover 13-03
Burbank oil field, repressuring **44-20**
Bureau of Mines established **24-12**
Buried placers 10-535
  valleys, danger from 13-03
Burma Corp, accounts **21-25**
Burned cut 10-94
  in tunneling 6-08
Burnettizing of timber **43-33**
Burning point, defined **41-12**
  stumps 3-12
Burns, treatment of **23-64**
Burra Burra mine, raise round 10-114
  sub-level stoping 10-185
  tunneling 6-17
Burrell methane indicator **23-29**
Burro Mt, N M, churn-drill sampling 10-47
Burrowing animals as aids in prospecting 10-24
Burt solar attachment **17-25**
  solar compass **17-26**
Business management of mines 20-02
Bustenari oil mining **44-24**
Butane in mine air **23-06**
Butte, back filling method 10-244
  boring record 10-49
  Calyx drill in winzes 10-122
  copper deposits 2-23
  erecting square-sets 10-225
  extinguishing fires 10-428
  filled rill stope 10-264
  flat-back filled stopes 10-244
  headframes at 12-77
  hoisting guides 12-83
  jackhammer drifting 10-101
  machine loading 10-105, **27-30**
  mine car 11-07
  mine mapping **18-26**
  mines, cooling 14-58, 14-61
  recovery of caved stope 10-233
  rill stoping 10-205
  shafts, cost 7-25
  shaft-plumbing device **18-17**
  sill timbering 10-220
  silver ores 2-25
  sorting chute 10-404
  timber consumed 10-225
  tramming 11-32
  trolley locos 11-41
Butterfly chute-gate 10-410
Butters filter **33-22**
By-product coke ovens **35-34** *et seq*
By-products of coking **35-38**

Cabezas del Pasto mine, filled stope 10–259
Cable leads underground **23–36**
  oil-well rig 9–10
  sizes on tramways **26–09**
Cables, formulas for **26–02** *et seq*
  twin-cable tramway **26–35**
Cable-reel locos **16–14**
Cable-tool drilling for oil 9–09 *et seq*
  rigs, specifications 9–14
  vs rotary drilling 9–24
Cableways **26–02, 26–44** *et seq*
  light **26–48**
  movable **26–46**
  at open-cut mines 10–433
  in placer mining 10–544
  in rock excavation 5–22
  trench 3–11, 3–14, 3–15
Cadmium, source of 2–26
Caesium, source of 2–26
Cage and skip accidents **23–41**
Cages, hoisting 12–97 *et seq*
  passing point of 12–10
Caging of mine cars 12–45, 12–103
Cain's formulas for bins 12–132
Caisson disease **15–47** *et seq*
  work, N Y laws on 8–14
Calamine 2–23
Calamon mine, filled-rill stope 10–273
Calaveras Central drift mine 10–610
Calaveras Co, Cal, placer mining 10–548
Calculations, milling **31–19** *et seq*
  from sampling **25–18**
Calculus **36–26** *et seq*
Calibrating watt-hr meter **42–32**
Calif, central, dredging in 10–588
  coal mining 10–500
  cost of oil wells 9–36 *et seq*

  mining 10–533 *et seq*
    methods classified 10–540
  sampling **25–13, 25–14**
Placers, examination of **25–29**
  test-pitting in 10–23
Placing concrete **43–11**
Plagioclases 1–05
Plane, equations of **36–24**
  motion and rotation **36–56, 36–57**
Planes, self-acting, curves on 11–18
Plane-table surveys **17–46**
Planimeter **17–09**
Planimetric map **17–52**
Plank, allowable loads on **43–35**
  chutes 10–403
Plant, surface, for tunneling 6–06
Planté storage battery **42–35**
Plaster, testing on 1–08
Plastering in buildings **43–41**
Plate amalgamation **31–15, 33–02** *et seq*
  feeder for coal **35–03**
Plates, steel, in sluices 10–568
Platinum dredging, Alaska 10–594
  metals, assaying **30–16**
  sources of 2–27
Plat-O coal-washing table **35–20**
Pleistocene rocks 2–18
Plotting traverses 17–11 *et seq*
Plowing in earth 3–05
Plow-steel hoisting ropes 12–19
Plug and feathering 5–24
Plugs for underground survey stations **18–02**
Plumb-bobs, surveying **18–05**
Plumbing shaft instrumentally **18–21**
  in taping **17–18**
Plunger pump **40–29**
Pneumatic flotation, testing **31–12**
  shaft-sinking 8–12 *et seq*
  signals for shafts 12–86
Pneumatogen apparatus **23–55**
Pocahontas field coal mining 10–487
Pocket compass **17–05**
Pockets, coal-loading **34–14**
  shaft 12–119 *et seq*
  in square-set stopes 10–212
Pod auger boring cost 9–04
Pointing holes in headings 10–94
Poise **38–03**
Poisoning by cyanide **33–30**
Poisson's ratio 10–A–21, **43–02**
  ratios for rocks 10–A–38
Polar distance of Polaris **17–26, 17–27**
Polaris, observations on **17–26**
Poles and cross-arms **16–05**
  for elec distribution **42–30**
Polish rod, oil well **44–15, 44–17**
Polished surfaces, exam of 1–09
Polishing commutators **42–09**
Polyconic projection **17–13**
Polygon, area of **36–11**
  moment of inertia **36–47**
Polyphase circuits **42–15**

Polyphase transformations 42–15
Pontoon hull for dredges 10–581
Pony sets 10–351, 10–376, 10–380
Pooled comp fund 22–05
Pools, petroleum 2–31
Porcupine, Ont, diamond drilling 10–40
  headframe 12–69
Pore space fillings 10–16
Porosity of brick 43–10
  measurements in wells 10–A–20
  of rocks 10–A–38
Porphyritic texture in rocks 2–03
Porphyry copper deposits, boring in 10–57
    test boring 10–74
  mines, haulage in 10–90
  stripping limits 10–470
Porphyry shaft, Ariz, cost 7–26
Portable cable-tool rigs 9–14
  churn drills 9–41
  compressors 15–16
  gas analyzers 23–30
  magazine for explosives 4–15
  steam hoists 12–50
Portland cement, properties 43–09
  sources of 2–29
  mine, overhand stoping 10–165
    tramming 11–32
Porto Rico, public lands 24–05
Post brake for hoists 12–15
Post-butting square-sets 10–214
Post-hole digger 9–04
Posting notice on claim 24–13, 24–18
Posts, sill-floor 10–220
  spacing in square-sets 10–213
Potash for assaying 30–05
  deposits 10–16
  salts, diamond drilling 9–60
Potassium salts, occurrence 2–32
Potential control for d-c motors 42–02, 42–11
    of induction motor 42–20
  ratio elec prospecting method 10–A–17
Potosí, Bolivia, hand drilling in stopes 10–125
Potrerillos, Chile, block-caving 10–365
Potsdam gold ore, So Dak 2–25
  sandstone for building 2–28
Powder consump in drifting 10–93
  drift 10–295
Power 36–58
  of alt current 42–14
  for anthracite breakers 34–26
  of belts 41–04, 41,05, 41–07
  for bucket elevators 27–33
  for coal crushing 35–08
  comp-air 15–02 *et seq*
  for compressors 15–03, 15–06
  for cone crusher 28–09
  consumed, Alaska Treadwell 21–11
    Goldfield Cons 21–06
  conversion factors 39–20
  cost of 40–05 *et seq*
  for crushing rolls 28–11, 28–12
  diagram, conical-drum hoist 12–34, 12–37
    cylindro-conical hoisting drum 12–40
  for dragline dredging 10–601
  for dragline excavators 10–455
  for dredges 10–584
  elec, for mines 16–02 *et seq*
    units of 42–02
  excavators in placer mining 10–549
  factor of alt current 42–14
    of induction motors 42–19
  for feeders 27–36
  generation, costs of 40–07
  for gravity stamps 28–14
Power for gyratory crushers 28–05, 28–06
  for hoisting 12–60
  hydro-elec, cost of 10–596
  for jaw crushers 28–03, 28–04
  lines in mines 23–50
  measurement of 40–44
  for mine fans 14–51
  plants, electric 42–24
    heat rates of 40–04
  requirements, mining, etc 40–03
  in rope drives 41–10, 41–11
  scrapers in placer mining 10–545
  shovel for coal stripping 10–464
    in placer mining 10–546
  shovels 3–08, 3–15
    economics 3–02
    in open-cut mines 10–434 *et seq*
    in stopes 10–421
  systems 40–02 *et seq*
  tramway 26–24
  for tube-mills 33–12
  ventilating-current 14–24
  for ventilating mines 14–07, 14–33
Power-driven tramways 26–27
Power-factor meter 42–06
Power-plant testing 40–43
Power-shovel tonnage estimates 10–74
Powers, algebraic 36–04
Pre-Cambrian rocks 2–17
Pre-cast shaft sets 7–18
Precipitates, rock-forming 2–09
Precipitation from cyanide sols 33–08, 33–10, 33–22 *et seq*
  of sulphide ores 10–19
Precise leveling 17–36
  levels 17–09
Precision in surveys 17–17
Preformed wire rope 12–21
Preliminary RR survey 17–60
Premature blasts 23–35
Premier diamond mine, open-cut 10–433
Preparation of coal 35–02 *et seq*
"Prepared sizes" of anthracite 34–02
Present worth of money 43–02, 45–54
Preservative treatment of timber 7–17, 10–235, 43–33
Presidio mine, drift round 10–100
Pressure for air drills 15–35
  atmospheric 38–03
    measuring 14–23
  due to explosions 23–46
  gage, recording 14–24
  gages 40–44
  hydraulic, measuring 38–29
  hydrostatic 38–04 *et seq*
  maintenance in oil wells 44–04
  mean effec 39–04, 39–16, 39–18
  of mine air 14–03, 14–07
  of mine fans 14–45, 14–52
  of mud fluids 9–20
  natural, of gas 44–02
  natural-draft 14–35
  potential, airways 14–32
  on shaft walls in soft ground 8–02
  staging of turbines 40–16
  steam, for hoists 12–46
  system of ventilation 14–06
  in ventilating circuits 14–25
Prevention of mine fires 23–49
Prices of metals, etc 25–23 *et seq*
Primacord blasting fuse 4–28
Primary elec batteries 42–36
  minerals 1–10
Primers, blasting 6–12, 6–13

Priming in boilers **40–20**
  centrifugal pumps 13–19, **16–15**
  of explosives 4–19
  of pumps **40–39**
Priming-pumps 13–20
Prince Leopold mine, top-slicing 10–324
Principal point **17–50**
Prins multi-flow coal washer **35–20**
Prismatic compass **17–05**
  telescope on transits **18–11**
Prismoidal formula **17-38, 36–16**
Prisms, mensuration of **36–13**
Private lands, minerals on **24–05**
Probability **36–06**
Probing, prospecting by 10–24
Problems, mine-survey **18–23**
Producer gas for dredge fuel 10–599
Producers, gas **40–42**
    reactions in **39–33**
Production cost, estimating **25–23**
Products made from minerals 1–12
Profile leveling **17–35**
  paper **17–10**
Profit, daily estimate **20–03**
  from mechanization **27–20**
Prony brake for measuring power **40–44**
Propagation of explosions **23–43, 23–44**
Propane in mine air **23–06**
Propeller fans 14–41
Propelling force of explosives 5–17
Property boundaries, legal **17–29**
Proportion, mathematical **36–05**
Proportioning concrete **43–10, 43–11, 43–12**
Proprietary mine, NSW, filled stope 10–259
Props in barricades 10–518
  top-slicing 10–299
Prop-slicing 10–299
  Mesabi 10–307
Prorating of oil wells **44–04**
Prospect 10–03
  shaft, cost 7–23
Prospecting 10–03
  with augers 9–03
  with churn drills 9–41 *et seq*
  concession, Mexican **24–39**
  conditions for 10–04
  cost of 10–05
  equipment, etc 10–77
  geological data for 10–06 *et seq*
  methods 10–21 *et seq*
  permits, U S **24–12**
  placer gravel 10–605
Prospective ore, estimating **25–22**
Prospects, valuation of **25–27**
Protecting trolley wire **16–07**
Protective clothing for miners **23–37**
Proto oxygen apparatus **23–55**
Provisions for prospectors 10–78 *et seq*
Proximate coal analysis 2–29, **30–20**
Psychology of sampling **29–02**
Psychozoic rocks 2–18
Psychrometers **23–02, 23–03**
Public domain, U S **24–04**
Puddling clay 10–620
Puertocitos, Mex, open-cut mine 10–431
Pull in taping **17–18**
Pulleys for belts **41–07**
Pulling of nails **43–37**
  stumps 3–12
Pulmotor **23–57**
Pulp consistency formulas **31–31**
Pulverized coal fuel **40–13**
Pumice 2–04
Pump, air-lift **15–42** *et seq*
Pump, for concreting 6–24
  rooms 13–15
    Lansford, Pa 13–05
Pumping by comp air **15–42**
  at Fla phosphate mines 10–459
  jacks, oil-well **44–18**
  oil wells **44–12** *et seq*
  station, Greenwood colliery 13–17
    Hazleton shaft 13–07
Pumps **40–28** *et seq*
  diamond-drill 9–50
  displacement **15–42**
  on dredges 10–584
  elec **16–15**
  for gravel 10–624
    placer mining 10–575
  for grouting 6–26
  for hydraulic stripping 10–595
  installing **40–38**
  mining 13–11 *et seq*
    makers **16–31**
Purchased power **40–06**
Pure ores, crucible assay **30–08**
Purification of boiler water **40–20**
  of water **22–27** *et seq*
Push shovels, mechanical 3–10
Pyramid stopes 10–204
Pyramid-cut in shafts 7–08
  tunneling 6–08
Pyramids, mensuration of **36–14**
Pyrite in assay charges **30–09**
  sale of **32–17**
Pyrotannic monoxide tester **23–30**
Pyroxenite 2–06
Pyrrhotite in sand filling 10–421

Quadratic equations **36–06**
Quadrilateral, area of **36–11**
Quarries, blasting in 4–24
  churn-drilling in 9–44
  fatality rates **23–37, 23–39**
  underground slate 10–177
Quarry bar 5–08, **15–35**
  blasting 5–12
  tools, pneumatic **15–40**
  tramway loading **26–30**
Quarrying 5–23 *et seq*
Quarter-girth rule for timber 10–225
Quartering of samples **29–03**
Quarter-section, U S lands **17–32**
Quartz-diorite 2–06
Quartzite 2–09
Quaternary rocks 2–18
Quebec, asbestos mining 10–453
  mining law **24–36**
  prospecting in 10–30, 10–31, 10–77
Queen mine, slicing system 10–227
Quenching of drill steel 5–06
Questa, N M, drifting data 10–93
  resuing 10–245
Quicklime, source of 2–28
Quicksand, nature of 3–03
Quincy mine, haulage in 10–90
  hoisting 12–59
  hoisting drum 12–10
  hoisting speed 12–46
  open stoping 10–174
  scrapers **27–25**
  skip 12–107
  skip dumping 12–113
Quit-claim deed **24–28**

Raccoon Bend oil field practice **44–05**
Rack-a-rock at Golden Ridges mine 10–459

Rack-rail locos 11-36
Radial slicing 10-335
  Mesabi 10-304
 top-slicing 10-312
Radialaxe coal cutter **15-41**
Radian **36-11**
Radiating offsets, surveying by **18-16**
Radiation of heat **39-35**
Radicals, algebraic **36-04**
Radio waves for prospecting 10-A-19
Radioactivity of rocks 10-A-41
 surveys 10-A-28
 testing for 10-25
Radium, source of 2-27
 testing for 10-24
